Preface

Heuristics have become a very popular family of solution methods for optimization problems because they are capable of finding *acceptable* solutions in a *reasonable* amount of time. The word heuristic means *serving to discover* or *find out*. It is an irregular formation from the Greek term *heuretikos*, which means *inventive*. It is related to the Greek word *heuriskein*, meaning *to find* and the word *Eureka*, which comes from the ancient Greek word *eurika*, which means *I have found it*.

In the last decades, algorithmic advances as well as hardware and software improvements have provided an excellent environment on which to build heuristic-based decision support systems based on new and effective methodologies. To the layman, heuristics may be thought of as *rules of thumb,* but despite its imprecision, the field of heuristics is very rich and refers to experience-based techniques for problem-solving, learning, and discovery. Any given heuristic solution is not guaranteed to be optimal, but heuristic methods are used to speed up the process of finding satisfactory solutions where optimal solutions are impractical. Despite the dynamic state of heuristic optimization, we feel that the time is ripe to bring together in one handbook the major algorithmic and methodological advances in this field. Leading experts in heuristic optimization have contributed to this handbook.

The main goal of this handbook is to provide the basic principles and fundamental ideas that will enable students and practitioners to create valuable applications based on heuristic technologies. Specifically, the *Handbook of Heuristics* is aimed at engineers, scientists, operations researchers, and other applications specialists who are looking for the most appropriate and recent optimization tools based on heuristic and metaheuristic methodologies to solve particular problems. The Handbook provides a broad spectrum of advances in heuristic optimization with a focus on its algorithmic and computational aspects.

The Handbook consists of five main parts: search strategies, local search, metaheuristics, analysis and implementations, and applications. In the part devoted to search strategies, we cover methodological aspects, from multi-objective and re-start mechanisms to *matheuristics,* the exciting field in which mathematical programming is combined with heuristics. As it is well known to practitioners of heuristic optimization, local search constitutes the core of many methodologies. For this reason, we devote an entire part of the Handbook to local search. In the metaheuristics part of the Handbook, 14 important methodologies in the major field of heuristic optimization are described. We also focus on the analysis and

implementation of these methods in this part of the book. Finally, the purpose of the part on applications is to provide the practitioner with a description of some relevant optimization issues in a number of specific application areas, such as scheduling, vehicle routing, network optimization, supply chain, diversity models, as well as some examples of applied optimization in specific areas.

The first edition of the *Handbook of Heuristics* was published in 2018 and contained 47 chapters. In this second edition, the authors revised 30 of them to include new developments in the area that appeared in the last few years. The inclusion of 14 new chapters makes this second edition even more comprehensive, totaling 61 chapters. In particular, the reader may find 14 chapters in search strategies, including a new chapter on deep learning, 4 in local search, 14 in metaheuristics, 5 in analysis and implementations, and 24 in implementations.

Finally, we would like to take the opportunity to thank Springer for inviting us to edit this Handbook, their staff for helping put the Handbook into production, the authors for their contributions, and the anonymous referees for their valuable comments and suggestions.

Contents

Volume 1

Part I Search Strategies **1**

1 Adaptive and Multi-level Metaheuristics 3
Marc Sevaux, Kenneth Sörensen, and Nelishia Pillay

2 Biased Random-Key Genetic Programming 25
José Fernando Gonçalves and Mauricio G. C. Resende

3 Data Mining in Heuristics 41
Marcelo R. H. Maia, Isabel Rosseti, Simone de Lima Martins, and Alexandre Plastino

4 Deep Learning in Search Heuristics 71
Nayeli Gast Zepeda, André Hottung, and Kevin Tierney

5 Evolution Strategies 89
Michael Emmerich, Ofer M. Shir, and Hao Wang

6 Evolutionary Algorithms 125
David Corne and Michael A. Lones

7 Innovative Applications of Metaheuristics to Supervised Machine Learning 147
Pritam Paral, Amitava Chatterjee, and Patrick Siarry

8 Matheuristics by Examples 177
Martina Fischetti and Matteo Fischetti

9 Multi-start Methods 211
Rafael Martí, Jose A. Lozano, Alexander Mendiburu, and Leticia Hernando

10 Multiobjective Optimization 231
Carlos A. Coello Coello

11 Quantum-Inspired Heuristics 259
Seán McGarraghy and Milena Venkova

12 Restart Strategies 319
Oleg V. Shylo and Oleg A. Prokopyev

13 Simheuristics 335
Angel A. Juan, Majsa Ammouriova, Javier Faulin, Javier Panadero, and Daniele Ferone

14 The Hybrid Metaheuristic CMSA 363
Christian Blum and Jaume Reixach

Part II Local Search **387**

15 Constraint-Based Local Search 389
L. Michel and P. Van Hentenryck

16 Guided Local Search 427
Christos Voudouris, Abdullah Alsheddy, and Ahmad Alhindi

17 Theory of Local Search 469
W. Michiels, E. H. L. Aarts, and J. Korst

18 Variable Neighborhood Descent 511
Abraham Duarte, Nenad Mladenović, Jesús Sánchez-Oro, and Raca Todosijević

Part III Metaheuristics **541**

19 Ant Colony Optimization: A Component-Wise Overview 543
Manuel López-Ibáñez, Thomas Stützle, and Marco Dorigo

20 Estimation of Distribution Algorithms 583
Pedro Larrañaga and Concha Bielza

21 Fundamentals of Scatter Search 599
Rafael Martí, José Laguardia, and María Teresa León

22 Genetic Algorithms 627
Carlos García-Martínez, Francisco J. Rodriguez, and Manuel Lozano

23 GRASP 663
Daniele Ferone, Paola Festa, and Mauricio G. C. Resende

24 Hyper-heuristics 687
Michael G. Epitropakis and Edmund K. Burke

25 Iterated Greedy 745
Thomas Stützle and Rubén Ruiz

26 Iterated Local Search 779
Thomas Stützle and Rubén Ruiz

27 Memetic Algorithms 809
Carlos Cotta, Luke Mathieson, and Pablo Moscato

28 Particle Swarm Optimization 851
Dimitra G. Triantali and Konstantinos E. Parsopoulos

29 POPMUSIC 903
Éric D. Taillard and Stefan Voß

30 Random-Key Genetic Algorithms: Principles and Applications 921
Mariana A. Londe, Luciana S. Pessoa, Carlos E. Andrade, José Fernando Gonçalves, and Mauricio G. C. Resende

31 Tabu Search 941
Manuel Laguna

32 Variable Neighborhood Search 959
Pierre Hansen and Nenad Mladenović

Volume 2

Part IV Analysis and Implementation 989

33 A History of Metaheuristics 991
Kenneth Sörensen, Marc Sevaux, and Fred Glover

34 Alternate Optima in Combinatorial Optimization 1011
Marc Benito-Marimón, Anna Martínez-Gavara, and Rafael Martí

35 Heuristics in Design of Deep Neural Networks 1031
Ricardo Martins de Abreu Silva and Andersson Alves da Silva

36 Parallel Meta-heuristic Search 1087
Teodor Gabriel Crainic

37 Time Complexity Analysis of Stochastic Search Algorithms 1131
Pietro S. Oliveto

Part V Applications 1173

38 City Logistics 1175
Jaume Barceló, Hanna Grzybowska, and Jesús Arturo Orozco

39 Cutting and Packing 1219
Ramón Alvarez-Valdes, Maria Antónia Carravilla, and José Fernando Oliveira

40 Diversity Optimization Models 1269
Fernando Sandoya, Anna Martínez-Gavara, Ricardo Aceves, Abraham Duarte, Nilse Romero, Osvaldo Palma, and Rafael Martí

41 Evolutionary Algorithms for the Inverse Protein Folding Problem 1295
Sune S. Nielsen, Grégoire Danoy, Wiktor Jurkowski, Roland Krause, Reinhard Schneider, El-Ghazali Talbi, and Pascal Bouvry

42 Graph Layout Problems 1321
Sergio Cavero, Eduardo G. Pardo, Abraham Duarte, and Rafael Martí

43 Heuristics in Vehicle Routing 1353
Claudia Archetti, Kris Braekers, and Diego Cattaruzza

44 Last-Mile Delivery with Crowdshipping 1385
Tiago Monteiro, João Pedro Pedroso, and Ana Viana

45 Maritime Container Terminal Problems 1411
Christopher Expósito-Izquierdo, Eduardo Lalla-Ruiz, Jesica de Armas, Belén Melián-Batista, and J. Marcos Moreno-Vega

46 Metaheuristics for Medical Image Registration 1445
Andrea Valsecchi, Enrique Bermejo, Sergio Damas, and Oscar Cordón

47 Metaheuristics for Natural Gas Pipeline Network Optimization 1469
Roger Z. Ríos-Mercado

48 Metaheuristics for Problems in Sports Scheduling 1493
Celso C. Ribeiro, Sebastián Urrutia, and Dominique de Werra

49 Network Optimization 1523
Luciana S. Buriol

50 Optimization Problems, Models, and Heuristics in Wireless Sensor Networks 1541
Vinicius Morais, Fernanda S. H. Souza, and Geraldo R. Mateus

About the Editors

Rafael Martí
Operations Research and Statistics Department
School of Mathematics
University of Valencia
Valencia, Spain

Rafael Martí is a Professor of Statistics and Operations Research at the University of Valencia, Spain. He earned his PhD in Mathematics from the same university in 1994. His research focuses extensively on metaheuristics for complex optimization problems. He has published over 200 papers, most of them in indexed journals (JCR), including the *European Journal of Operational Research*, *INFORMS Journal on Computing*, *IIE Transactions*, *Journal of Global Optimization*, *Computers & Operations Research*, and *Discrete Applied Mathematics*. He is the co-author of several monographic books, the most recent being *Discrete Diversity and Dispersion Maximization* (Springer, 2023) and *Exact and Heuristic Methods in Combinatorial Optimization* (Springer-Verlag, 2022).

He serves as Area Editor for the *Journal of Heuristics* and as Associate Editor for the *European Journal of Operational Research* and *Mathematical Programming Computation*. He is also a senior research scientist at the Spanish logistics consulting firm OGA and holds a US patent. He has delivered around 50 invited and plenary talks and is a recurring visiting professor at the University of Colorado (USA), Molde University College (Norway), and University College Dublin (Ireland). He has participated in over 20 government-funded research projects, and his publications have received more than 15,000 citations.

Distinguished Emeritus Professor
Panos M. Pardalos
University of Florida
Gainesville, FL, USA

Panos Pardalos was born in Drosato (Mezilo) Argitheas GR in 1954 and graduated from Athens University (Department of Mathematics). He received his PhD (Computes and Information Sciences) from the University of Minnesota. He is an Emeritus Distinguished Professor in the Department of Industrial and Systems Engineering at the University of Florida, and an affiliated faculty of Biomedical Engineering and Computer Science & Information & Engineering departments. Since 2011 he has been the academic advisor at *LATNA, HSE*.

He is a world-renowned leader in Global Optimization, Mathematical Modeling, Energy Systems, Financial applications, and Data Sciences. He is a Fellow of *AAAS, AAIA, AIMBE, EUROPT*, and *INFORMS* and was awarded the 2013 Constantin Caratheodory Prize of the International Society of Global Optimization. In addition, He has been awarded the 2013 EURO Gold Medal prize bestowed by the Association for European Operational Research Societies. This medal is the preeminent European award given to Operations Research (OR) professionals for "scientific contributions that stand the test of time."

He has been awarded a prestigious Humboldt Research Award (2018–2019). The Humboldt Research Award is granted in recognition of a researcher's entire achievements to date – fundamental discoveries, new theories, insights that have had significant impact on their discipline.

He is also a member of several Academies of Sciences, and he holds several honorary PhD degrees and affiliations. He is the Founding Editor of *Optimization Letters* and *Energy Systems*, and Co-Founder of the *International Journal of Global Optimization, Computational Management Science*, and Springer Nature *Operations Research Forum*. He has published over 600 journal papers, and edited/authored over 200 books. He is one of the most cited authors and has graduated 71 PhD students so far. Details can be found in https://faculty.eng.ufl.edu/pardalos/publications/.

Mauricio G. C. Resende
University of Washington
Seattle, WA, USA

Mauricio G. C. Resende is an Affiliate Professor of the Graduate Program in Operations Research of the Aeronautical Institute of Technology (ITA) and the Federal University of São Paulo (UNIFESP) and a Permanent Member of the Center for Discrete Mathematics and Theoretical Computer Science (DIMACS). He is most known for his work with metaheuristics and interior point methods for linear programming and network flows. He has published 5 books and over 200 papers on optimization. He holds 15 US patents. With a successful career spanning over four decades, he has brought his expertise to various industrial research laboratories worldwide: electrical power systems at Furnas Centrais Elétricas in Brazil; semiconductor device manufacturing at Fairchild Semiconductor Corporation in Silicon Valley, California; telecommunications at AT&T Bell Labs Research and AT&T Labs Research in New Jersey; and retail logistics at Amazon in Seattle. He holds a PhD in operations research from the University of California, Berkeley. He is an INFORMS Fellow.

Abstract

In recent decades, metaheuristics have become increasingly popular as a tool for solving a large class of difficult optimization problems. However, determining the best configuration of a metaheuristic, which includes the program flow and the parameter settings, remains a difficult task. Adaptive metaheuristics (that change their configuration during the search) and multi-level metaheuristics (that change their configuration during the search by means of a metaheuristic) can be a solution for this. This chapter intends to give a quick review of the latest trends in adaptive metaheuristics and multi-level metaheuristics.

Keywords

Metaheuristics · Multi-level · Adaptive · Configuration · Hyper-heuristics

Introduction

Metaheuristics are flexible frameworks that can be used to design heuristics for virtually any combinatorial optimization problem. This flexibility also comes at a cost: many researchers in metaheuristics spend a large amount of time to properly design and tune their algorithm in a trial-and-error fashion. As mentioned and observed in many published papers, designing an efficient metaheuristic is an art, requiring a lot of intuition on the part of the metaheuristic designer. However, there is no doubt that the parameters and structure of the metaheuristic may influence the performance of the solution approach and the quality of the results in the end.

In the design of a metaheuristic, a large fraction of the time is usually spent on determining the *control flow*, i.e., the order in which the different components of the metaheuristic are used, and the optimal levels of the various parameters of the metaheuristic. A more structured approach than the one commonly used is needed. The purpose of this chapter is to discuss one of the ways to alleviate this problem, through adaptive and multi-level metaheuristics.

Our overview is necessarily very short and cannot replace the many years of research and the large number of books and papers that have tried to clarify the topic. We encourage the reader to address the existing work that we have pointed out and to explore the references that we may have missed here. This chapter is not a complete review of all papers in the field of adaptive or multi-level metaheuristics but rather a set of good practices that can be done when designing metaheuristics.

In the first section, we will try to clearly define some concepts to arrive at a definition of the terms *adaptive* and *multi-level* (section "Definitions"). We will also discuss the impact of heuristic parameters on the behavior of a metaheuristic algorithm (section "Configuring a Metaheuristic") and how we can reduce the number of parameters or how we can automatically tune some parameters. Adaptive

metaheuristics are discussed in section "Adaptive Metaheuristics" and multi-level metaheuristics and hyper-heuristics in section "Multi-Level Metaheuristics and Hyper-Heuristics." Section "Conclusion" will conclude the chapter.

Definitions

The terms *adaptive* and *multi-level* do not have a single, generally accepted definition within the metaheuristics community. The aim of this section is to develop clear definitions for both. Both *adaptive* and *multi-level* refer to the evolution of the *configuration* of a metaheuristic algorithm during the optimization process. We must therefore first define the term *configuration*. Our definitions will be intuitive rather than formal.

Each metaheuristic algorithm consists of several *components*, i.e., parts that form a more or less logical and atomic unit. Examples are a local search operator in a variable search algorithm, a tabu list in a tabu search algorithm, a crossover operator, or a selection operator in an evolutionary algorithm. Each of these components can exist more or less independently of the rest of the metaheuristic algorithm, which includes their use in a different metaheuristic algorithm for the same problem. Within the same metaheuristics, components can often be rearranged in the overall structure of the algorithm. For example, local search operators in a variable neighborhood search algorithm can be executed in a specific order; an evolutionary algorithm may use its selection operator before or after the crossover operator (or both), etc. In programming, this is called the *control flow*, a term we will adopt here. Clearly, not every control flow makes sense, but generally speaking, a sizeable number of possibilities exist. Determining the control flow of the algorithm, i.e., the order in which the components are executed, is a task for the algorithm designer.

Each component may have one or more parameters that determine its functioning. Such parameters may be numerical, such as the tabu tenure of a tabu list, the number of iterations without improvement before a perturbation move is used, etc. Other parameters may be nonnumerical, like the choice of a discrete set of move strategies to use in a local search operator (steepest descent, mildest descent, random improving, etc.). The algorithm designer usually defines a finite set of potential (or sensible) values, e.g., the restricted candidate list of a GRASP algorithm is defined to be an integer number between 5 and 20. In some situations, a parameter might also be a real number.

Using these concepts, we may now define the term *configuration*.

Definition 1. Given the set of components of a metaheuristic algorithm together with the set of all potential control flow alternatives, as well as its parameters and their potential values, the **configuration** of a metaheuristic algorithm defines the specific control flow and the specific set of parameter values it uses.

For example, a local search-based metaheuristic like the most basic tabu search method depicted in Algorithm 1 has one parameter, the tabu tenure (the length of the tabu list), and needs one type of neighborhood. It also needs several functions such as *initialize* and *update memory*. One specific tabu tenure, one type of neighborhood, and the set of necessary functions will be the configuration of the current search method.

Algorithm 1: Basic tabu search

```
1 initialize: find an initial solution x
2 repeat
3 |   neighborhood search: find a solution x' ∈ N*(x)
4 |   update memory: tabu list, frequency-based memory, aspiration level, ...
5 |   move x ← x'
6 until stopping criterion satisfied
```

For a simple variable neighborhood search heuristic presented in Algorithm 2, the order in which neighborhoods are explored (or whether they are explored at all), the way in which the starting solution in the current neighborhood is generated, and the local search method that is applied to improve the solution with the current neighborhood, as well as the total number of iterations k_{max}, define the configuration of the VNS.

Algorithm 2: Basic variable neighborhood search

```
1 initialize: find an initial solution x, k ← 1
2 repeat
3 |   shake: generate a point x' at random from the neighborhood N_k(x)
4 |   local search: apply a local search procedure starting from the solution x' to find a
  |   solution x''
5 |   if x'' is better than x then
6 |   |   x ← x'' and k ← 1 (center the search around x'' and search again with
  |   |   neighborhood 1)
7 |   else
8 |   |   k ← k + 1 (enlarge the neighborhood)
9 until k = k_max
```

We can now define the terms *adaptive* and *multi-level* in the context of metaheuristic algorithms.

Definition 2. A metaheuristic is **adaptive** when it includes a mechanism to modify its configuration *during* its execution.

In other words, an adaptive heuristic includes a mechanism to modify either the control flow or the parameter values (or both) of a heuristic, and, by doing so modify

the behavior of the metaheuristic. As an example, consider the basic tabu search shown in Algorithm 1. A common adaptive mechanism might make some changes to the *update memory*: the length of the tabu list, the aspiration level, etc.

Even though the definition has been conceived to be as watertight as possible, there is always room for interpretation. For example, considering the VNS heuristic in Algorithm 2, the basic design of the heuristic is such that the order in which the neighborhoods are searched depends on the instance being solved. Since the heuristic will move to the next neighborhood once a local optimum has been reached (and local optima are different for every instance), the control flow of the algorithm will be different for every instance. Yet, most researchers would not call a simple VNS heuristic adaptive.

There is a potential for recursion in the definition as well. A mechanism to determine the control flow or parameter values, by definition, becomes a component of the metaheuristic. This component must be integrated into the control flow itself and may also introduce its own parameters. This setup could potentially lead to a new level of adaptiveness, where an even higher-level component is introduced to control the parameters of the control mechanism, and so on. However, most adaptive metaheuristics include only one additional control component. In these cases, the parameter values are either self-defined or determined externally, so this recursion does not pose a problem.

The mechanism that does the actual adaptation can range from very simple to complex. Essentially, the aim of the mechanism is to search for the best configuration of the metaheuristic algorithm. This search can itself be seen as a combinatorial optimization problem, and an optimization algorithm may be used to solve it. When the adaptation mechanism itself is a metaheuristic algorithm, we call the overall result a *multi-level metaheuristic*.

Definition 3. A **multi-level** metaheuristic algorithm is a metaheuristic algorithm for which the configuration is altered by another metaheuristic algorithm.

Note that, since the algorithm doing the adapting is itself a heuristic, with its own components and parameters, the road is paved (again) for a recursive structure in which the configuration of the lowest-level heuristic is adapted by a higher-level metaheuristic, the configuration of which is adapted by an even higher-level heuristic, the configuration of which is adapted by ..., ad infinitum. However, the complexity added by implementing a higher-level metaheuristic algorithm to adapt the configuration of a lower-level metaheuristic is usually considerable, which precludes the design of a multi-level heuristic having many levels.

For reasons of clarity, a hybrid metaheuristic, i.e., a metaheuristic algorithm that combines ideas from several metaheuristic frameworks, for which the configuration remains unchanged throughout the search, is not considered a multi-level metaheuristic in this chapter. Also, the term multi-level is often used to denote optimization problems that can be decomposed into several (simpler) problems (e.g., a location-routing problem can often be decomposed into a location problem and a routing problem). Each of the problems may be separately solved by a metaheuristic

algorithm. In this chapter, we do not use the term multi-level metaheuristics to describe such approaches.

Configuring a Metaheuristic

An optimization method and especially a metaheuristic has several (potentially hundreds) possible configurations. Among all of them, only a few will allow the search to reach the optimal solution or the best possible solution, but not for all instances and not at all time. The configuration may have a great influence on the quality of the final solution or the effectiveness of the search method. This is the reason why properly tuning the parameters, or choosing the right configuration, is a very important task. Because of the "no free lunch theorem" [42], we know that there is no optimal configuration of a metaheuristic that will outperform all others on all problems and all instances.

Despite this fact, it is necessary to find an initial configuration, suitable to solve the problem at hand. This initial part will be described in this section. If the configuration is not satisfying, instead of starting again the resolution with a new configuration, one can change the configuration during the search (see section "Adaptive Metaheuristics").

As noted by several researchers [e.g., 16], the first step of setting up a metaheuristic has to go through the configuration phase during which the control flow is established and the parameters are tuned. This phase is sometimes called "offline parameter initialization." This is long and fastidious and usually done with a trial-and-error method. Moreover, even when this step is completed, its efficiency is often effective only on a subset of instances (usually close to the instances on which the parameters have been calibrated). In addition, as already mentioned for metaheuristics, the parameters are not only numerical values, but can be search components, updating function, etc. [38].

As a general observation, tuning these parameters is often so difficult that the designers change them one by one until they get the right configuration. And the value of these parameters is obtained empirically. Hence, the final combination of the parameters deduced from a sequential empirical adaptation of the parameters cannot guarantee that the final configuration is optimal. Furthermore, by changing the parameters one by one, it is impossible (or too difficult) to detect the possible interactions between these parameters. Moreover, the parameters and the control flow of a heuristic generally heavily influence each other, which makes the process of determining both even more difficult.

Eiben et al. [19] clearly define the parameter tuning for evolutionary algorithms: *By parameter tuning we mean the commonly practiced approach that amounts to finding good values for the parameters before the run of the algorithm and then running the algorithm using these values, which remain fixed during the run.*

Once this initial tuning phase is completed, most metaheuristics designers keep the configuration as it is to run their solution approach on the set of instances studied.

This configuration remains the same (as cited above) until the designer believes that it is not adapted anymore and should be reconfigured again with the same process.

Among the potential methods for tuning the parameters before solving, one can list:

- Manual tuning (usually from the experience of a metaheuristic designer),
- Parameter tuning on a subset of representative instances,
- Automatic parameter tuning by the use of an external method.

An experienced metaheuristic designer is often able to decide the value of a large number of parameters beforehand. The rules of thumb prevail on every other considerations. The reason for this is that after several years of practicing, one can know that some parameters need to have certain values, and the values that are close to it will not make a big difference on the final effectiveness of the results.

The population of a genetic algorithm is a rather good example. A small population will have a premature convergence because too many individuals will be the same (clones), and to avoid this without a specific mechanism, it is important to have a population of a large size. Many papers on genetic algorithms have a population of 100 individuals, but none mentioned how they have obtained this value, or the motivations to set it to this value. No analysis is done to see if 95 or 105 will give better results.

Only a few researchers report the difficulty of finding the right parameter settings and the limitations of this kind of approach [41]. Moreover, the manual tuning, without post-analysis experiments, has the drawback of not being applicable to different instances than the one presented in the paper. This is even more the case for transferring the method to any similar industrial application.

Whatever the technique used for tuning these parameters or configurations beforehand, it is important to keep in mind that every metaheuristic should be well balanced between *intensification* and *diversification* [37]. Hence, the tuning of the parameters should take this into account for ensuring that the metaheuristic is not converging too fast (too much intensification or exploitation) or is wandering in the search space without converging (too much diversification or exploration). Of course, for being able to detect this, one has to set up some indicators showing the speed of convergence, the evolution of the solution quality, the evolution of the solutions themselves, etc.

The best practice is to report the results as Prins [31] has done in his paper on the vehicle routing problem. In that paper, the tables present at the same time the results obtained on a set of instances with some "standard parameter settings" and the results obtained with the "best parameter settings." This is a fair comparison to existing work. The only drawback is the missing information on the time needed to set up the standard parameter settings as well as the best parameter settings. This can be a long and fastidious task and the total computational time can be high.

Setting up the parameters of a metaheuristic based on preliminary experiments is probably the most common technique used in designing metaheuristics. A subset of

representative instances is selected, and the parameters are tested on these instances until they converge to stable results. Hence, they are applied to the whole set of instances and the results are reported. The subset of instances should be carefully selected to be representative of the future experiments.

Usually, the designer selects one parameter at a time, adjust its value to the best one, and reiterate with the next parameter. Only a few reports that they practice a full factorial design as stated by Hooker [22]. With such a design, authors may try to understand the relative contribution of each parameter to the global effectiveness of the metaheuristic and the possible influence of the parameters between them. One of the best examples of the application of this type of parameter design is presented by Xu and Kelly [45] on a tabu search algorithm. In their paper, they have selected a small subset of seven instances to tune five components of the tabu search. A more general approach is presented by Xu et al. [46] but still based on the same factorial analysis.

Another technique to find the right parameter settings is to let an external method to tune the parameters for the metaheuristic designers. Very few studies exist on that issue if they are not used intrinsically during the metaheuristic search. Dean and Voss [12] in their book present a technique known as the *response surface methodology* in statistics. This method has been effectively used in [1]. This technique consists in running a local search method in the space of the parameters. A specific metric measuring the distance between each pair of parameters is calculated by running the metaheuristic. For a fixed setting of parameters (or a point in the search space of the parameters), the neighbors are also explored. If no better neighbor can be found, the value for the parameters is fixed and the search stops; otherwise, the search continues with the best neighbor and the new parameter settings.

Of course, one cannot guaranty the optimality for all the parameters at once and even at the end of the search. But usually, this technique is able to discover good parameter settings. One important drawback is the definition of the metric that is very sensitive, especially if an order cannot be defined on the variables.

For a more elaborate discussion on this topic, we refer the reader to [5] and to section "Hyper-Heuristics for Metaheuristic Configuration" in this chapter.

Adaptive Metaheuristics

As stated in the previous section, once a designer has the best parameter settings for its metaheuristics, he is able to run it confidently on the set of targeted instances and produce results. The question is: "Can it go further?" And the answer is yes. Yes, there is always some space for improvement. A parameter setting that works very well on one instance might work poorly on another one.

To overcome this difficulty, it is always possible to analyze the behavior of the metaheuristic during the search and adapt it to obtain better results. This phase can be named "online parameter tuning." Based on indicators (e.g., convergence, solution quality, similarity of explored solutions), the configuration of the metaheuristic

is changed. This technique is particularly appealing when one has to solve only one large instance and the tuning of parameters cannot be done beforehand.

Simple Adaptive Mechanisms

Detecting why a metaheuristic is not giving satisfying results is not an easy task. It largely depends on the type of metaheuristic itself. For example, identical individuals (clones) in a genetic or memetic algorithm are one of the known consequences of premature convergence. In a local search method, cycling in the objective space, or in the solution space, is also a situation that needs to be avoided.

The online parameter tuning can be simple as in [36] where a tabu search procedure is having a *cycle detection mechanism* and increases the tabu tenure along the search when cycles are detected. To really improve the behavior of a metaheuristic algorithm, however, more elaborate methods can be used during the search and exploited for a better efficiency.

One such mechanism includes Boutillon et al. [7] which can be activated during the search like *retroactive loops* where a simulated annealing temperature parameter is controlled during the search to follow a predefined probability acceptance decreasing scheme.

Reactive Search

Among all existing methods, the work of Battiti [2] had traced the path a long time ago. In the most simple reactive search, the past history of the search is intensely used for *feedback-based parameter tuning* and for *automated balance of diversification and intensification*. In the former, the tuning of parameters is automated, and decisions on the new values of parameters are made based on the past events of the search. In the latter, the concept of balancing exploration *vs.* exploitation is used to guide the search.

One of the simplest forms of reactive search is reactive tabu search. The main idea is to change the length of the tabu list (i.e., the tabu tenure) based on the search trajectory. Essentially, the tabu list is made longer if the search is not finding better solutions, and shorter if it does.

Greedy Randomized Adaptive Search Procedure

GRASP (greedy randomized adaptive search procedure) is a constructive metaheuristic, the main idea of which is to balance greediness and randomness. Many constructive heuristics are greedy, which means that, at every iteration, they pick the best element from the set of potential solution elements. An example is the nearest-neighbor heuristic for the TSP which starts from a given city and moves to the closest unvisited city at every iteration. The drawback of a fully greedy

heuristic is that it only generates a single solution, which is most likely suboptimal. A wrong decision early on in the constructive procedure may lead to bad solutions in the end.

GRASP attempts to overcome this drawback by introducing randomness into the solution construction process. Instead of picking the best element at each iteration, GRASP creates a *restricted candidate list*, i.e., a list of the α best elements and picks one element from this list *at random* (α represents a number of elements). By doing this, GRASP generates a different solution at each iteration. After several iterations, some solutions will likely have been found that are better than the one found by a purely greedy heuristic.

In *reactive* GRASP, introduced by Prais and Ribeiro [30], the parameter α is randomly chosen from a set of discrete value. Initially, each possible α_i has the same probability of being chosen. The search remembers the quality of the solutions found for each possible value of α_i. After some iterations, the probabilities of selecting α_i are updated to reflect the quality of the solutions it produced. The probabilities corresponding to α_i's that have resulted in good solutions are increased, the others are decreased.

The reactive GRASP by Delorme et al. [13], e.g., works as follows. A *value* λ_i is defined for each α_i. The probability of selecting α_i, p_i is calculated as follows:

$$p_i = \frac{\lambda_i}{\sum_{k=1}^{n} \lambda_k},$$

supposing that n different α_i's have been defined.

Whenever a good solution is found using a certain α_i, this solution is added to the *pool* P_i for this α_i. Periodically, the values of λ_i (and hence p_i) are updated according to the following formula:

$$\lambda_i = \left(\frac{\text{mean}_{x \in P_i}[f(x) - f(\underline{x})]}{f(\overline{x}) - f(\underline{x})} \right)^{\delta},$$

where $\underline{x}$ and $\overline{x}$ are the worst and best solutions found so far and δ is a parameter introduced to attenuate the update of the probabilities p_i.

Adaptive Large Neighborhood Search

Large neighborhood search (LNS) is a constructive metaheuristic that works by building solutions from their constituting elements. For this purpose, it relies on a set of simple constructive procedures to build solutions, and on a set of destructive procedures to partially destroy these solutions so they can be rebuilt. For this reason, LNS has also been called ruin-and-recreate. At each iteration, LNS selects a pair consisting of one destructive heuristic and one constructive heuristic. Using this pair, a new solution is obtained. Most LNS implementations use a probabilistic

mechanism to select both the destructive and the constructive heuristic at each iteration. A (nonadaptive) LNS algorithm could, e.g., assign equal probabilities to each constructive heuristic and to each destructive heuristic.

Adaptive large neighborhood search goes a step further by selecting the heuristic pair with a probability determined by the previous performance of both the constructive and the destructive heuristic. As a result, constructive and destructive heuristics that perform well will have a higher probability of being selected, whereas those that will not have a lower probability. Usually, however, the probabilities are bounded by some values that ensure all heuristics have at least a tiny chance of being selected.

An example of an ALNS adaptive constructive/destructive heuristic selection mechanism is the following. Suppose an ALNS heuristic has n constructive and m destructive heuristics. Initially, each constructive heuristic i (and each destructive heuristic j) is assigned a *value* $\lambda_i^c = 1$ ($\lambda_j^d = 1$). Then, a constructive heuristic is selected from the set of constructive heuristics with a probability p proportional to its value:

$$p_i = \frac{\lambda_i}{\sum_{k=1}^{n} \lambda_k}$$

Similarly, a destructive heuristic is selected according to an equivalent rule.

Using the pair of destructive and constructive heuristic, a new solution is generated. The quality of the new solution is evaluated, and the values of the selected constructive and destructive heuristic are updated.

$$\alpha = \begin{cases} 0.5 & \text{if the new solution is worse than the current solution} \\ 1.5 & \text{if the new solution is better than the current solution} \\ 2 & \text{if the new solution is better than the global best solution} \end{cases}$$

$$\lambda_{i,\text{new}}^c = \gamma \lambda_i^c + (1 - \gamma)\alpha$$

$$\lambda_{j,\text{new}}^d = \gamma \lambda_j^d + (1 - \gamma)\alpha$$

where γ is a parameter between 0 and 1.

Using the formulas above, the probabilities of selection for each constructive and destructive heuristic will adapt to the problem at hand. Moreover, using the formulas above, the values can never increase above 2 and never drop below 0.5. In other words, all constructive and destructive heuristics will keep having a positive probability of being selected, even if they consistently fail to find improving solutions.

A recent meta-analysis by Turkeš et al. [40] critically examines the effectiveness of the adaptive layer in adaptive large neighborhood search (ALNS) algorithms. By systematically reviewing existing studies, the authors assess whether adaptiveness—

dynamically adjusting heuristic selection probabilities based on performance—significantly enhances ALNS performance. Their findings indicate that, on average, the adaptive layer contributes to only a marginal improvement of approximately 0.14% in solution quality. This suggests that the complexity introduced by adaptiveness may not yield substantial benefits, prompting a reevaluation of its necessity in ALNS implementations.

While there are many more adaptive mechanisms than the one described here, the study by Turkeš et al. [40] demonstrates the importance of evaluating whether making a metaheuristic's adaptiveness genuinely improves its performance. One of the study's main conclusions is that adaptivity may be advantageous in scenarios where the heuristic needs to address a wide variety of fundamentally different problems or problem instances with substantial internal diversity. In such cases, incorporating an adaptive mechanism could offer tangible benefits.

Multi-Level Metaheuristics and Hyper-Heuristics

In the previous section, we have examined different techniques for adapting the configuration of metaheuristics. In this section we look at multi-level metaheuristics, i.e., metaheuristic algorithms for evolving the configuration of a metaheuristic. Much of the research in this area has used evolutionary algorithms to configure metaheuristics with one of the earliest studies being that conducted by Bölte and Thonemann [6] which uses genetic programming for generating annealing schedules, which were previously manually created, in a simulated annealing algorithm to solve the quadratic assignment problem. Various evolutionary algorithms, namely, genetic algorithms, evolutionary strategies, and estimation of distribution algorithms, have been used for parameter tuning of evolutionary algorithms [18]. These are referred to as meta-EAs and operate on the design level, while the EA solving the problem at hand is considered to form the algorithm layer. Hyper-heuristics are proving to be effective for the automatic configuration of metaheuristics, and we provide an overview of the use of hyper-heuristics for this purpose.

Hyper-Heuristics

Hyper-heuristics were initially introduced as "heuristics to choose heuristics" Burke et al. [8], Ross [33]. Hyper-heuristics aim at providing a more generalized solution for a problem domain rather than producing the best solution for certain problem instances. This is achieved by exploring a space of low-level heuristics rather than a solution space directly. The low-level heuristics can be constructive or perturbative. Constructive low-level heuristics are used to create an initial solution, while perturbative heuristics are used to improve an existing candidate solution. The first generation of hyper-heuristics was essentially selection hyper-heuristics which chose which constructive or perturbative heuristics to use at a particular point in constructing or improving a candidate solution respectively.

Selection constructive hyper-heuristics are used to select the low-level construction heuristic at each stage in constructing a solution. Similarly, in the case of selection perturbative hyper-heuristics, the hyper-heuristic chooses a perturbative low-level heuristic at each stage of the improvement process. We use an application of hyper-heuristics to the domain of examination timetabling to illustrate these concepts. Low-level construction heuristics generally used to solve examination timetabling problems are the graph coloring heuristics, namely, largest degree, largest weighted degree, largest color degree, largest enrolment, and saturation degree [32]. Each of these heuristics assesses the difficulty associated with allocating an examination to the timetable. For example, the saturation degree heuristic is the number of timetable slots; given the current state of the timetable at the particular point in construction, an examination can be allocated to without causing hard constraint violations such as a student being scheduled to write more than one examination at the same time. A selection hyper-heuristic chooses which of the low-level heuristics to use to schedule each of the examinations. This has proven to be effective as different low-level heuristics work well for different problem instances and more importantly different low-level heuristics are more effective at different points of solution construction. Metaheuristics such as simulated annealing, tabu search, variable neighborhood search, and genetic algorithms have generally been used to search the heuristic space [8, 11].

Examples of low-level perturbative heuristics for the examination timetabling domain include swapping examinations, swapping rows of the timetable, de-allocating examinations, and allocating examinations. Selection perturbative hyper-heuristics can perform a single-point search or a multipoint search. In the case of the former, the hyper-heuristic is comprised of a heuristic selection and move acceptance component [11]. Different techniques are employed to for heuristic selection and move acceptance. This technique can be as simple as randomly selecting a low-level heuristic and accepting on moves that results in improvement. Metaheuristics can also be employed for heuristic selection and move acceptance, e.g., simulated annealing and tabu search have previously been employed for this purpose. Multipoint search selection perturbation hyper-heuristics employ population-based methods such as evolutionary algorithms and particle swarm optimization to explore the heuristic space, with the population-based approach, by its nature, performing both the heuristic selection and move acceptance.

As the field developed, the idea of creating new low-level heuristics emerged resulting in a second category of hyper-heuristics, namely, generation hyper-heuristics. Generation hyper-heuristics generate low-level constructive or perturbative heuristics. Genetic programming has primarily been employed by generation hyper-heuristics to create low-level heuristics [10, 11]. An example of a generation hyper-heuristic is that implemented by Burke et al. [9] for the one-dimensional bin-packing problem. Construction low-level heuristics, e.g., first-fit, best-first, and next-fit, are used to choose which bin to allocate an item to. In this study, genetic programming is used to evolve low-level heuristics to decide which bin to allocate an item to. In the study conducted by Sabar et al. [34], grammatical evolution, a variation of genetic programming, is used to evolve new low-level perturbative

heuristics by combining mechanisms for heuristic selection and move acceptance. Generated low-level heuristics can be reusable or disposable. In the case of reusable heuristics, the generated low-level heuristic created to solve the problem for one instance can be used to solve other problem instances without any regeneration. Disposable low-level heuristics are generated for the specific problem instance and cannot be reused.

Selection and generation hyper-heuristics have generally been used for the automatic configuration of metaheuristic algorithms. In this case, the low-level heuristics represent parameters or operators of the metaheuristic and are essentially perturbative. The hyper-heuristic employs a metaheuristic to explore the space of low-level heuristics. Selection hyper-heuristics are used to determine control flow and for parameter tuning. In this case the hyper-heuristic selects a component at each point in the application of the algorithm to solve the problem. Furthermore, generation hyper-heuristics are used to create new low-level heuristics; in this context these represent the components of the metaheuristic.

Hyper-Heuristics for Metaheuristic Configuration

Control flow is achieved by producing a combination of low-level heuristics, each a component of the metaheuristic algorithms, i.e., the hyper-heuristic selects which low-level heuristic to apply at each point in a metaheuristic algorithm. The low-level heuristics are components of the metaheuristic algorithm. Lourenço et al. [25] use grammatical evolution to evolve evolutionary algorithms for the Royal Road Functions. The aim is for the evolutionary algorithm to adapt itself during the evolutionary process. Evaluating the evolutionary algorithm proved to be a computationally intensive task, and hence a limited number of runs were performed. Grammatical evolution combines the different evolutionary algorithm components, namely, mutation, crossover, and selection components and parameter values for these components. The evolved evolutionary algorithms are applied to a seeded initial population. One instance was used for training, and the evolved evolutionary algorithms were tested on the remaining four instances. Performance was found to be similar to that of the standard evolutionary algorithm. The evolved EA that performed better than the standard EA did not follow the standard structure and contained two types of crossover. There are a number of early initiatives that can be categorized as hyper-heuristics for inducing evolutionary algorithms, although this is not explicitly stated in the papers. Oltean and Groşan [28] use multigene expression programming to evolve an evolutionary algorithm to induce Griewang's function. Algorithms comprised of initialization, mutation, and crossover components are evolved. The number of crossover, initialization, and mutation components in the best individual was found to increase as the evolution progressed. Linear genetic programming has also been used for purposes of evolutionary algorithm induction [27]. Each algorithm evolved is a generational evolutionary algorithm composed of selection, crossover, and mutation components and is applied to an initial population of randomly generated elements. Evolutionary

algorithms are evolved for function optimization, the traveling salesman problem, and quadratic assignment problem. For all three problems, the evolved algorithms are trained on a problem instance and are able to generalize and solve other problem instances. In later work, Dioşan and Oltean [15] use genetic algorithms to evolve evolutionary algorithms for function optimization. Each chromosome is comprised of a combination of selection, mutation, and crossover operations as well as population altering strategies to place the newly created offspring into the population. A different evolutionary algorithm was evolved to induce each of the ten functions. As in previous studies, the crossover operator was the most prevalent in evolved evolutionary algorithms producing the best results.

In some studies the hyper-heuristic achieves both control flow and parameter tuning. In this case the hyper-heuristic selects the component of the metaheuristic and the parameter value. Tavares and Pereira [39] employ grammatical evolution to automatically configure ant colonization algorithms for solving the traveling salesman problem. The architecture of the ant colonization algorithm including the components of the algorithm, e.g., method for evaporation, and parameter values are evolved. The evolved architecture was found to be effective when applied to problem instances different from those used for training during evolution. The evolved architectures producing the best results were found to be different from those of the standard ant colonization algorithms. Lourenço et al. [26] use grammatical evolution to design evolutionary algorithms to solve the knapsack problem. The evolved evolutionary algorithms are applied to unseen instances. Each evolved evolutionary algorithm specifies the type of selection, type of crossover, type of mutation, and parameter values. Evolved evolutionary algorithms using binary swap mutation and uniform crossover performed the best.

Generation hyper-heuristics go a step further, and instead of choosing a component of a metaheuristic to decide the control flow, these hyper-heuristics create a new component. In the study conducted by Hong et al. [21], a generative hyper-heuristic, employing genetic programming, is used to evolve mutation operators for evolutionary programming. The terminal set is comprised of random numbers produced by a Gaussian random number generator, and the function set is comprised of arithmetic operators. The approach was used to evolve ten function classes, seven unimodal, and three multimodal, and was found to require less processor time than the man hours needed to design new mutation operators. A different mutation operator was evolved for each function class using one instance of the class. Woodward and Swan [44] use local search, namely, hill-climbing, to evolve mutation operators for genetic algorithms. These mutation operators were found to outperform human-created mutation operators. Register machines are used to simulate the behavior of mutation operators. Seven function classes were used to test the effectiveness of the evolved mutation operators. Different mutation operators were created for each function class. Woodward and Swan [43] evaluate a similar approach which uses random search to generate search heuristics for a genetic algorithm. As in the previous study, register machines are used to emulate the selection process. Selection is based on the fitness or rank of a bit string. The evolved selection heuristics were tested for the mimicry problem set and

were found to perform better than the human-designed selection heuristics. In the study conducted by Dioşan and Oltean [14], genetic programming induces crossover operators for a genetic algorithm for function optimization. A different crossover operator is evolved for each of the 11 function classes. The performance of the evolved operators was found to be comparative to human-designed crossover operators. Drake et al. [17] also employ grammatical evolution to design the construction heuristic and move operators used by variable neighborhood search to solve the vehicle routing problem. The move operators generated are ruin and insertion heuristics which are used to perform the shaking process in the variable neighborhood search. The variable neighborhood search produced results close to the global optimum for all problem instances. Løkketangen and Olsson [24] use the ADATE system to generate the move selection, tabu tenure, and the aspiration criteria in a tabu search for solving the Boolean optimization problem (BOOP). The authors describe ADATE as a generation hyper-heuristic that performs offline learning. ADATE is an automatic programming system that produces functional programs in metalanguage ML. The generated components were found to perform better than manually designed components. One of the generated components producing good results was found to give good moves a longer tabu tenure which is not typical of human-designed tabu searches. This again emphasizes the advantage of automatic generation of metaheuristic components.

Discussion

Multi-level metaheuristics can be categorized as selection or generation perturbative hyper-heuristics. As previously outlined designing a metaheuristic involves making decisions regarding what parameter values to use, what operators to use, and the control flow of the overall algorithm. From the survey presented above, it is evident that hyper-heuristics have been fairly effective in making these design decisions. Selection perturbative hyper-heuristics are used to select numerical and discrete parameter values. Hence, the hyper-heuristic explores the space of parameter values. Evolutionary algorithms have chiefly been used for this purpose. The parameter values can be either coevolved while solving the problem at hand or optimized separately. In the latter case, the parameters can be determined offline during the training phase. Selection perturbative hyper-heuristics can also be used to make control flow decisions. This essentially involves selecting different operators at different stages of solving the problem. Hence, the decision of which operator to use can be made as part of the control flow decision. Evolutionary algorithms, including linear genetic programming, genetic algorithms, multigene expression programming, and grammatical evolution, have been used for control flow design. The decision regarding which operator to use may not be a matter of selecting an existing operator but creating a new operator. Generation hyper-heuristics can be used to generate new operators. This research has focused to a large extent on selection, mutation, and crossover operators in evolutionary algorithms. Genetic programming has primarily been used to generate new operators. Grammatical

evolution, local search, and random search have also been used for this purpose. A hyper-heuristic can be used to make all three design decisions simultaneously. This can be seen in the studies conducted by Lourenço et al. [25, 26] and Tavares and Pereira [39] where grammatical evolution is used to make this decision for the induction of an evolutionary and an ant colonization algorithm simultaneously.

In the case of all three design decisions, the parameter values, operators, and algorithms induced by the hyper-heuristic can be reusable or disposable. In the case of reusability, two phases are performed, a training phase and a testing phase. During the training phase, one or a subset of problem instances are used. The induced parameter values, operators, and algorithms are then used to solve unseen instances. Disposable parameter values, operators, and algorithms are induced for the particular problem instance, and hence a training phase is not required. Reusability has the advantage of the time required for design being reduced as redesign is not needed for every new instance; however, there may be a limited number of instances for which the generated design is applicable.

One of the challenges associated with using hyper-heuristics for the design of metaheuristics is the processing time needed. Given the advances made in multicore architectures and the availability of multicore architectures on a standard desktop machine, distributed architectures can be designed for the implementation of these hyper-heuristics. Most of the research conducted this far has focused on the configuration of evolutionary algorithms. These ideas can be transferred to the design of other metaheuristics. Evolutionary algorithms have primarily been used for design purposes. These have ranged from genetic algorithms through to grammatical evolution. A comparative study into the performance of the different types of evolutionary algorithms and their contribution to the design process would be interesting.

In most research using hyper-heuristics for parameter configuration in metaheuristics, this is done offline. However, more recently the effectiveness of online parameter configuration of metaheuristics has been established. For example, in the study conducted in [29], the effectiveness of combining online and offline parameter configuration of metaheuristics is shown. Thus, a current recent trend in the field is using hyper-heuristics for online parameter configuration of metaheuristics. This also helps alleviate the computational cost of offline parameter configuration in some instances.

Conclusion

A metaheuristic algorithm's configuration is the combination of its control flow and its parameter settings. Determining the best possible configuration for a metaheuristic is a difficult task, which is commonly done by trial and error and based on the experience of the algorithm designer. For this reason, metaheuristics have been developed that are able to adapt their configuration during the search (adaptive metaheuristics), potentially using a higher-level metaheuristic (multi-level metaheuristics). In this chapter, we have surveyed the literature on this topic. The

chapter has also highlighted the effectiveness of hyper-heuristics as multi-level metaheuristics. This serves as a starting point for researchers wanting to use hyper-heuristics for the automated design of metaheuristics. Hyper-heuristics have been fairly effective for the purpose of design, and in most cases the generated designs have produced better results than the manually designed metaheuristic, in some experiments producing designs that have not previously been thought of. This overview has also brought to light certain research questions and hence areas for future research. Research thus far has highlighted the potential of hyper-heuristics in the automated configuration of metaheuristics. This has now set the foundation for wider application, including more complex problems.

Perspectives

Recent advances in artificial intelligence (AI) have transformed how metaheuristics can be designed, tuned, and adapted. This chapter would not offer enough space to describe this new trend, but instead, we will provide a few insights in this section.

AI techniques, particularly machine learning (ML), offers the potential to automate and enhance the configuration of metaheuristics, minimizing the need for human intervention and improving performance across diverse problem instances.

AI-Driven Parameter Tuning One of the critical challenges in metaheuristics is determining optimal parameter settings. AI addresses this challenge through techniques like reinforcement learning (RL) and Bayesian optimization [4], which model the configuration task as a learning problem. RL-based methods, for example, can adapt parameter values dynamically during the search process, optimizing the balance between exploration and exploitation based on feedback from the solution space.

Meta-Learning and Transferability Inspired by the meta-learning paradigm proposed by Finn et al. [20], AI systems can generalize configuration strategies across problem domains. By analyzing a repository of solved instances, AI models can learn patterns in parameter effectiveness, enabling them to suggest configurations for unseen problems. This transferability reduces the computational overhead of parameter tuning and improves scalability.

Evolving Control Flow with AI Control flow, or the sequence in which metaheuristic components are executed, significantly impacts algorithm performance. AI-based approaches, such as neural architecture search (NAS) and genetic programming [47], allow for the automatic design of metaheuristic control flows. These techniques evolve control flow structures to maximize performance metrics, uncovering novel algorithmic combinations that human designers may overlook.

Adaptive Metaheuristics Through AI AI enhances adaptivity in metaheuristics by integrating predictive models that anticipate performance shifts and adjust configurations accordingly. For instance, deep neural networks can predict convergence

trends and suggest changes to the algorithm's strategy or parameters [35]. This predictive capability ensures that the metaheuristic remains effective even as the problem landscape evolves.

AI-Enabled Multi-Level Metaheuristics The recursive nature of multi-level metaheuristics aligns well with AI's hierarchical learning capabilities. AI can operate at multiple levels of the metaheuristic design process, optimizing both high-level strategies and low-level components [3]. For example, at the higher level, AI might determine whether to use an evolutionary algorithm or a simulated annealing approach, while at the lower level, it could fine-tune specific operators or hyperparameters.

Despite its promise, the integration of AI in metaheuristic configuration faces several challenges. Computational cost is a significant barrier, particularly for methods requiring extensive training data or repeated simulations [23]. Interpretability is another concern; AI-designed configurations may outperform traditional methods but lack the transparency needed for scientific understanding.

Future research should focus on hybrid approaches that combine the strengths of traditional metaheuristics with AI-driven enhancements. Developing lightweight, interpretable AI models tailored for metaheuristics could democratize access to these techniques, enabling broader application in real-world optimization problems.

the continuous interval [0, 1]. A decoder maps each vector of random keys to a solution program and assigns it a measure of quality. A Program-Expression is encoded in the chromosome using a head-tail representation which is later transformed into a syntax tree using a prefix notation rule. The artificial simulated evolution of the programs is accomplished with a biased random-key genetic algorithm. Examples of the application of this approach to symbolic regression are presented.

Introduction

Genetic programming (GP) is an evolutionary metaheuristic inspired by biological evolution to find computer programs that perform a predefined user computational task.

GP has its origins around 1954 with the evolutionary algorithms applied by Nils Aall Barricelli to evolutionary simulations [2]. One of the earliest practitioners of the GP methodology was Lawrence J. Fogel who, in 1964, applied evolutionary algorithms to the problem of discovering finite-state automata [9]. The first paper on tree-based genetic programming was presented in [5] and was later expanded by John R. Koza, who pioneered the application of genetic programming in various complex optimization and search problems [20–23].

Traditionally, GP has favored the use of programming languages that naturally embody tree structures [1], but several new non-tree representations were suggested and successfully implemented, such as linear genetic programming (LGP) [4], gene expression programming (GEP) [6], and Parallel Distributed Graphical Programming (PDGP) [24].

Genetic programming is still a young field of research. It attracts a growing research community, and there are many avenues of research yet to be explored. In this chapter, we introduce biased random-key genetic programming (*BRKGP*), a novel metaheuristic for computer program evolution.

The remainder of the chapter is organized as follows. In section "Program Representation" we describe the program representation. In section "Biased Random-Key Genetic Programming" we introduce the new approach, describing in detail the BRKGA, the chromosome structure and the decoding procedure, and the fitness function. Finally, in section "Examples" we illustrate the application of the approach to two cases in the area of symbolic regression, and in section "Conclusions" we make concluding remarks.

Program Representation

In genetic programming programs are usually expressed by syntax trees (ST). Figure 1 shows the tree representation of the program:

$$\max\left(2.2 - \frac{X}{11}, 7 \times \cos(Y)\right).$$

The variables and constants in the program (X, Y, *2.2, 11*, and *7*) are leaves of the tree. In GP the nodes that correspond to the leaves are called *terminals*, and the internal nodes represent the operations ($-$, $\div$, $\times$, cos, and max) and are called *functions*. The sets of allowed functions ($\mathcal{F}$) and terminals ($\mathcal{T}$) together form what is called the *primitive set* ($\mathcal{P}$) of a GP system.

In this chapter a linear representation of syntax trees is used. This indirect representation, called Program-Expression (*PE*), encodes a syntax tree as a sequence of elements of the primitive set which will be later translated, according to some predefined rules, into a syntax tree.

The set of rules used to translate a *PE* into a *ST* follows a prefix notation convention (*P-rule*). The *P-rule* translates a *PE* into a *ST* by reading sequentially, from left to right, each element in the *PE* and placing it in the bottom-most (first-criteria) and left-most (second-criteria) available node in the partial *ST* being constructed. Note that if there are no nodes available, in the partially built syntax tree, in which to place an element in the *PE,* then the process stops and the remaining

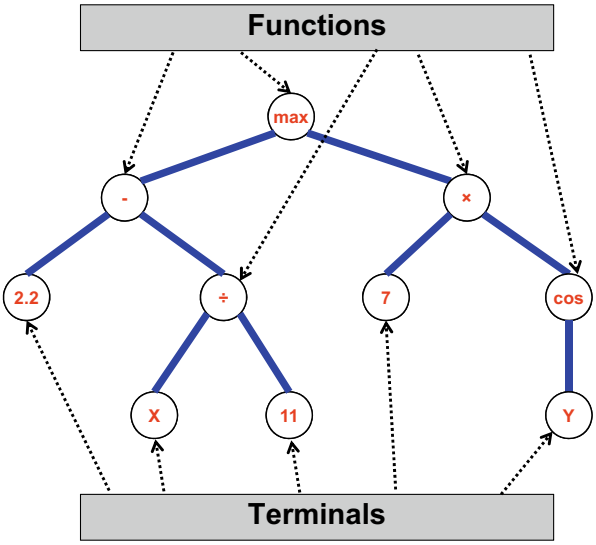

Fig. 1 Syntax tree of program $\max\left(2.2 - \frac{X}{11}, 7 \times \cos(Y)\right)$

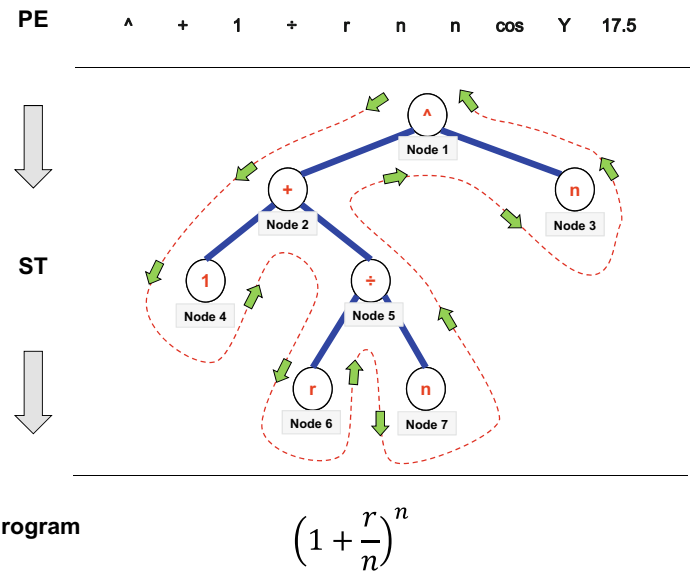

Fig. 2 Translation of a *PE* into a program using the *P-rule*

primitive elements in the *PE* are discarded and are called noncoding elements. Figure 2 demonstrates how the *PE*

$$\wedge + 1 \div r \;\; n \;\; n \;\; \cos \;\; Y \;\; 17.5$$

can be translated into a *ST* following the *P-rule*. The first primitive element in the *PE* is $|\wedge|$ and is placed in node 1 (the root of the tree). The second element in the *PE* is $|+|$ and is placed in node 2. The third primitive element in the *PE* is $|1|$ and is placed in node 4. The fourth primitive element in the *PE* is $|\div|$ and is placed in node 5. This process will be repeated until all elements in the *PE* are placed or there are no nodes available in the tree in which to place an element.

Note that the last three elements of the *PE,* $|\cos|$, $|Y|$, and $|17.5|$, are not included in the *ST*. The program that corresponds to the final *ST* is

$$\left(1+\frac{r}{n}\right)^n.$$

Biased Random-Key Genetic Programming

This section begins with an overview of the proposed biased random-key genetic programming *(BRKGP)* methodology. This is followed by a discussion of the biased random-key genetic programming algorithm, including detailed descriptions of the program encoding and decoding and the fitness measure.

Overview

The *BRKGP* metaheuristic presented in this chapter is based on four main components: a biased random-key genetic algorithm (*BRKGA*) [13], chromosomes, a decoding procedure to translate a chromosome into a syntax tree, and a fitness measure to assess the quality of the resulting programs.

The role of the *BRKGA* is to supply and evolve the chromosomes. A chromosome (genotype) indirectly represents a syntax tree (phenotype) that corresponds to a program. The decoding procedure receives as input a chromosome and in a first phase translates it into a Program-Expression (*PE*). Then, in a second phase the *PE*, obtained in the first phase, is translated into a syntax tree using the *P-rule* described in section "Program Representation."

Figure 3 illustrates the sequence of steps applied by the *BRKGP* to each chromosome.

The remainder of this section describes in detail the biased random-key genetic algorithm, the chromosome structure, the decoding procedure that maps a chromosome into a syntax tree, and the fitness measures.

Biased Random-Key Genetic Algorithms

Genetic algorithms with random keys, or *random-key genetic algorithms* (*RKGA*), were introduced by [3] for solving sequencing problems. In an *RKGA*, chromosomes

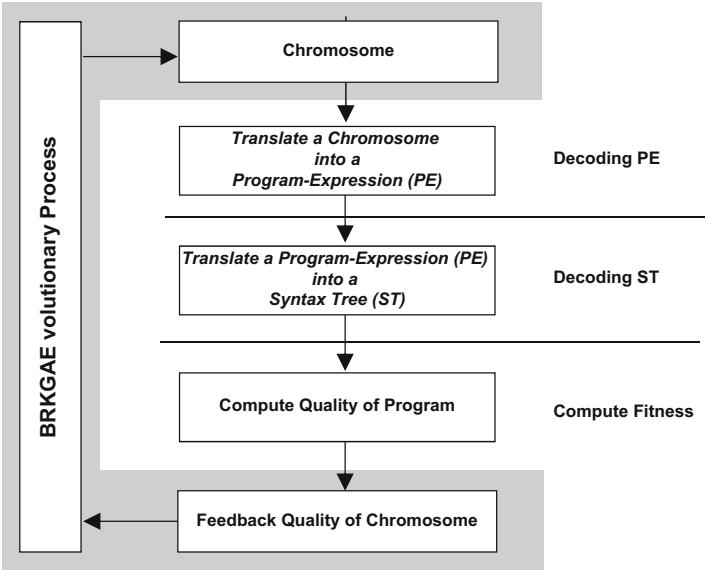

Fig. 3 Architecture of the *BRKGP*

are represented as vectors of randomly generated real numbers in the interval [0, 1]. A *decoder* is a deterministic algorithm that takes as input a chromosome and associates it with a solution of the combinatorial optimization problem for which an objective value or *fitness* can be computed.

An *RKGA* evolves a *population* of random-key vectors over a number of *generations* (iterations). The initial population is made up of p vectors each with r random keys. Each component of the solution vector, or random key, is randomly generated, independently, in the real interval [0, 1]. After the fitness of each individual is computed by the decoder in generation g, the population is partitioned into two groups of individuals: a small group of p_e *elite* individuals, i.e., those with the best fitness values, and the remaining set of $p - p_e$ *nonelite* individuals. To evolve the population of generation g, a new generation $(g + 1)$ of individuals is produced. All elite individuals of the population of generation g are copied without modification to the population of generation $g + 1$. *RKGAs* implement mutation by introducing *mutants* into the population. A mutant is a vector of random keys generated in the same way that an element of the initial population is generated. Its role is similar to that of mutation in other genetic algorithms [11], i.e., to introduce noise into the population and avoid convergence of the entire population to a local optimum. At each generation, a small number p_m of mutants is introduced into the population. With $p_e + p_m$ individuals accounted for in population $g + 1, p - p_e - p_m$ additional individuals need to be generated to complete the p individuals that make up population $g + 1$. This is done by producing $p - p_e - p_m$ offspring solutions through the process of *mating* or *crossover*.

A *biased random-key genetic algorithm* [13], *or simply BRKGA*, differs from an *RKGA* in the way parents are selected for mating. While in the *RKGA* of [3] both parents are selected at random from the entire current population, in a *BRKGA* each element is generated combining a parent selected at random from the elite partition in the current population and one from the rest of the population. Repetition in the selection of a mate is allowed, and therefore an individual can produce more than one offspring in the same generation. As in a *RKGA*, *parametrized uniform crossover* [25] is used to implement mating in a *BRKGA*. Let ρ_e be the probability that an offspring inherits the vector component of its elite parent. Recall that r denotes the number of components in the solution vector of an individual. For $i = 1, \ldots, r$, the i-th component $c[i]$ of the offspring vector c takes on the value of the i-th component $e[i]$ of the elite parent e with probability ρ_e and the value of the i-th component $\overline{e}\,[i\,]$ of the nonelite parent $\overline{e}$ with probability $1 - \rho_e$.

When the next population is complete, i.e., when it has p individuals, fitness values are computed for all of the newly created random-key vectors, and the population is partitioned into elite and nonelite individuals to start a new generation. Figure 4 depicts the transitional process between two consecutive generations.

A *BRKGA* searches the solution space of the combinatorial optimization problem indirectly by searching the continuous r-dimensional unit hypercube, using the

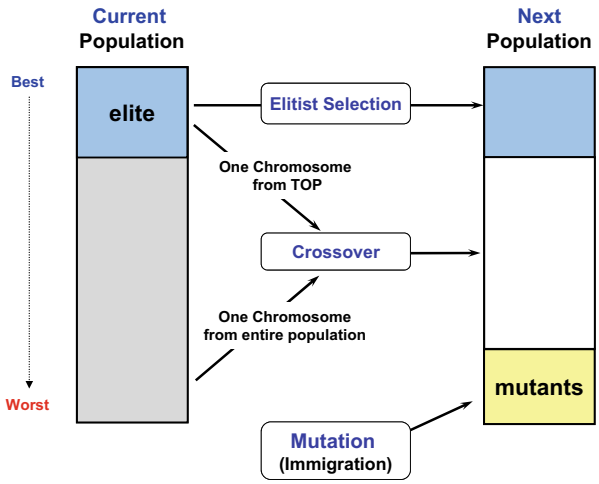

Fig. 4 Transitional process between consecutive generations

decoder to map solutions in the hypercube to solutions in the solution space of the combinatorial optimization problem where the fitness is evaluated.

*BRKGA*s have been applied with success to solve many types of combinatorial problems (see [10, 12, 14–19]).

A biased random-key genetic algorithm is specified by the parameters, the encoding and decoding of the solutions, and by the fitness measure. In the next section the algorithm is specified by first showing how programs are encoded and then decoded and how their fitness evaluation is computed.

Encoding and Chromosome Structure

A chromosome represents a program and is made of two parts. The first part encodes a *PE* and the second part encodes the values of the constants that can be used in the *PE*. To encode a *PE* a head-tail representation is proposed as in [6–8]. The head, h, represents the maximum number of internal nodes that can be in the syntax tree (*ST*) and can contain both functions (elements from set $\mathcal{F}$) and terminals (elements from the set $\mathcal{T}$), whereas the tail, t, represents the number of leaves of the *ST* and can only contain terminals (elements from the set $\mathcal{T}$). For each problem, the length of the head, h, is chosen, whereas the length of the tail, t, depends on h and on the arity, a, of the function with the most arguments and is determined by the expression

$$t = h\,(a - 1) + 1. \tag{1}$$

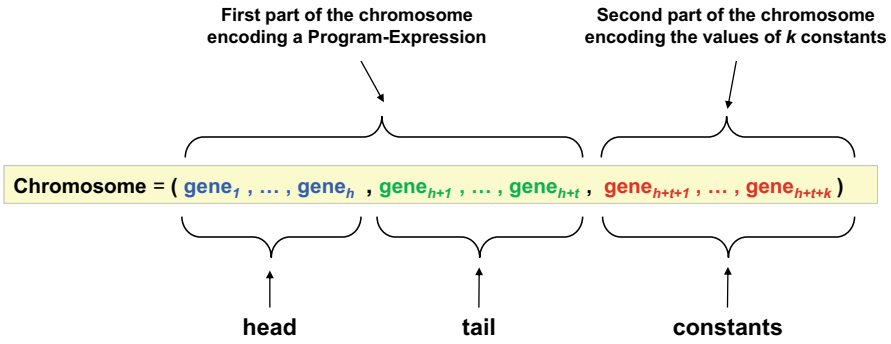

Fig. 5 Chromosome structure used to encode a *PE* with a vector of $h + t + k$ random keys

This way of determining the length of the tail guarantees that there will always be enough terminals to create syntactically valid *PE*s (assuming closure among the set of primitives).

Assuming that the terminal set includes k constants, then every chromosome supplied by the *BRKGA* encodes a Program-Expression (*PE*) as a vector of $(h + t + k)$ random keys, and Fig. 5 depicts the corresponding chromosome structure.

Decoding a Chromosome into a *PE*

The decoding of a chromosome into a Program-Expression (*PE*) has the following three steps:

- Decoding the head of the *PE*;
- Decoding the tail of the *PE*;
- Decoding the values of the constants.

Let the terminal set $\mathcal{T}$ be divided into the two mutually exclusive sets $\mathcal{V}$ and $\mathcal{K}$ which represent the set of variables and the set of constants, respectively, and let vF, vV, and vK represent vectors containing all the elements in the sets $\mathcal{F}$, $\mathcal{V}$, and $\mathcal{K}$, respectively. Additionally, let nF, nV, and nK represent the number of elements in the vectors vF, vV, and vK, respectively.

To better illustrate the various steps in the decoding process, an example based on the information presented in Table 1 is used.

According to Table 1 and the chromosome structure defined in the previous section, the chromosome will have 13 $(5 + 6 + 2)$ random keys. Furthermore, assume that the chromosome being decoded is

$$c = (0.25, 0.35, 0.93, 0.75, 0.05, 0.32, 0.67, 0.58, 0.15, 0.26, 0.86, 0.64, 0.43)\ . \tag{2}$$

Table 1 Information relative to the example

$\mathcal{F} = \{+, - \times \div, \surd\}$	$\Rightarrow$	$vF = \left(+, - \times \div, \surd\right)$ $nF = 5$
$\mathcal{T} = \{X, Y, Z, K_1, K_2\}$	$\Rightarrow$	$vV = \{X, Y, Z\}, nV = 3$ $vK = \{K_1; K_2\}$, $nK = 2$
$h = 5, a = 2$	$\Rightarrow$	$t = 5 \times (2 - 1) + 1 = 6$

```
procedure DecodeHead (vF, vV, vK, c, PE)
1   for r = 1, ..., h do
2       idx = ⌈c[r] × (nF + nV + nK)⌉
        // where ⌈x⌉ is the smallest integer greater or equal to x.
        // ** Decoding c[r] → PE[r] **
3       if (idx ≤ nF) then
            // it going to be a function
4           PE[r] = vF[idx];
5       else if (nF < idx ≤ nF + nV) then
            // it going to be a variable
6           PE[r] = vV[idx − nF];
7       else if (nF + nV < idx ≤ nF + nV + nK) ≤then
            // it going to be a constant
8           PE[r] = vK[idx − nF − nV];
9       endif
10  end for
end DecodeHead;
```

Fig. 6 Pseudo-code for the `DecodeHead` procedure

The decoding of the head of the *PE* is based on the fact that the head can be made of elements in any of the sets $\mathcal{F}$, $\mathcal{V}$, and $\mathcal{K}$. The mapping of the random key in position $r = 1, \ldots, h$ of the chromosome c, $c[r]$, into the primitive element in position r of the *PE*, $PE[r]$, is accomplished by the procedure DecodeHead whose pseudo-code is shown in Fig. 6.

Table 2 presents the results of the decoding of the head of the *PE* corresponding to the first five components of the chromosome given in expression (2).

At this point the first five components of the *PE* will be

$$\times \div \quad K_2 \quad Z + .$$

Table 2 Decoding the Head of the *PE*

r	$c[r]$	idx	Head of the *PE*
1	0.25	$\lceil 0.25 \times (5+3+2) \rceil = 3$	$vF[3] = \times$
2	0.35	$\lceil 0.35 \times (5+3+2) \rceil = 4$	$vF[5] = \div$
3	0.93	$\lceil 0.93 \times (5+3+2) \rceil = 10$	$vK[10-5-3] = K_2$
4	0.75	$\lceil 0.75 \times (5+3+2) \rceil = 8$	$vV[8-5] = Z$
5	0.05	$\lceil 0.05 \times (5+3+2) \rceil = 1$	$vF[1] = +$

```
procedure DecodeTail (vV, vK, c, PE)
1   for r = h + 1, ..., h + t do
2       idx = ⌈c[r] × (nV + nK)⌉
        // where ⌈x⌉ is the smallest integer greater or equal to x.
        // ** Decoding c[r] → PE[r] **
3       if (idx ≤ nV) then
            // it going to be a variable
4           PE[r] = vV[idx];
5       else if (nV < idx ≤ nV + nK) then
            // it going to be a constant
6           PE[r] = vK[idx − nV];
7       endif
8   end for
end DecodeTail;
```

Fig. 7 Pseudo-code for the `DecodeTail` procedure

The decoding of the tail of the *PE* is based on the fact that the tail can only consist of elements in sets $\mathcal{V}$ and $\mathcal{K}$. The mapping of the random key in position $r = h+1, \ldots, h+t$ of the chromosome c, $c[r]$, into the primitive element in position r of the *PE*, $PE[r]$, is accomplished by the procedure DecodeTail which has the pseudo-code presented in Fig. 7.

Table 3 presents the results of the decoding of the head of the *PE* corresponding to the chromosome given in expression (2).

At this point the components of the *PE* will be

$$\times \quad \div \quad K_2 \quad Z \quad + \quad Y \quad K_1 \quad Z \quad X \quad Y \quad K_2.$$

Table 3 Decoding the tail of the *PE*

r	$c[r]$	idx	Tail of the PE
6	0.32	$\lceil 0.32 \times (3+2) \rceil = 2$	$vV[2] = Y$
7	0.67	$\lceil 0.67 \times (3+2) \rceil = 4$	$vK[4-3] = K_1$
8	0.58	$\lceil 0.58 \times (3+2) \rceil = 3$	$vV[3] = Z$
9	0.15	$\lceil 0.15 \times (3+2) \rceil = 1$	$vV[2] = X$
10	0.26	$\lceil 0.26 \times (3+2) \rceil = 2$	$vV[4-3] = Y$
11	0.86	$\lceil 0.86 \times (3+2) \rceil = 5$	$vK[5-3] = K_2$

This *PE* is translated with the *P-Rule* into

$$\frac{K_2}{Z} \times (Y + K_1)\,. \tag{3}$$

Note that the last four components in the *PE* are noncoding elements.

The final step in the decoding process consists in decoding the values of the constants in the terminal set. That is accomplished by using the decoding expression

$$K_i = fk\left(c\left[h+t+i\right], p_1, p_2, \ldots, p_p\right) \quad i = 1, \ldots, nK,$$

where $fk()$ is a function that accepts as input a random key, $c[r]$, and a set of parameters $p_1, p_2, \ldots, p_p$ and outputs a real or integer value. The simplest case can be obtained when $fk(c[r]) = c[r]$, i.e., the value of the constant is equal to the value of the random-key input. Many functions can be used for $fk()$. However, the following functions were used:

1. **randReal**$(c[r], l, u) = l + c[r] \times (u - l)$ – which generates a real value between l and u;
2. **randInt**$(c[r], l, u) = \lfloor l + c[r] \times (u - l) \rfloor$ – which generates an integer value between the integers l and u.

For the example, assuming $fk(c[r]) = c[r]$, the values of the constants K_1 and K_2 are, respectively, $c[5+6+1] = 0.64$ and $c[5+6+2] = 0.43$. The final program can be obtained by replacing the constants K_1 and K_2 in expression (3) by 0.64 and 0.43, respectively, i.e.:

$$\frac{0.43}{Z} \times (Y + 0.64)\,. \tag{4}$$

Fitness Function

The objective of the fitness measure is to assign a quality value to each chromosome so that the evolutionary process differentiates the different chromosomes and directs

Table 4 Dataset for *SR*-example 1

x	y	x	y	x	y
1	10	11	62,810	21	806,610
2	98	12	88,428	22	969,958
3	426	13	121,186	23	1,156,946
4	1252	14	162,302	24	1,369,752
5	2930	15	213,090	25	1,610,650
6	5910	16	274,960	26	1,882,010
7	10,738	17	349,418	27	2,186,298
8	18,056	18	438,066	28	2,526,076
9	28,602	19	542,602	29	2,904,002
10	43,210	20	664,820	30	3,322,830

the search to better solutions (chromosomes). Depending on the problem being solved, different fitness measures can be used.

Suppose that a symbolic regression problem is to be solved where the best fitting function to a set of points is to be found. In this case the usual measures used in the linear or nonlinear regression can be used, least squares, mean squared error, etc. However, if, for example, a rule to decide when to buy or sell a certain stock in the NYSE is to be discovered, then the quality of rule could be evaluated by using historical data, and the profit obtained with the rule, over a certain number of historical days, could be considered the measure of fitness.

Examples

This section presents two examples in the area of symbolic regression (*SR*) to illustrate the application of *BRKGP*. The mean absolute error (MAE)

$$\text{MAE} = \frac{1}{ND} \sum_{d=1}^{d=ND} |f_d - y_d|$$

is used as fitness measure, where ND is the number of data points, y_d is the value of data point d, and f_d is the value obtained by the expression generated by the *BRKGP* for data point d.

SR-Example 1

Table 4 presents 30 data points that are sampled from the function $y = x + 2x^2 + 3x^3 + 4x^4$. *BRKGP* is used to try to discover the polynomial that best fits the data.

The *BRKGP* configuration used for this example is given in Table 5.

Table 5 *BRKGP* configuration for the *SR*-example 1

$\mathcal{F} = \{+, -, \times, \div\}$	$p = 500$
$\mathcal{T} = \{x\}$	$p_e = 100$
$h = 5, 10, 15$	$p_m = 100$
$a = 2$	$\rho_e = 0.85$
$t = h \times (a - 1) + 1$	Fitness = mean absolute error (MAE)
	Stopping criterion = 100 generations

Table 6 Dataset for *SR*-example 2

R	*Area*	*R*	*Area*
10	314.1592654	21	1385.44236
11	380.1327111	22	1520.530844
12	452.3893421	23	1661.902514
13	530.9291585	24	1809.557368
14	615.7521601	25	1963.495408
15	706.8583471	26	2123.716634
16	804.2477193	27	2290.221044
17	907.9202769	28	2463.00864
18	1017.87602	29	2642.079422
19	20,1256.637061	30	2827.433388

Note that, since the best value of h to use is not known, three possibilities for h ($h = 5$, $h = 10$, $h = 15$) are tried. For $h = 5$ and $h = 10$ the *BRKGP* was not able to find the correct polynomial (i.e., MAE > 0). However, with $h = 15$ it was able to find the correct polynomial (i.e., MAE = 0) after 12 generations. The final expression was

$$(((((X + X) \times (X \times X)) + X) \times ((X + X) + (X \div X))) + ((X \times X) \times X))$$

which after being simplified gives the correct polynomial.

SR-Example 2

In this example *BRKGP* is used to try to discover the relation between the *Area* of the circle and its radius *R* that best fits the 20 data points presented in Table 6. The 20 data points were sampled from the function $Area = \pi R^2$.

The *BRKGP* configuration used for this example is given in Table 7. Note that, in this case, three constants K_1, K_2, K_3 are included that will be decoded using $fk() =$ **randInt**(1, 10,000).

For $h = 10$ *BRKGP* found, after 67 generations, the expression

$$((R + ((R \div 689) \div 689)) \times (((9151 \div 4273) \times R) + R))$$

Table 7 *BRKGP*configuration for the *SR*-example 2

$\mathcal{F} = \{+, -, \times, \div\}$	$p = 500$
$\mathcal{T} = \{R, K_1, K_2, K_3\}$	$p_e = 100$
$fk() =$ **randInt**(1, 10,000)	$p_m = 100$
$h = 10, 15$	$\rho_e = 0.85$
$a = 2$	Fitness = mean absolute error (MAE)
$t = h \times (a - 1) + 1$	Stopping criterion = 100 generations

which after being simplified is equivalent to $Area = 3.1415933\ R^2$ and has MAE = 0.00027997.

For $h = 15$ *BRKGP* found, after 82 generations, the expression

$$((R \times (((R + R) + R) \times ((476 + 9787) - (6699 \div 476)))) \div 9787)$$

which after being simplified is equivalent to $Area = 3.1415939\ R^2$ and has MAE = 0.00051594.

Note that, in both cases, the value of π was approximated to five decimals.

Conclusions

This chapter introduced biased random-key genetic programming, a novel metaheuristic for genetic programming. After introducing how programs are represented using a linear Program-Expression representation, the chapter presents the head-tail encoding and explains how the decoding of the chromosome can be accomplished. The chapter concludes by illustrating how *BRKGP* can be applied to solve problems using two symbolic regression examples.

Abstract

This chapter explores some heuristics incorporating data mining procedures. The basic idea of using data mining inside a heuristic is to obtain knowledge from previous iterations performed by a heuristic to guide the search in the subsequent iterations. Patterns extracted from good-quality solutions can be used to guide the

search, leading to a more effective exploration of the solution space. This survey shows that heuristics may benefit from data mining by obtaining better solutions in shorter computational times.

Keywords

Data mining · Frequent patterns · Hybrid metaheuristics · Problem decomposition · Problem size reduction

Introduction

Many combinatorial optimization problems of practical relevance are classified as NP-hard, which generally means they cannot be solved efficiently. As a result, one approach to tackling these challenging problems is to accept suboptimal solutions rather than attempting to find the optimal ones. Heuristics serve as computational methods designed to generate and evaluate candidate solutions iteratively. Although the complexity of finding optimal solutions can grow exponentially with the size of NP-hard problem instances, the evaluation of candidate solutions can often be conducted much more efficiently, typically in polynomial time [5].

Metaheuristics have been developed to enhance the performance of heuristics in exploring solution spaces. These high-level procedures provide a framework that guides basic heuristics, improving their effectiveness. Well-known metaheuristics, such as Simulated Annealing, Tabu Search, GRASP, and Iterated Local Search (ILS), utilize stochastic local search (SLS) methods. These iterative processes usually yield feasible candidate solutions at each iteration and can be applied to many combinatorial optimization problems.

Data mining is crucial in extracting valuable knowledge from data [4, 15, 17, 19]. It involves automatically identifying patterns representing significant features and revealing concepts embedded in raw data. As a result, data mining becomes essential for informed decision-making in various contexts.

In [7], we presented a survey about incorporating data mining into hybrid metaheuristics to extract patterns from high-quality solution sets. The core idea is to use knowledge from previous heuristic iterations to guide future searches. It has been shown that heuristics can achieve a more effective exploration of the solution space by analyzing patterns derived from high-quality solutions.

This chapter updates the survey presented in [7] by highlighting recent advancements in applying data mining techniques within heuristics. In section "Strategies to Use Data Mining in Heuristics," we review strategies from the earlier survey that combine metaheuristics with data mining processes and introduce a new approach called MineReduce. Then, in section "Hybrid Heuristics with Data Mining: A Selection of Cases," we analyze various implementations across different applications and the corresponding computational results. Finally, section "Conclusion" offers concluding remarks and discusses potential future work in this evolving field.

Strategies to Use Data Mining in Heuristics

This section describes some strategies already presented in [7] to incorporate data mining in metaheuristics and a new approach called MineReduce.

DM-MSH and MDM-MSH Strategies

As described in [5], given a (combinatorial) problem Π, a stochastic local search algorithm for solving an arbitrary problem instance $\pi \in \Pi$ is defined by the following components:

- the search space $S(\pi)$ of instance π, which is a set of candidate solutions to π;
- a set of (feasible) solutions $S'(\pi) \subseteq S(\pi)$;
- a neighborhood relation on $S(\pi)$, $N(\pi) \subseteq S(\pi) \times S(\pi)$;
- an initialization procedure INIT_PROC(π) that draws an element from a probabilistic function $init(\pi)$, which specifies a probability distribution over initial search positions;
- a step procedure STEP_PROC(π, s) that draws an element from a probabilistic function $step(\pi, s)$, which maps each given position s onto a probability distribution over its neighboring positions, for specifying the local search steps;
- a termination procedure TERM_PROC(π, s) which uses a terminate predicate T that indicates the probability the search will be terminated upon reaching a specific point in the search space.

When using stochastic local search, the solutions obtained may differ in each algorithm run, so multistart SLS metaheuristics can find a different solution in each iteration.

So, the basic concept of incorporating a data mining process in multistart SLS metaheuristics is that patterns found in high-quality solutions obtained in earlier iterations can be used to conduct and improve the search process.

Two strategies to use data mining were presented in [7]. In the first, DM-MSH, the multistart heuristic (MSH) is divided into two phases. The first one is called *Elite Set Generation Phase*. It executes gen_elite_iter MSH iterations to obtain a set $\mathscr{S}$ of different solutions. The d best solutions from $\mathscr{S}$ compose an elite set $\mathscr{D}$.

Between the two phases, the data mining procedure is applied. It is responsible for extracting a set of patterns $\mathscr{P}$ from the elite set $\mathscr{D}$. The patterns to be mined are sets of elements frequently appearing in solutions in $\mathscr{D}$, which characterizes a frequent itemset mining application. A frequent itemset mined from $\mathscr{D}$ with support $s\%$ represents a set of elements that occur together in $s\%$ of the elite solutions.

Next, in the second phase, called *Hybrid Phase*, several slightly different MSH iterations are executed. The construction and local search heuristics may use a mined pattern $p \in \mathscr{P}$ in these iterations. For example, in constructive heuristics,

all elements of a pattern p may be inserted into the partial solution, from which a complete solution will be built by executing the standard construction procedure. This way, all constructed solutions will contain the elements of a pattern $p \in \mathscr{P}$. Likewise, local search procedures may use the elements of pattern p by requiring that only neighbors that contain elements from pattern p should be evaluated.

The pseudo-code of DM-MSH is illustrated in Fig. 1. In line 1, the elite set $\mathscr{D}$ is initialized with an empty set. The loop from line 3 to line 8 corresponds to the *Elite Set Generation Phase*, in which gen_elite_iter iterations of the multistart heuristic are performed. The original construction method is executed in line 4. Then, a local search method is performed in line 5. The elite set $\mathscr{D}$ is updated in line 6. In case of improvement, the best solution is updated in line 7. The data mining procedure extracts the set of patterns $\mathscr{P}$ from $\mathscr{D}$ in line 9. The loop from line 10 to line 15 corresponds to the *Hybrid Phase*. Each iteration is based on a pattern $p \in \mathscr{P}$, selected in line 11. The construction procedure that may use data mining is performed in line 12. In line 13, the local search that may use data mining is executed. In case of improvement, the best solution is updated in line 14. The best solution is returned in line 16.

The second strategy, called MDM-MSH, was developed to improve the results further. The main idea of this strategy is to mine more than once whenever the elite set is stable and good enough to be mined. The mining process will be executed: (a) as soon as the elite set first becomes stable, which means that no change in the elite set occurs throughout a given number of iterations, and (b) whenever the elite set has been changed and again has become stable.

Figure 2 shows the pseudo-code of MDM-MSH. The loop from line 4 to 10 corresponds to the first elite set generation phase, in which MSH iterations are performed until the elite set becomes ready to be mined or the total number of

Fig. 1 Pseudo-code of DM-MSH

```
begin DM_MSH(n_iter, π, f())
1  𝒟 ← ∅;

4      s ← CONSTRUCT_SOL(π, f);
5      s ← LOCAL_SEARCH(s, π, f);
6      UPDATE_ELITE(𝒟, s);
7      if f(π,s) < f(π, best_sol) then best_sol ← s;
8  end-for;
9  𝒫 ← MINE(𝒟);
10 for it = gen_elite_iter + 1,...,n_iter do
11     p ← SELECT_PATTERN(𝒫);
12     s ← DM_CONSTRUCT_SOL(p, π, f);
13     s ← DM_LOCAL_SEARCH(p, s, π, f);
14     if f(π,s) < f(π, best_sol) then best_sol ← s;
15 end-for;
16 return best_sol;
end DM_MSH.
```

Fig. 2 Pseudo-code of MDM-MSH

```
begin MDM_MSH(n_iter, π, f())
1   𝒟 ← ∅;
2   f(π, best_sol) ← ∞;
3   it ← 0;
4   repeat
5       s ← CONSTRUCT_SOL(π, f);
6       s ← LOCAL_SEARCH(s, π, f);
7       elite_set_is_ready ← UPDATE_ELITE(𝒟, s);
8       if f(π, s) < f(π, best_sol) then best_sol ← s;
9       it ← it + 1;
10  until elite_set_is_ready or it = n_iter;
11  while it < n_iter do
12      if elite_set_is_ready then 𝒫 ← MINE(𝒟);
13      p ← SELECT_PATTERN(𝒫);
14      s ← DM_CONSTRUCT_SOL(p, π, f);
15      s ← DM_LOCAL_SEARCH(p, s, π, f);
16      elite_set_is_ready ← UPDATE_ELITE(𝒟, s);
17      if f(π, s) < f(π, best_sol) then best_sol ← s;
18      it ← it + 1;
19  end-while;
20  return best_sol;
end MDM_MSH.
```

iterations is executed. Next, in the loop from line 11 to 19, the data mining procedure is performed in line 12 whenever the elite set is ready. In line 13, a pattern is selected. Then, the adapted construction is performed in line 14, and in line 15 the adapted local search is executed. The best solution is updated in line 17 if a better solution is found. After executing all iterations, the best solution is returned in line 20.

DM-MSH and MDM-MSH share a common approach. At some point, the algorithm benefits from knowledge accumulated in previous iterations. This approach relies on the assumption that there is a high probability that frequent patterns mined from a restricted set of high-quality solutions are part of other suboptimal and maybe even optimal solutions to the same problem instance. Thus, they may be inserted in initial solutions or required in neighbor solutions during a local search. The main difference between DM-MSH and MDM-MSH is when and how often patterns are mined.

According to Talbi's taxonomy for metaheuristics that incorporate machine learning (ML) [14], DM-MSH and MDM-MSH can be classified as *online low-level* ML-supported metaheuristics since they gather knowledge during the search while solving the problem (hence, online) and use that knowledge in processes that drive the initialization of solutions or local search (low-level components).

Experimental evidence shows that incorporating those strategies improved the effectiveness and efficiency of several heuristics for different combinatorial optimization problems, indicating that their underlying assumption holds.

MineReduce Strategy

Another approach named MineReduce was proposed based on the previous ideas. Since the mined patterns are assumed to likely be part of the best solutions to a problem instance, this approach temporarily fixes items from a pattern in the solution, equivalent to fixing (or at least constraining) values of decision variables related to those items. Therefore, the MineReduce approach applies a decomposition strategy that reduces the original problem instance to a subproblem by deleting or aggregating items based on the information obtained from a pattern. In essence, a pattern $p \in \mathscr{P}$ is selected for driving the following three-step process:

1. *Reduce*: A reduction operation is applied to the original problem instance $\pi \in \Pi$, removing or aggregating items from p (for being fixed in the solution), which results in a reduced instance $\pi' \in \Pi$;
2. *Optimize*: A solution $s' \in S'(\pi')$ – i.e., a feasible (and presumably good) solution to the reduced instance π' – is obtained through the application of some optimization method (e.g., SLS);
3. *Expand*: An expansion operation is applied to s', reinserting or disaggregating the items from p, which results in a solution $s \in S'(\pi)$ – i.e., a feasible solution to the original instance π.

To picture this process more concretely, consider the classical 0-1 knapsack problem (01-KP), where we have a knapsack and a set of items, each with a weight and a value, and the objective is to fill the knapsack with the most valuable subset of items that it can accommodate. Specifically, consider the following toy instance of the 01-KP:

$$\pi = (W = 90, I = \{a, b, c, d, e, f, g, h, i, j\})$$

The knapsack in instance π has a capacity $W = 90$. It can hold items from the set $I = \{a, b, c, d, e, f, g, h, i, j\}$, whose properties are in Table 1.

Table 1 Items' properties for the 01-KP toy instance

Item	Weight	Value
a	9	50
b	13	35
c	18	20
d	38	16
e	15	60
f	68	45
g	27	60
h	39	40
i	23	30
j	52	10

Imagine we have designed and applied a problem-specific MSH for the 01-KP to our toy instance π. Suppose we have kept the best five solutions found across several iterations in an elite set $\mathscr{D} = \{s_1, s_2, s_3, s_4, s_5\}$, which are in Table 2.

Now, consider we have mined patterns from $\mathscr{D}$ with a minimum support of 60%. That means extracting the maximal frequent itemsets from $\mathscr{D}$, considering an itemset frequent if it is present in at least 60% of the solutions of $\mathscr{D}$. In this example, that would produce a pattern set $\mathscr{P} = \{p_1, p_2\}$. Those mined patterns are described in Table 3.

Once patterns have been mined, we can select one to drive MineReduce's reduce-optimize-expand process. For example, consider p_1 is selected. In the *reduce* step, we would assume that the items from p_1 must be part of a solution to π. Therefore, we would temporarily fix them in the solution and remove them from I, obtaining the following reduced instance:

$$\pi'_1 = (W'_1 = 53, I'_1 = \{c, d, f, g, h, i, j\})$$

In contrast, if pattern p_2 is selected instead of p_1, then a different reduced instance is obtained:

$$\pi'_2 = (W'_2 = 39, I'_2 = \{b, c, d, f, h, i, j\})$$

Note that the knapsack capacity is considerably lower in the reduced instances (we subtract the pattern weights since its items are fixed in the solution), and so is the number of items one can pick to fill the knapsack. Hence, these instances have a much smaller solution space, which means they are much easier to solve than the original one.

Now, in the *optimize* step, consider that we applied an optimization method (e.g., SLS) to π'_1 and obtained the following solution: $s'_1 = \{g, i\}$ (with weight = 50 and value = 90). Finally, we must reverse the reduction operation in the *expand* step. That is, the items from p_1 (which had been fixed in the solution) must be inserted in s'_1, which will produce a new solution to the original instance π: $s = \{a, b, e, g, i\}$ (with weight = 87 and value = 235).

Table 2 Elite solutions for the 01-KP toy instance

Solution	Weight	Value
$s_1 = \{a, b, e, h\}$	76	185
$s_2 = \{a, d, e, g\}$	89	186
$s_3 = \{a, b, c, e, i\}$	78	195
$s_4 = \{a, e, g, h\}$	90	210
$s_5 = \{a, b, c, e, g\}$	82	225

Table 3 Patterns mined for the 01-KP toy instance

Pattern	s_1	s_2	s_3	s_4	s_5
$p_1 = \{a, b, e\}$	✓		✓		✓
$p_2 = \{a, e, g\}$		✓		✓	✓

Fig. 3 Pseudo-code of MR-MSH

```
begin MR_MSH(n_iter, π, f())
1   𝒟 ← ∅;
2   f(π, best_sol) ← ∞;
3   it ← 0;
4   repeat
5       s ← CONSTRUCT_SOL(π, f);
6       s ← LOCAL_SEARCH(s, π, f);
7       elite_set_is_ready ← UPDATE_ELITE(𝒟, s);
8       if f(π, s) < f(π, best_sol) then best_sol ← s;
9       it ← it + 1;
10  until elite_set_is_ready or it = n_iter;
11  while it < n_iter do
12      if elite_set_is_ready then 𝒫 ← MINE(𝒟);
13      p ← SELECT_PATTERN(𝒫);
14      π′ ← REDUCE(π, p);
15      s′ ← CONSTRUCT_SOL(π′, f);
16      s′ ← LOCAL_SEARCH(s′, π′, f);
17      s ← EXPAND(s′, p);
18      s ← LOCAL_SEARCH(s, π, f);
19      elite_set_is_ready ← UPDATE_ELITE(𝒟, s);
20      if f(π, s) < f(π, best_sol) then best_sol ← s;
21      it ← it + 1;
22  end-while;
23  return best_sol;
end MR_MSH.
```

Since MDM-MSH has generally performed better than DM-MSH, its adaptive multi-mining structure has been adopted in the MineReduce-based MSH. Figure 3 shows the pseudo-code of MR-MSH. It has essentially the same structure as MDM-MSH. The differences can be observed from line 14 to line 18. In line 14, the problem instance π is reduced to π' based on the selected pattern p. Lines 15 and 16 correspond to a typical implementation of the *Optimize* step from the MineReduce approach, consisting of one MSH iteration (construction and local search) on $S(\pi')$, which produces a locally optimal solution s' to the reduced instance π'. In line 17, s' is expanded into the corresponding solution s to instance π based on pattern p. Finally, in line 18, s is the initial solution for a local search on $S(\pi)$.

According to Talbi's taxonomy [14], like DM-MSH and MDM-MSH, MR-MSH can be classified as an *online low-level* ML-supported metaheuristic. However, it is additionally (and primarily) classified as a *problem-level* ML-supported metaheuristic since it uses the discovered knowledge for hierarchical problem decomposition (defining and solving smaller subproblems).

The following section presents several cases showing that incorporating data mining using the above strategies improved the base heuristics' solution quality and convergence speed.

Hybrid Heuristics with Data Mining: A Selection of Cases

This section presents a selection of cases where data mining has been incorporated into heuristics for different combinatorial optimization problems.

In [7], several examples show the integration of data mining with heuristics based on Greedy Randomized Adaptive Search Procedures (GRASP) applied to problems with different characteristics. The first was proposed to solve the server replication for reliable multicast problem. A solution to this problem is an unordered set of elements. The second GRASP was proposed to solve the traveling salesperson problem with pickup and delivery. This problem has solutions that are ordered sets of elements, which require a different approach. In the last two of these four cases, data mining was integrated with hybrid versions of GRASP that include a path-relinking strategy, one for the two-path network design problem and another for the p-median problem. Data mining was also integrated with heuristics based on Iterated Local Search (ILS) to solve the set covering with pairs problem in [7].

Section "DM-Supported HGS for the Capacitated VRP" shows the results obtained by incorporating the MDM-MSH strategy into a Hybrid Genetic Search (HGS) heuristic for the capacitated vehicle routing problem.

Then, in section "DM-Supported MS-ILS for the Heterogeneous Fleet VRP," three multistart versions of ILS using data mining strategies (respectively DM-MSH, MDM-MSH, and MR-MSH) are presented and evaluated for the heterogeneous fleet vehicle routing problem.

Finally, in section "DM-Supported MS-ILS for the Multisource Capacitated FLP with Customer Incompatibilities," the MR-MSH approach is combined with the ILS heuristic for the multisource capacitated facility location problem with customer incompatibilities.

The computational results from all these applications confirm that frequent patterns mined from restricted sets of high-quality solutions can improve the performance of heuristic methods regarding solution quality and convergence speed.

DM-Supported HGS for the Capacitated VRP

This section summarizes the results obtained by incorporating data mining into a multistart SLS heuristic for the capacitated vehicle routing problem (CVRP). An application of the MDM-MSH strategy was proposed for this problem [10] and ranked 2nd in the CVRP track of the 12th DIMACS Implementation Challenge (http://dimacs.rutgers.edu/programs/challenge/vrp/cvrp).

Problem Definition

The CVRP is described as follows. Let $G = (V, A)$ be a directed graph, where $V = \{0, 1, \ldots, n-1\}$ is a set composed of n vertices and $A = \{(i, j) : i, j \in V, i \neq j\}$ is the set of arcs. Vertex 0 is the depot from where the vehicles depart, whereas the

set $V' = V \backslash \{0\}$ consists of the remaining vertices representing $n - 1$ customers. Each customer $i \in V'$ is associated with a nonnegative quantity q_i that specifies the demand for some resource, and a vehicle can carry a maximum quantity Q of the resource. Each arc $(i, j) \in A$ has an associated cost d_{ij} representing the distance between vertices i and j. A route is defined by a sequence of vertices $R = (i_1, i_2, \ldots, i_{|R|})$, $i_1 = i_{|R|} = 0$, and $\{i_2, \ldots, i_{|R|-1}\} \subseteq V'$; that is, each route is a circuit in G that starts and ends at the depot. A route R is feasible if the sum of all customers' demands on R does not exceed the vehicle capacity Q. A route's cost is the sum of the costs (distances) associated with each traversed arc. The aim is to discover feasible routes such that each customer is visited precisely once, and the sum of all route costs is minimized. There are no restrictions on the number of routes in a solution.

Data Mining Application

The proposed method was built by incorporating data mining into a state-of-the-art Hybrid Genetic Search (HGS) metaheuristic for the CVRP [16]. HGS is an iterative population-based metaheuristic that restarts the population whenever it completes a number of consecutive iterations without improving the overall best solution.

In MDM-HGS, the elite set E is updated whenever a new feasible solution is inserted in the population if E is not full or the new solution is better than the worst solution in E. It is considered $stable$ when one of the following criteria is met: (i) E has not been mined yet, and its contents have not changed for a number of consecutive restarts greater than or equal to δR_{MAX}, where δ is a parameter and R_{MAX} is the maximum number of restarts, dynamically estimated based on the time limit, the elapsed time, and the number of completed restarts; or (ii) the contents of E have changed after it was last mined, but they have not changed for a number of consecutive restarts greater than or equal to δR_{MAX}.

The data mining method returns frequent patterns found in E. Each pattern is a set of paths connecting customers. Figure 4 illustrates this data mining process with four distinct solutions for a CVRP instance. Suppose these solutions compose an elite set for the corresponding instance and let the minimum support be 100%. In that case, the data mining method would extract a pattern composed of the paths that appear in all four solutions (thick lines in the figure).

A new solution generation method is introduced in MDM-HGS. It is based on a randomized version of the Clarke and Wright (CW) heuristic and uses the paths from a mined pattern to initialize routes. Its randomization mechanism is a roulette wheel selection as in the CW implementation discussed in [13]. The *savings list S* is built when the problem instance data is loaded. It contains all edges that connect two customers in the input graph, sorted in decreasing order of their corresponding savings values. A savings value represents the cost savings obtained by concatenating two routes, one where customer i is adjacent to the depot and another where customer j is adjacent to the depot, via the insertion of the edge $\langle i, j \rangle$ in the solution. It is given by $s_{ij} = d_{0i} + d_{0j} - d_{ij}$, where d_{ij} is the distance between vertices i and j, and vertex 0 is the depot.

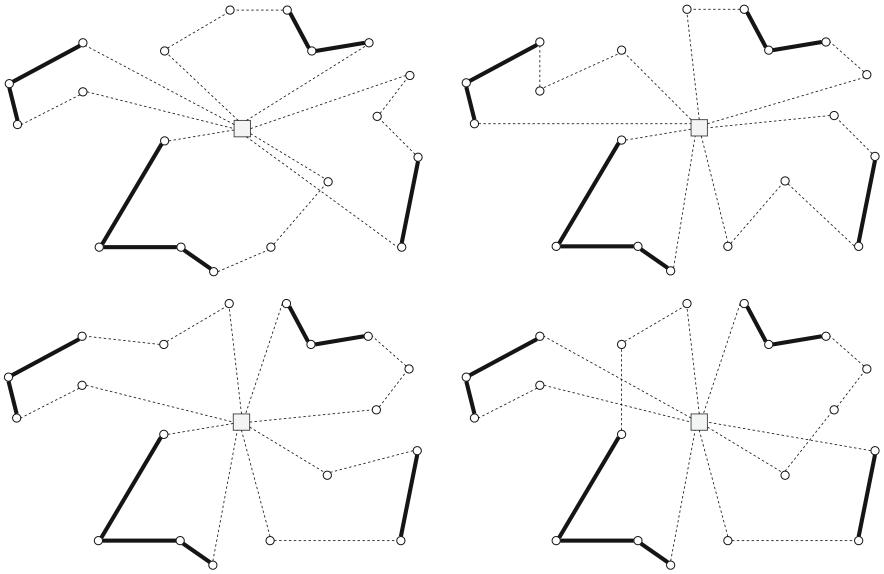

Fig. 4 Four distinct solutions for a CVRP instance and a pattern with 100% support. (Source: [10, p. 5])

The randomized CW solution generation based on a pattern p is described in Fig. 5. The solution is initialized with one route for each path in p (lines 1–3) and one for each customer not in p (lines 4–6). Then, the savings list S is iteratively processed (lines 7–13). At each step, an edge $\langle i, j \rangle$ is selected among the t (a random number between 2 and 6, inclusive) first unvisited entries in S using the roulette wheel method (line 9). Suppose customers i and j are adjacent to the depot on two different routes, and the vehicle capacity is sufficient for the total demand of both routes. In that case, these routes are concatenated by inserting $\langle i, j \rangle$ in the solution (lines 10–12). Finally, after S has been processed, a greedy strategy is used to avoid an excessive number of routes: for each route with only one customer i, i is moved to the end of a route with more than one customer. Each move is the cheapest, feasible if possible (line 16), infeasible otherwise (line 18).

Computational Results

Extensive computational experiments were conducted to compare MDM-HGS and the original method HGS-CVRP concerning the best solution found (within a given time-out) and the primal integral (PI) [1], which aims to measure the progress of the primal bound's convergence toward the optimal solution over the entire solving time. The smaller it is, the better the expected quality of the incumbent solution if the solving procedure is stopped at an arbitrary point in time. For each combination of instance and algorithm, the following values were registered: the average solution

```
begin DM_RCW(p)
1  for each path in p do
2      Initialize a route with the current path;
3  end-for;
4  for each customer not in p do
5      Initialize a route with the current customer;
6  end-for;
7  while S contains unvisited positive-valued entries do
8      t ← RAND(2,6);
9      ⟨i, j⟩ ← ROULETTE_WHEEL(S,t);
10     if two routes can be feasibly concatenated through ⟨i, j⟩ then
11         Concatenate the two routes through ⟨i, j⟩;
12     end-if;
13 end-while;
14 for each route with only one customer i do
15     if i can be feasibly moved to a route with more than one customer then
16         Make the cheapest feasible move of i to the end of another route;
17     else
18         Make the cheapest infeasible move of i to the end of another route;
19     end-if;
20 end-for;
21 return the generated solution;
end DM_RCW.
```

Fig. 5 Pseudo-code of the pattern-based randomized CW solution generation

cost (Avg Cost), the percentage gap of Avg Cost to the BKS (Gap), the best solution cost (Best Cost), and the average primal integral (Avg PI).

Table 4 summarizes the results, showing for each algorithm the following: the average Gap (Avg Gap); the global average PI; the number of wins in Avg Cost, Best Cost, and Avg PI; and the number of best-known solutions found. Improving values are highlighted in bold. This comparison shows that MDM-HGS obtains solutions of higher quality and better PI values than HGS-CVRP in most instances. The only exception is the DIMACS subset, where HGS-CVRP has a slightly lower PI, but that difference is not statistically significant. On the other hand, MDM-HGS has a statistically significant advantage in the average gap for the same subset.

The 12th DIMACS Implementation Challenge had 16 teams competing in the CVRP track. All competing algorithms were ranked according to their PI value for each instance. The best algorithm got 10 points, the second 8, then 6, 5, 4, 3, 2, and 1. The final ranking is based on the total point score obtained by each method in all instances. Table 5 presents the rankings from Phase 1 for all instances and the five subsets separately.

The Phase 1 results show that MDM-HGS was very competitive. It ranked first in 2 of the 5 instance subsets: X, the largest one with 100 instances, and Classic, for which MDM-HGS achieved an almost perfect score with 66 points of the 70 possible. Besides, despite ranking fourth in the Golden subset, that was a good performance, considering that the margin among the top-four algorithms in this

subset was very tight (only six points). The results obtained in the remaining two subsets were also above average, ranking fifth and sixth, respectively.

The top 8 competitors from Phase 1 qualified for the second and final phase, in which 100 new (undisclosed) instances were used. Table 6 presents the rankings from Phase 2 for all 100 instances and partitions concerning customer positioning and average route size.

Phase 2 results confirmed that MDM-HGS is very competitive. The instance partitioning reveals that it outperforms all competitors for two classes and ties in first for another. Regarding customer positioning, the instances are partitioned into three classes: "clustered," "random," and "random-clustered" (half of the customers are clustered, and the remaining customers are randomly positioned). MDM-HGS ranked first in the clustered instances. Naturally, these instances are more prone to the occurrence of patterns than random ones, favoring the pattern-based strategy applied in the MDM-MSH framework. Nevertheless, MDM-HGS also achieved high scores for the other partitions, tying for first place with FHCSolver in the random instances and ranking second in the random-clustered ones.

The average route size is defined as the number of customers divided by the minimum number of vehicles. Regarding this aspect, the instances are partitioned into "long-route" (the 50 with longest routes) and "short-route" (the 50 with shortest routes). MDM-HGS ranked first in the long-route instances. The longer the routes in solutions to an instance, the more likely long paths will occur in patterns mined from those solutions. Hence, long-route instances seem to favor the pattern-based strategy applied in the MDM approach more than short-route ones.

MDM-HGS was a close second to FHCSolver in the overall ranking. One interesting observation is that FHCSolver combines the original HGS-CVRP with an adapted version of another algorithm (FILO). Its strategy relies primarily on selecting which algorithm to use based on the instance's number of customers and average route size. Since the experimental results provide evidence that MDM-HGS outperforms HGS-CVRP, ultimately, FHCSolver's performance could probably be improved by simply replacing HGS-CVRP with MDM-HGS within its framework.

These results show that MDM-HGS is a competitive method in the CVRP state of the art, overcoming the original HGS-CVRP and many other novel algorithms. MDM-HGS was the first heuristic to apply this pattern-based approach in a population-based algorithm, which depicts an evolutionary framework, showing that data mining can improve performance in such a context.

DM-Supported MS-ILS for the Heterogeneous Fleet VRP

This section summarizes the results obtained by incorporating data mining into a multistart SLS heuristic for the heterogeneous fleet vehicle routing problem (HFVRP). Applications of the DM-MSH and MDM-MSH strategies were proposed for this problem in [8], and an application of the MR-MSH strategy was proposed in [9], the very first application of the MineReduce approach.

Problem Definition

The HFVRP is described as follows. Let $G = (V, A)$ be a directed graph, where $V = \{0, 1, \ldots, n\}$ is a set composed of $n + 1$ vertices and $A = \{(i, j) : i, j \in V, i \neq j\}$ is the set of arcs. Vertex 0 is the depot, where the vehicle fleet is located, whereas the set $V' = V \backslash \{0\}$ consists of the remaining vertices representing the n customers. Each customer $i \in V'$ is associated with a nonnegative demand q_i. The fleet comprises m distinct vehicle types, which compose a set $M = \{1, \ldots, m\}$. For each vehicle type $u \in M$, there are m_u vehicles available, each with a capacity Q_u and a fixed cost f_u. Finally, for each combination of an arc $(i, j) \in A$ and a vehicle type $u \in M$, there is an associated cost $c_{ij}^u = d_{ij} r_u$, where d_{ij} is the distance between vertices i and j, and r_u is the dependent (variable) cost per unit distance associated with the vehicle type u.

A route is defined by a pair (R, u), where $R = (i_1, i_2, \ldots, i_{|R|})$, $i_1 = i_{|R|} = 0$, and $\{i_2, \ldots, i_{|R|-1}\} \subseteq V'$; that is, each route is a circuit in G that starts and ends at the depot and is assigned to a vehicle of type $u \in M$. A route (R, u) is feasible if the sum of all customers' demands on R does not exceed the capacity Q_u of the vehicle assigned to it. A route's cost is the sum of the assigned vehicle's fixed cost and the dependent costs associated with each traversed arc and the vehicle type. Thus, the aim is to discover feasible routes such that each customer is visited precisely once, the total quantity of routes assigned to vehicles of each type $u \in M$ does not exceed m_u, and the sum of all route costs is minimized.

Data Mining Application

The proposed methods were built by incorporating data mining into a multistart ILS (MS-ILS) heuristic for the HFVRP [12], based on the DM-MSH, MDM-MSH, and MR-MSH strategies. They are called DM-MS-ILS, MDM-MS-ILS, and MR-MS-ILS, respectively.

In these proposals, solutions in the elite set are represented as sets of pairs containing an arc and a vehicle type. This representation allows the application of the data mining procedure to extract maximal frequent itemsets. For each route (R, u), the list R is decomposed into a set of arcs $\{(i_1, i_2), (i_2, i_3), \ldots, (i_{|R|-1}, i_{|R|})\}$. Then, the vehicle type u is assigned to each arc in the set, resulting in a set in which each element is a pair composed of an arc (i_r, i_{r+1}), $r = 1, 2, \ldots, |R| - 1$, in R and the vehicle type u, with the form $\{((i_1, i_2), u), ((i_2, i_3), u), \ldots, ((i_{|R|-1}, i_{|R|}), u)\}$. An arc must be present and associated with the same vehicle type in a minimum number of solutions in the elite set to belong to a pattern. Consequently, the patterns mined are formed of route segments, each with a vehicle type assigned.

In MR-MS-ILS, the *Reduce* step of MineReduce relies on the use of patterns mined from the elite set to perform a vertex-based reduction procedure by merging customer vertices that appear consecutively (in the same route segment) in a pattern into one customer cluster vertex.

It is necessary to extend the HFVRP model to use this strategy. Since it must be possible to represent a route segment as a customer vertex, each customer $i \in V$ must have an associated l_i value corresponding to the inner length of the underlying

route segment. This value is used to calculate the cost $c_i^u = l_i r_u$, which represents the variable cost for a vehicle of type u to traverse the route segment represented by i, for each combination of a customer $i \in V$ and a vehicle type $u \in M$. Customer vertices of regular (non-reduced) instances and those of reduced instances that are not customer cluster vertices have an inner length of 0. The cost of a route becomes, in this extended model, the sum of the fixed cost of the vehicle associated with the route and the variable costs related to (i) the combination of the vehicle type and each traversed arc and (ii) the combination of the vehicle type and each visited customer vertex.

Let $G = (V, A)$ be a directed graph associated with an HFVRP instance and p a pattern consisting of a set of route segments in that instance, each segment defined by a pair (R', u), where $R' = (i_1, i_2, \ldots, i_{|R'|})$. Let $G^* = (V^*, A^*)$ be a directed graph associated with a reduced version of the instance associated with G based on p. Such a reduced version can be obtained as follows. Initially, G^* is defined as a copy of G. For each route segment $(R', u) \in p$, each of the customers in R' is removed from G^* – that is, the vertex corresponding to the customer is removed from V^* and the arcs that connect that vertex to the others are removed from A^*. Also, a customer cluster vertex $i_{R'}$ corresponding to the route segment is added to V^* and arcs connecting $i_{R'}$ to the other vertices in V^* are added to A^*. The demand for $i_{R'}$ is given by $q_{i_{R'}} = \sum_{r'=1}^{|R'|} q_{i_{r'}}$, that is, the sum of customer demands in R'. The distance from each vertex $i^* \in V^*$ to $i_{R'}$ is given by $d_{i^* i_{R'}} = d_{i^* i_1}$, that is, the distance from i^* to i_1 (the first customer in R'). The distance from $i_{R'}$ to each vertex $i^* \in V^*$ is given by $d_{i_{R'} i^*} = d_{i_{|R'|} i^*}$, that is, the distance from $i_{|R'|}$ (the last customer in R') to i^*. Finally, the inner length of $i_{R'}$ is given by $l_{i_{R'}} = \sum_{r=1}^{|R'|-1} d_{i_{r'} i_{r'+1}}$, that is, the sum of the distances between consecutive customers in R'.

Figure 6a presents a representation of a graph $G = (V, A)$ in the extended model described above. In this representation, the customer vertices present, in addition to the value of the demand, the value of the inner length. In this non-reduced instance, all customers have inner length 0. The pattern used in the presented reduction is highlighted in the graph. It consists of a single route segment: (R'_1, u_1), where $R'_1 = (d, e, f)$. The graph $G^* = (V^*, A^*)$ associated with the reduced version of the instance is presented in Fig. 6b. The customer vertices in R'_1 are replaced in the graph by a customer cluster represented by vertex g. This customer cluster's demand q_g is given by the sum of the customers' demands it replaces: $q_g = q_d + q_e + q_f = 4 + 2 + 2 = 8$. The distance from each of the other vertices to g is given by the distances from these vertices to d (first customer in R'_1): $d_{Dg} = d_{Dd} = 3$, $d_{ag} = d_{ad} = 5$, $d_{bg} = d_{bd} = 4$, and $d_{cg} = d_{cd} = 3$. The distance from g to each of the other vertices is given by the distances from f (last customer in R'_1) to these vertices: $d_{gD} = d_{fD} = 1$, $d_{ga} = d_{fa} = 2$, $d_{gb} = d_{fb} = 2$, and $d_{gc} = d_{fc} = 4$. Finally, the inner length l_g of g is given by the sum of the distances between consecutive customers in R'_1: $l_g = d_{de} + d_{ef} = 2 + 2 = 4$.

Computational Results

Extensive computational experiments were conducted to compare the original MS-ILS and its hybrid versions with data mining. The first experimental comparison [8] showed that both DM-MS-ILS and MDM-MS-ILS significantly outperformed the original MS-ILS, with MDM-MS-ILS being the most effective and efficient of those two methods with data mining. The most recent computational experiments [9] compared MS-ILS, MDM-MS-ILS, and MR-MS-ILS.

The problem instances used in the computational experiments were the HFVRP benchmark instances proposed in [2], divided into 4 sets: Set 1, with 15 instances having fewer than 100 customers; Set 2, with 38 instances ranging from 100 to 150 customers; Set 3, with 31 instances ranging from 151 to 200 customers; and Set 4, with 12 instances having more than 200 customers. One instance from each set was reserved for parameter tuning and not used in the comparison.

Table 7 summarizes the results from this comparison, presenting the numbers of wins/ties (the number of instances for which a method achieved the best results) and the average percentage difference (APD) to the original MS-ILS for each instance set separately and for all instances (global).

The results show a clear superiority of MR-MS-ILS to the other two methods. It achieved better solution quality for most instances and much faster convergence for all of them, as it executes the same number of iterations in less computational time. MR-MS-ILS attained better average costs for 83% of the instances (65% with statistical significance) compared to the MS-ILS and better average costs for 76% of the instances (64% with statistical significance) in comparison with the MDM-MS-ILS. If we exclude the small instances (Set 1) where the three heuristics have shown similar performance, the superiority of MR-MS-ILS becomes more evident. It has better average costs for 91% of the instances (76% with statistical significance) compared to MS-ILS and better average costs for 86% of the instances (74% with statistical significance) compared to MDM-MS-ILS.

Additional analyses were performed to inspect the behavior of the methods further. Figure 7 evaluates the solution costs obtained throughout one execution of each method. The charts in the first row present, for each method, the solution costs obtained per iteration in the generation and local search phases, whereas the second row provides enlarged views focusing on the local search phase curve. The charts in Fig. 8 exhibit the computational time spent in the generation and local search phases per iteration. The dashed vertical lines indicate the iterations preceding a data mining method run.

In Fig. 7, the charts in the first row show that the reduction in the costs of the solutions generated by MR-MS-ILS after data mining is much more expressive than that observed for MDM-MS-ILS. The enlarged views in the second row show that the costs of generated solutions fall to a level even lower than that of the costs of solutions discovered through the local search in previous iterations, and the local search finds even better solutions after each run of the data mining procedure.

On the other hand, as shown in the last chart of Fig. 8, the computational time spent in the generation phase – which is close to zero in the initial iterations –

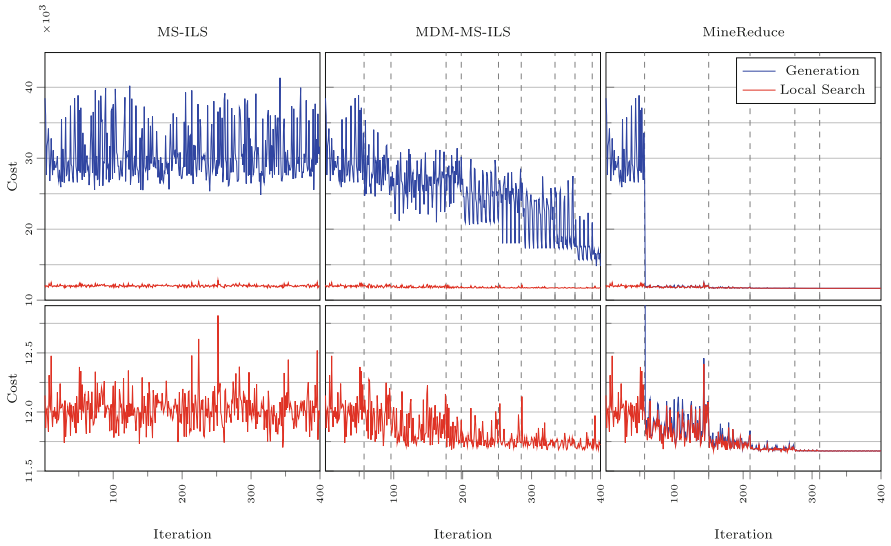

Fig. 7 Cost vs. iteration charts illustrating the behavior of MS-ILS, MDM-MS-ILS, and MR-MS-ILS (MineReduce). (Source: [9, p. 11])

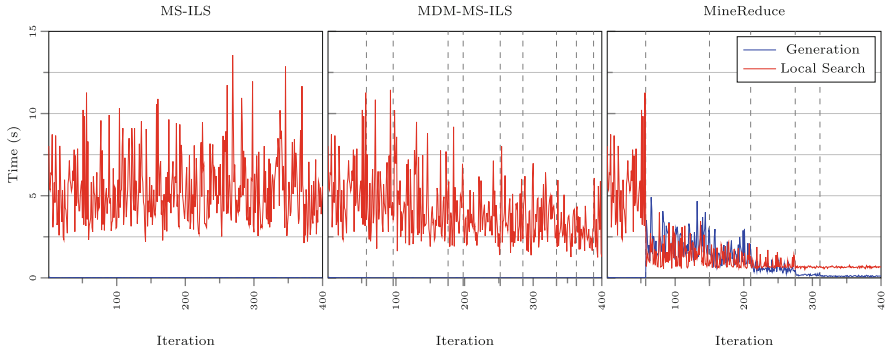

Fig. 8 Time vs. iteration charts illustrating the behavior of MS-ILS, MDM-MS-ILS, and MR-MS-ILS (MineReduce). (Source: [9, p. 11])

increases after the first run of the data mining procedure. This increase is due to the execution of the problem size reduction process, which includes a local search on a reduced version of the problem instance. However, the increase in time spent in the generation phase is compensated by an expressive reduction in time spent in the local search phase. After data mining, the combined time spent in the generation and local search phases per iteration is significantly reduced.

The overall reduction in computational time can be explained by the fact that MineReduce shrinks the problem instance and, consequently, the search space. Therefore, the first local search (embedded in MineReduce's generation phase over

the reduced instance) performs a much smaller number of movement evaluations. Afterward, the second local search (actual local search phase, over the original instance) starts from a higher-quality solution, converging faster.

In MR-MS-ILS, as the charts show, the reduction of solution costs and computational time is intensified after each execution of the data mining procedure, reaching very low levels in the last iterations, which explains the superiority demonstrated by the results of the experiments presented in Table 7.

One last experiment was conducted to assess convergence speed based on a time-to-target (TTT) plot. The target was a solution with a cost lower than or equal to the average cost obtained by MS-ILS in the experiment summarized in Table 7. The obtained chart is shown in Fig. 9.

The chart shows that MR-MS-ILS converges faster than the other methods. It is possible to observe that the probability that the target will be reached within 200 seconds, for example, is approximately 97% for MR-MS-ILS, 76% for MDM-MS-ILS, and 67% for MS-ILS.

The analyses of the charts presented in Figs. 7, 8, and 9 clearly illustrate the influence of the MineReduce approach in the behavior of metaheuristics. As expected, this behavior improves solution quality and convergence speedup.

DM-Supported MS-ILS for the Multisource Capacitated FLP with Customer Incompatibilities

This section summarizes the results obtained by incorporating data mining into a multistart SLS heuristic for the Multisource Capacitated Facility Location Problem with Customer Incompatibilities (MS-CFLP-CI). The MS-CFLP-CI is a recently

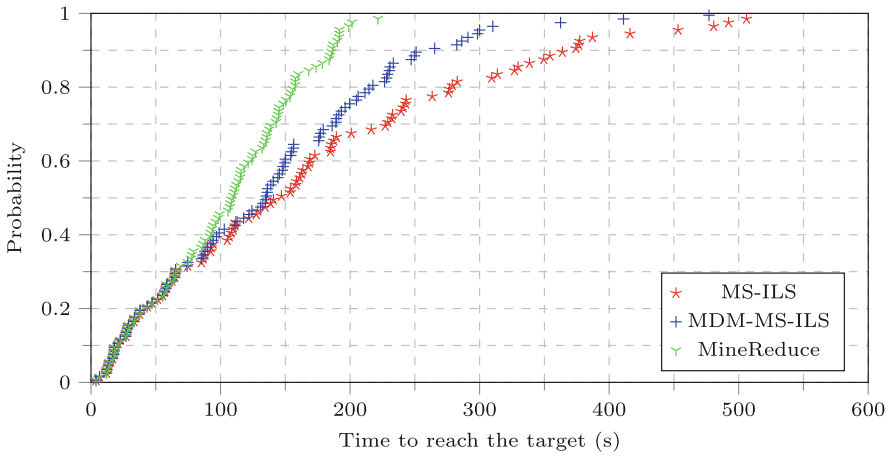

Fig. 9 TTT plot comparing MS-ILS, MDM-MS-ILS, and MR-MS-ILS (MineReduce). (Source: [9, p. 12])

introduced variant of the capacitated facility location problem, proposed in the MESS 2020+1 Metaheuristics Competition (https://www.ants-lab.it/mess2020/#competition). A MineReduced-based multistart ILS (MR-MS-ILS) heuristic was proposed for this problem and ranked first in the competition [11].

Problem Definition

Let $\mathscr{J} = \{1, \ldots, J\}$ be a set of facilities such that each facility $j \in \mathscr{J}$ has a capacity s_j and an opening cost f_j, and let $\mathscr{I} = \{1, \ldots, I\}$ be a set of customers such that each customer i has a demand of quantity of goods d_i to be completely satisfied by one or more facilities. The shipping cost c_{ij} is the cost per unit of transporting goods from facility j to customer i. Finally, a set Γ of pairs of incompatible customers is defined.

The problem consists of defining the number of goods moved from each facility $j \in \mathscr{J}$ to each customer $i \in \mathscr{I}$ to minimize the sum of the cost of opening facilities and the cost to ship the goods from the facilities to the customers. The constraints are the following:

- The total quantity of goods taken from an open facility cannot exceed its capacity;
- The total quantity of goods supplied to a customer must be exactly equal to its demand;
- The same facility cannot supply two incompatible customers.

Data Mining Application

In the proposed method, the mined patterns are frequent sets of pairs $\langle i, j \rangle$, i.e., sets of customer-facility assignments frequent in solutions of the elite set E. Since each decision variable x_{ij} in this problem represents an integer quantity of goods supplied to a customer i by a facility j, the search space reduction is achieved by constraining the decision variables' domains as a consequence of fixing a supplied quantity for each frequent assignment. Hence, after the frequent itemsets are mined, their assignments are filled with the corresponding minimum quantities in E, i.e., for each pair $\langle i, j \rangle$ in a frequent itemset, a supplied quantity q is set, which corresponds to the minimum positive supplied quantity for that pair among all solutions in E. Therefore, each final pattern is a set of assignments $\langle i, j, q \rangle$.

Patterns are used to reduce the size of the problem instance based on the assumption that their elements shall be part of the solution. In the particular case of reducing this problem, an extension to the problem formulation is needed, with the introduction of incompatibilities between customers and facilities, represented by a set Γ', such that for each $\langle i, j \rangle \in \Gamma'$, i cannot be supplied by j. Hence, an additional set of constraints is introduced:

- An incompatible facility cannot supply a customer.

The reduction process works as follows. Given a problem instance $\mathscr{P}$ and a pattern p, the reduced instance $\mathscr{P}'$ is initialized as a copy of $\mathscr{P}$. Then, for each

assignment $\langle i, j, q \rangle$ in p, the following changes are applied to $\mathscr{P}'$: (i) decrease both s_j and d_i by q (a supply of q goods to customer i by facility j is fixed); (ii) set $f_j = 0$, because since facility j is already open, there is no additional cost to use it; and (iii) for each customer i' incompatible with i (from Γ), add a pair $\langle i', j \rangle$ to Γ' (facility j cannot supply any customer that is incompatible with i).

Consequently, the domain of each x_{ij} variable will be reduced since the customer's demands and facilities capacities are reduced, leading to diminished maximum values for x_{ij}. Also, additional constraints will fix the values of many other decision variables, effectively reducing the problem instance size.

Computational Results

Four methods have been compared in [11]: the MineReduce-based Multi-Start ILS (MR-MS-ILS); a Greedy Randomized Adaptive Search Procedure (GRASP); a Permutation Coded Evolutionary Algorithm (PcEA); and a Multistart Greedy (MG) heuristic.

The methods have been tested on artificial instances created for the competition. Instances have been partitioned into two sets, a *training* set with 20 instances, which was publicly available since the competition started so the competitors could use it for tuning their algorithms, and a *validation* set with 10 instances, which was kept hidden during the competition as it was used for defining the final ranking.

The comparisons are based on the best solution found by each method in a given time-out (t). Two different time-outs are used based on the number of facilities J in the problem instance. The first is the one proposed for the competition, which grants $10\sqrt{J}$ seconds for solving each instance, whereas the second grants J seconds per instance.

Tables 8 and 9 summarize the results for the first and the second time-outs, respectively, presenting the numbers of wins (the number of instances for which a method achieved the best results) and the average percentage difference (APD) to PcEA for the training and validation sets separately and for all of them together (global).

Additionally, Table 10 shows the average ranks throughout all runs (10×4) upon all instances for each combination of dataset and time-out, which was the criteria adopted in the competition for ranking the methods. Note that if a method had been better than all others in all runs, it would have obtained ranks $1, 2, \ldots, 10$ for its ten runs, resulting in an average rank of 5.5 (the average of numbers $1, 2, \ldots, 10$).

The results show that MR-MS-ILS was indisputably superior to the other methods. It achieved better solution quality for the vast majority of the instances and far better average ranks.

During the development of the proposed method, experiments comparing MR-MS-ILS to a version of it with the MineReduce-based components disabled (MS-ILS) were conducted to measure the effect of the MineReduce approach – using the training set instances with $t = 10\sqrt{J}$. Table 11 summarizes the results obtained in this comparison, showing that the MineReduce approach significantly improves the baseline method's performance.

Conclusion

This chapter presents some ideas for incorporating data mining in local search heuristics. Some applications have been described, showing that heuristics can benefit from data mining by obtaining better solutions in shorter computational times.

These results motivate the use of data mining in other metaheuristics, where the patterns can also be used to guide the search. Data mining can also be used in exact algorithms like branch-and-bound, where the values of some variables could be set based on the patterns extracted from previously found solutions.

Analyzing the obtained results, it seems reasonable to expect that incorporating data mining techniques into SLS heuristics can be helpful in general. Wolpert and Macread [18] presented a series of No Free Lunch theorems which establish that for any algorithm, the high performance on a class of problems is offset by the low performance of another class. So, they conclude that all black-box optimization algorithms perform exactly equally well. However, some subsequent studies [3, 6] have shown that these theorems apply to some specific classes of problems and that is expected that real-world problems are not of this particular class. Therefore, it is reasonable to expect that the good results obtained using the data mining techniques in the presented problems may also be achieved in other real-world problems.

Abstract

The integration of deep learning techniques into search heuristics presents a transformative approach to solving combinatorial optimization problems (COPs) and has revitalized interest in using deep neural networks (DNNs) in the field of optimization. This chapter explores application of DNNs in two state-of-the-art learning scenarios, namely controlling parameter values in search techniques and directly controlling decision making in heuristics. Despite challenges such as

Introduction

Artificial neural networks have a long history of being applied to heuristics [40, 55] for solving combinatorial optimization problems (COPs), starting with the Hopfield network [25] and elastic nets [15]. While early approaches effectively explored the bounds of what was possible with neural networks, they had a large performance gap to existing Operations Research (OR) methods. Recent advances in deep neural networks (DNNs) have renewed interest in using neural networks for solving COPs, as well as for creating DNN-heuristic hybrids. This has resulted in a wide range of highly competitive heuristic approaches, including providing high-level search guidance [28], dynamic parameter control [1], and learning policies for heuristic solution construction/improvement [34].

DNNs offer several advantages compared to other learning-based techniques in the field of heuristics, such as scoring mechanisms [18, 19], reactive search [6], and data mining techniques [44]. The first and more important advantage of DNNs is that they can perform automatic feature engineering, meaning users can input "raw" data, such as coordinates in a vehicle routing problem, and the network will synthesize this data to make predictions without the need for a data scientist to perform feature engineering, i.e., computing summary statistics about the input data. Second, DNNs allow optimization techniques to employ the GPU in addition to the CPU for solving problems, opening new possibilities for parallel heuristics. However, DNNs also come with some limitations, such as being black box (i.e., non-interpretable) models with many model parameters and associated complexity. Furthermore, training DNNs can be extremely time-consuming, both in terms of computational resources and human resources (finding a good architecture and parameter settings).

We attempt to highlight new, exciting areas of research on using DNNs to solve COPs, whether through hybridization or directly learning policies to solve COPs. Our goal is to offer a starting point for researchers and practitioners new to these areas. This chapter serves not only to highlight the unique advantages of DNNs versus other machine learning methods and strategies that have been integrated into heuristics over the years but also to point out limitations of DNN techniques.

This chapter is organized as follows. First, we provide preliminaries on DNNs, graph neural networks (GNNs), and transformer methods. We then investigate deep parameter control, which harnesses DNNs to dynamically adjust the parameters of a heuristic as the heuristic is solving a problem instance. We then examine deep-learned construction and improvement policies that directly learn to solve COPs using DNNs and GNNs. Finally, we conclude and discuss directions for future work.

Preliminaries

Deep Neural Networks

DNNs are a family of neural networks characterized by their multiple layers of perceptrons, i.e., interconnected nodes. The basic form of a DNN is the deep feedforward network, also called feedforward neural network (FNN), or multilayer perceptron (MLP). It defines a mapping $\boldsymbol{y} = f(\boldsymbol{x}; \boldsymbol{\theta})$, where $\boldsymbol{x}$ are the inputs, $\boldsymbol{y}$ the outputs, and $\boldsymbol{\theta}$ the parameters to be learned to best approximate the underlying function [22]. The concept of neural networks is loosely based on neuroscience, but we emphasize that this is just an inspirational metaphor and nothing more. As shown in Fig. 1, individual perceptrons (shown as nodes) are connected to layers, which are in turn interconnected. In the MLPs there are no feedback connections, i.e., information only flows forward from the inputs through the intermediate computations in the hidden units to the outputs. The error at the output is propagated back to compute gradients that guide weight adjustments in the network, minimizing future errors.

Convolutional neural networks (CNNs) [37] are specialized DNNs designed to process data with grid-like topology, such as images. Unlike MLPs, CNNs use convolutional layers that apply learnable filters across the input, exploiting sparse interactions, parameter sharing, and equivariant representations [22, p. 329 f.]. We note that, currently, CNNs are not commonly used in the optimization tasks

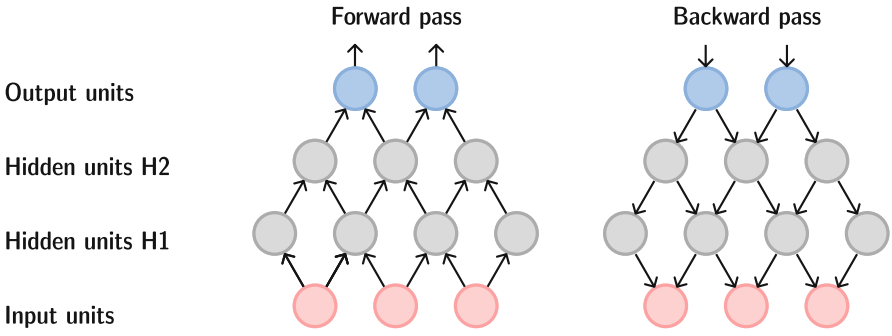

Fig. 1 Multilayer neural network forward and backward pass, simplified from [38]

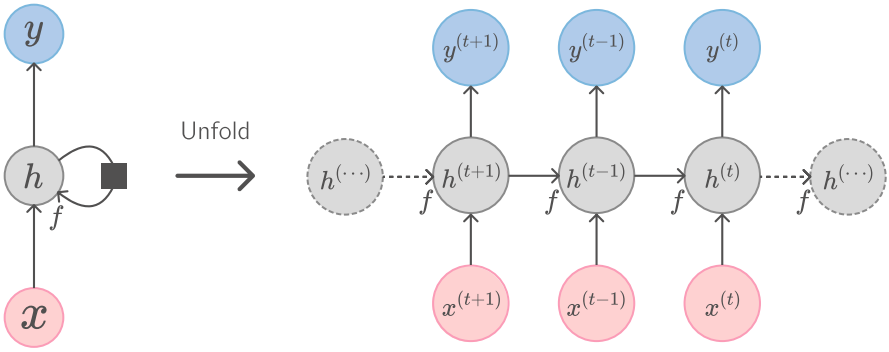

Fig. 2 Unfolding of a basic RNN: every node is now associated with a specific time step t. The square indicates a delay of a single time step. (Adapted from [22])

discussed in this chapter, although they have seen use on related applications, e.g., for algorithm selection portfolios [41].

Recurrent neural networks (RNNs) [46] extend DNNs to handle sequential data by maintaining an internal state (hidden state) that can capture temporal dependencies. At each time step t, an RNN processes input $\boldsymbol{x}^{(t)}$ along with the previous hidden state $\boldsymbol{h}^{(t-1)}$ to produce output $\boldsymbol{y}^{(t)}$ and update its hidden state to $\boldsymbol{h}^{(t)}$ (see Fig. 2). This recurrent connection allows information to persist across time steps. Variants like Long Short-Term Memory (LSTM) networks address the vanishing gradient problem that affects basic RNNs when processing long sequences [24]. The RNN concept is further generalized in Pollack [45] to support a computational graph structured like a deep tree as opposed to the chain-like structure of RNNs depicted in Fig. 2.

Graph Neural Networks

Graph neural networks (GNNs) were first introduced in [23] and later detailed more extensively in [48]. They extend RNNs by handling general graphs including cyclic, directed, and undirected graphs, although earlier approaches were limited to directed acyclic graphs (DAGs). The model also generalizes random walk approaches through learned parameters. Unlike traditional methods that require preprocessing graphs into vectors, GNNs can process graph-structured data directly [23, 48].

GNNs can be applied on both node-focused (e.g., object detection in an image) and graph-focused (e.g., image classification) problems. Both positional graphs, where the ordering of neighboring nodes matters, and non-positional graphs can be handled. The main idea is that individual nodes in the graph represent concepts, and the edges the relationships between them. A node n is associated with a state vector $x_n \in \mathbb{R}^s$ that aggregates information about the node's own labels, the labels of connected edges, and the states and labels of the neighboring nodes. The state vector

is iteratively updated based on these inputs until a stable fixed point is reached, allowing GNNs to naturally capture both local graph structures and global graph properties through the propagation of information across the graph [48].

Pointer Networks

The pointer network architecture (Ptr-Net), introduced by [59], supports variable-sized outputs that depend on the size of the input. For example, a standard MLP as shown before in Fig. 1 has a fixed input and output size that cannot be changed. In the context of combinatorial optimization, this is potentially problematic as it means problem instances of different sizes would require different network architectures. For example, imagine needing one network to solve a traveling salesperson problem (TSP) with 50 nodes and a different one for a TSP with 51 nodes.

Ptr-Nets allow for variable-sized inputs by harnessing the concept of *neural attention*. The attention mechanism was originally introduced in [5] in the context of machine translation. Summarized, attention allows a neural network to place weight on specific combinations of input values. We refer to Vaswani et al. [58] for the mathematical details. Bahdanau et al. [5] identify the use of fixed-sized vectors as a bottleneck to handle variable-sized data, particularly for long sentences, and instead propose to use a *sequence* of vectors and choose a *subset* of those vectors when decoding the output. This way the model can essentially *search* for parts of the input data that are relevant to predicting the target output [5].

Ptr-Nets use this neural attention as a pointer mechanism, i.e., they use attention to produce a softmax probability distribution over the input sequence positions and to select a member of the inputs for the output. This is particularly effective for combinatorial optimization problems where outputs are permutations of inputs, such as the TSP. The model demonstrates good generalization capabilities, often performing well on sequences longer than those seen during training [59].

Transformer Architecture

The transformer was first introduced in [58] and has since been leveraged to achieve new state-of-the-art performances in several fields [11, 14, 33]. The transformer mechanism also relies on attention as in the case of the Ptr-Net to model dependencies between model inputs and outputs. The transformer uses an encoder-decoder structure [57] with multi-head attention, meaning multiple attention mechanisms are stacked and aggregated, where both the encoder and the decoder are composed of "stacked self-attention and point-wise, fully connected layers" [58, p. 2]. The architecture is shown in Fig. 3. The encoder and decoder each are composed of a stack of N identical layers. For the encoder, each layer consists of two sublayers, a multi-head self-attention and a fully connected FNN. In the decoder, every layer has a third sublayer, a multi-head attention layer that processes the outputs of the encoder stack.

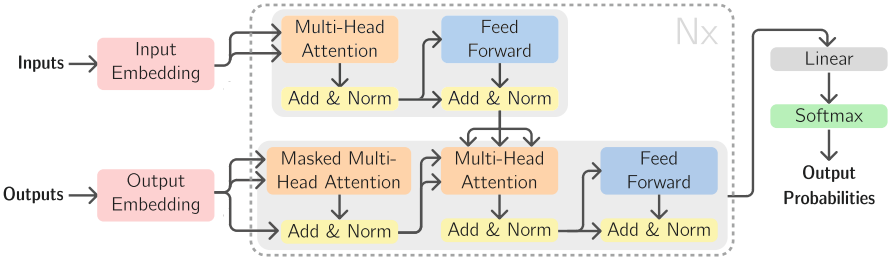

Fig. 3 The transformer architecture based on [58]

Relying on self-attention as opposed to recurrent architectures has three main advantages: (1) The computational complexity per layer is smaller for attention, as long as the sequence length n is smaller than the representation dimensionality d. (2) Computations can be parallelized compared to recurrent architectures, allowing for faster training, and (3) the number of operations needed to forward a signal is constant and thus independent of the path length between long-range dependencies.

Deep Parameter Control

Search heuristics often contain many parameters that directly influence their performance. These parameters have a direct impact on the exploitation/exploration trade-off, for example, the temperature reduction factor of simulated annealing [13] or the list size in tabu search [20]. Configuring these parameters to achieve high-quality solutions or fast runtimes is extremely time-consuming to do by hand. Hence, automated tools have been developed to assist in finding good values for parameters. See, e.g., Schede et al. [49] for an overview of automated algorithm configuration.

The metaheuristics literature has long sought to control parameters during search. Reactive search [6], for example, uses handcrafted strategies to adjust parameters based on the current search trajectory. Recent extensions of reactive search techniques use algorithm configuration tools to learn simple parameter policies offline [3, 4]. The evolutionary algorithms community has also investigated many strategies for controlling parameters during search [2, 39].

Deep learning offers opportunities for the parameter control setting, but also challenges. On the one hand, deep learning can accept a wide range of inputs (e.g., non-tabular inputs such as graphs) and offer powerful insights that simpler models (e.g., [3]) cannot provide. On the other hand, deep learning is computationally expensive and can slow down a solution procedure. Thus, the challenge of applying these methods lies in finding an acceptable balance between the efficiency of a heuristic (in terms of the number of solutions it can examine per second) and the quality of the parameters determined through the deep-learned model.

Learning a Control Policy

There are two main types of parameterized algorithms that can use a learned control policy that can be categorized as either *stepwise* or *non-stepwise* reconfigurable approaches. Stepwise reconfigurable algorithms are formally defined by [1] and involve optimization techniques that adjust their internal parameters at a predefined interval. Non-stepwise reconfigurable techniques, in contrast, update their parameters at undefined intervals, e.g., in the case of Ansótegui et al. [3]. In these approaches, whenever a parameter is used by a search algorithm, its value is queried from a model. The non-stepwise setting can potentially be more computationally efficient than the stepwise setting. However, due to the expense of querying DNNs, we are only aware of stepwise approaches involving these techniques and concentrate on them for the rest of this section.

Biedenkapp et al. [9] propose a general setting for learning control policies called the *dynamic* algorithm configuration (DAC) setting and refine it in Adriaensen et al. [1]. Figure 4 shows a general overview of the stepwise reconfigurable DAC setting for solving multiple instances in which a model is periodically queried for parameters that are inserted into the algorithm. Note that the length of a step is left to an algorithm designer: This could be a single iteration of a heuristic, or it could be an entire local search to improve a solution. The parameters for these models are generally learned in an reinforcement learning (RL) setting in which the reward for the learning is given by the best objective function value found by the algorithm.

The DAC literature has mostly applied standard deep reinforcement learning (DRL) techniques, e.g., double-deep $\mathcal{Q}$ networks [10, 53, 56], REINFORCE [21], and PPO [60]. The DACBench [16] also allows essentially any standard DRL framework to be used, enabling experimentation with multiple learning options. We note that while algorithm configuration techniques have been used to train DAC approaches for the non-stepwise setting without DNNs (e.g., [3]), we are unaware of any approaches combining such learning mechanisms with deep networks. Finally, the literature does not indicate that any of the standard DRL methods are necessarily better than any other, rather the critical ingredients to a DAC approach lie in the selection of parameters to configure and how to represent the search state.

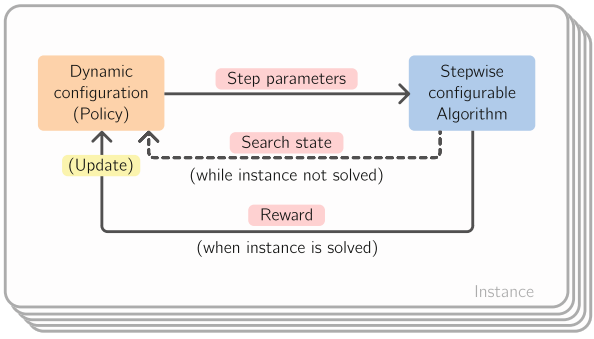

Fig. 4 An overview of DAC. (Adapted from [9])

Dynamically Configurable Parameters

Nearly every parameter that has an impact on the search behavior of a heuristic can be instrumented as a dynamically controlled parameter. Exceptions include the random seed provided to the algorithm and any parameters that, when adjusted, could result in infeasible solutions (e.g., floating point tolerances). The literature provides no clear guidance on how many parameters of an approach should be instrumented to be dynamic, and includes approaches that control as many parameters as possible (e.g., [3, 4]) as well as approaches controlling only a single parameter [43]. Commonly targeted parameters include those providing direct trade-offs between exploration and exploitation [43], step sizes [31, 52], and population adjustment mechanisms in evolutionary algorithms [53].

Parameters can be represented by the outputs of DNNs in two main ways. The network can either directly output the parameter value or output parameters for a distribution. The former is really only possible in the case of continuous parameters. In the latter case, the parameter is either sampled from the distribution or computed through the mode/mean of the resulting distribution. Discrete parameters can be determined through a softmax layer or through a beta distribution; see, e.g., [51]. In the case of softmax, a probability for each of the discrete values is directly generated by the deep learned model. Beta distributions are better suited to discrete parameters with large ranges, as they only require two output parameters (α and β), whereas a softmax requires output parameters for all discrete output values. The continuous value of the beta distribution must be discretized.

Representing Search State

The search state must be summarized in representative features that can be given to the learning approach to decide how to adjust its parameters. Features describing the search state can be partitioned into two sets: problem-independent and problem-dependent features. Problem-independent features can be further subdivided into algorithm-independent and algorithm-dependent features.

Problem-independent state features that are algorithm independent are mostly limited to descriptions of how long the search has been ongoing. A common choice for this is the number of elapsed iterations, e.g., in CMA-ES in the DACBench [16], or remaining budget, as in the SGD benchmark of DACBench. An alternative to iterations/budget is to use the elapsed CPU time such as in the MaxSAT solver from Ansótegui et al. [3]. The best known solution value can also be considered a problem and algorithm-independent feature, e.g., as used in Ma et al. [43]. However, we note that how this value is computed could be algorithm specific. In the case of Ma et al. [43], a global best solution from a population of an evolutionary algorithm is used, whereas in Ansótegui et al. [4], there is no population to select the global best solution. Statistics about the solution quality in a population are also used in Ma et al. [43] and provide a problem-independent view of search progress.

Even in the nascent literature on DAC, there is already a multitude of problem-dependent features. Thus, we provide a short overview of general ideas to inspire future work in this area and do not intend to be comprehensive. For the CMA-ES benchmark in DACBench, the search state is described through the current learning rate, current gradient, and the momentum of the algorithm. In contrast, the fast-downward benchmark of DACBench uses statistics about values found through its various planning heuristics. Historical observations can also be included in the current state, e.g., in Shala et al. [52], which tries to learn the step size of CMA-ES and includes the step size from previous iterations. Overall, the literature in this area so far indicates that while feature engineering on the search state will likely lead to better performance, many approaches do not report investing significant resources in creating/selecting features.

Deep-Learned Construction and Improvement Policies

Deep neural networks are frequently employed to learn *construction* or *improvement* strategies for various combinatorial optimization problems. Construction heuristics build solutions from scratch, starting from an empty solution, while improvement methods iteratively refine an existing solution by making small adjustments. For example, consider the TSP. A construction heuristic for the TSP builds a tour by starting from an initial city and adding one city at a time at each decision point until the tour is complete. In contrast, an improvement heuristic begins with a fully constructed tour and iteratively modifies it—such as by swapping edges—with the goal of enhancing the solution's quality.

In addition to construction and improvement methods, we introduce a third class of algorithms that combine aspects of construction and improvement methods, referred to as *transductive methods*. These methods iteratively build solutions from scratch over multiple iterations, progressively improving the quality of the solutions they produce. This improvement is achieved by updating the model parameters that guide the construction process after each iteration, based on the quality of the generated solutions. Like improvement heuristics, transductive methods seek better solutions through iteration, yet, similar to construction heuristics, they reconstruct the solution from the ground up at each iteration. In the following sections, we explore these three classes of algorithms in greater detail.

Construction Methods

Construction methods generate solutions for a problem instance from scratch. We categorize these methods into two main types: autoregressive and non-autoregressive. Autoregressive methods construct solutions by following a sequential decision-making process, where a DNN is queried at each step to determine the next decision, while taking into account all previous decisions. This process allows autoregressive methods to build solutions progressively, leveraging

each prior step to inform the subsequent one, which is particularly effective in problems with interdependent decisions. In contrast, non-autoregressive methods only query the DNN once. Instead of outputting a complete solution directly, the DNN in non-autoregressive methods produces an intermediate result that must undergo a post-processing step to be transformed into a complete solution. This approach can sometimes offer efficiency advantages since it requires only a single DNN call.

Autoregressive

Autoregressive construction methods excel at generating solutions through a step-by-step decision process and can be trained via RL. The first modern neural network-based autoregressive construction approach is introduced by Vinyals et al. [59] for the TSP. This pioneering method trains the model using supervised learning, establishing a foundation for neural network-based solution generation. Building on this approach, Bello et al. [7] propose training the network via reinforcement learning, showcasing its effectiveness in handling larger and more complex TSP instances without requiring labeled data for training. Later, Kool et al. [34] introduce a novel neural network architecture based on transformer networks. This architecture has been widely adopted, as it has proven capable of learning powerful construction strategies. With slight modifications, this architecture has been applied to generate solutions not only for routing problems, such as the vehicle routing problem (VRP), but also for scheduling problems, including the job shop scheduling problem, and other combinatorial optimization tasks [8]. Recognizing that many combinatorial optimization (CO) problems exhibit symmetries in their solution space, Kwon et al. [36] introduced POMO, a method that leverages these symmetries to enforce diverse solution rollouts, enhancing exploration during training. Building on this, Hottung et al. [29] proposed a novel construction method that trains a single model to learn multiple diverse construction strategies, enabling better search space exploration even in the absence of significant symmetries.

Figure 5 illustrates solution generation for a TSP instance using an encoder-decoder model as a construction method. The process begins with encoding the problem instance, where each node is transformed into a high-dimensional embedding that encapsulates essential features for solution construction. The encoder generates these embeddings, one for each node, capturing key information about the problem that will be used by the decoder to build the solution step by step.

During solution generation, the decoder sequentially constructs the tour. At each step, the decoder receives both the full set of node embeddings and context information specific to the current step—in the case of the TSP, this includes the previously selected node, indicating the current position. The model then outputs a probability distribution over possible next nodes, allowing the choice of the next visit either by sampling from this distribution or by selecting the node with the highest probability (greedy selection).

Autoregressive construction methods are particularly well-suited for training via RL. In contrast to supervised learning, RL approaches do not require reference solutions during training. As such, RL is ideal for discovering solution strategies

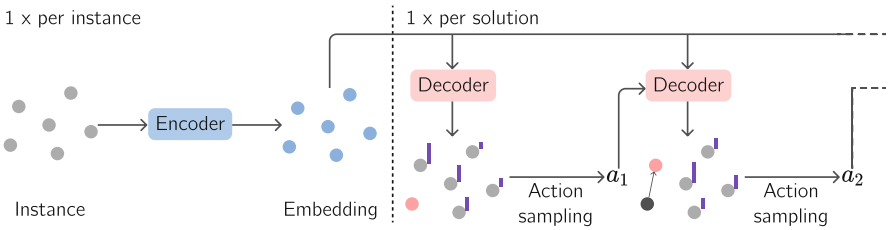

Fig. 5 Solution generation for the TSP with an encoder-decoder model, based on [28]

for novel problems where no existing methods can generate training solutions efficiently. However, this advantage comes with a computational cost: state-of-the-art RL approaches generally require the generation of millions of solutions during training to develop effective strategies. As a result, training often requires significant computational resources and is commonly parallelized on GPUs to meet practical time constraints.

To enable efficient RL training, it is essential to have a highly parallelizable implementation of the problem environment. For example, calculating objective function values should be optimized to run efficiently on a GPU. Additionally, state-of-the-art autoregressive methods limit the model's actions to ensure only feasible solutions are generated. For the TSP, for instance, the model is restricted to selecting nodes that have not yet been visited, a straightforward feasibility constraint that can be easily implemented on the GPU. However, for more complex optimization problems, determining feasible actions may not be as trivial, and difficult to implement using GPU-executable code.

Non-autoregressive

Non-autoregressive approaches generate solutions using a single model call, making them particularly efficient for large problem instances. In routing problems, these methods often use a DNN to produce a heatmap that reflects the likelihood of each edge being part of an optimal solution. This probability-based heatmap is then used in a post-processing step to construct a feasible solution. Figure 6 illustrates this two-step process for the TSP.

The concept of generating a heatmap as an intermediate solution representation was first introduced by Joshi et al. [32], where a graph convolutional model is trained via supervised learning to generate heatmaps based on instance-solution pairs. A beam search algorithm then utilizes this heatmap to assemble complete solutions by systematically selecting edges with the highest probabilities while ensuring feasibility.

Building on this heatmap concept, other methods introduce advanced post-processing techniques to improve solution quality. For instance, Kool et al. [35] employ dynamic programming to translate the generated heatmap into complete, high-quality solutions. Similarly, Ye et al. [61] use the heatmap to guide an ant colony optimization (ACO) algorithm, where the heatmap probabilities influence

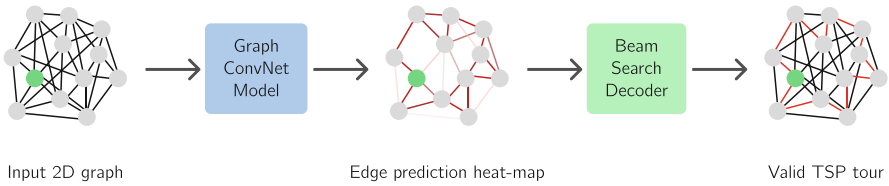

Fig. 6 Non-autoregressive solution generation, based on [32]

the ACO's exploration of edges, effectively combining learned model insights with traditional optimization heuristics.

The primary advantage of non-autoregressive approaches lies in their scalability: The number of model calls remains fixed regardless of the problem's size, making them suitable for larger instances where sequential decision processes could become computationally expensive. However, the effectiveness of these approaches often hinges on the strength of the post-processing strategies employed, as a single model output does not inherently guarantee solution feasibility or quality. Moreover, there is ongoing debate about how effectively the heatmap captures all the nuances needed for high-quality solution generation. While the heatmap successfully guides the post-processing strategies, recent studies suggest that it may not provide a significant advantage over simpler, distance-based measures, thus calling into question the usefulness of heatmap approaches [47].

Improvement Methods

Improvement methods aim to enhance a given initial solution through an iterative process. In each iteration, a (small) portion of the solution is modified, with the goal of producing a new solution that ideally has a better objective function value. These methods are particularly effective for problems where parts of the solution can be modified quickly without significantly affecting the rest of the solution, and where the change in the objective function resulting from the modification can be efficiently computed.

Improvement methods can be broadly categorized into two main types: local search methods and large neighborhood search methods. Local search methods focus on making small changes to a solution, guided by an explicitly defined neighborhood function. In contrast, large neighborhood search (LNS) methods implicitly define a solution's neighborhood and make more substantial modifications to the solution in each iteration. In the following sections, we will explore algorithms from both of these categories in greater detail.

Local Search Methods

We refer to improvement heuristics that only make small changes at each step as *local search* heuristics. Local search heuristics typically define a neighborhood function $N(s)$ that accepts a solution s and returns a set of similar (i.e., neighboring)

solutions to s. Starting with a given solution s, a local search method uses $N(s)$ to generate a set of neighboring solutions at each iteration. One solution s' is picked from $N(s)$ using a defined selection mechanism. For example, a simple selection mechanism is to select the neighboring solution with the lowest cost value. Finally, at the end of each local search iteration, s is set to s'. The search is usually continued until no improving solution in the neighborhood $N(s)$ exists, which means that a *local optimum* has been reached.

Large Neighborhood Search Methods

LNS methods generate new candidate solutions by removing certain components from a given solution and then rebuilding it. This fundamental approach has been widely adopted in various non-learning-based methods, including the rip-up and reroute technique by Dees and Smith [12], the original LNS by Shaw [54], and the ruin-and-recreate method by Schrimpf et al. [50]. In LNS, neighborhood functions are implicitly defined through destroy and repair operators: Destroy operators remove specific components, resulting in an incomplete and infeasible solution, while repair operators rebuild the solution to restore feasibility. Destroy operators typically remove a significant portion of the solution, enabling substantial modifications in a single iteration.

Thanks to its effectiveness and ease of use, the LNS framework has been widely adapted for learning-based methods addressing routing problems. Neural large neighborhood search (NLNS) methods, for instance, often replace the repair operators of LNS with a neural policy trained to learn the repair process. Repairing a destroyed solution closely resembles constructing a solution from scratch, making it possible to use similar, or even identical, learning setups and model architectures as those used in construction algorithms. Consequently, NLNS offers a straightforward way to extend a fast construction method into an approach that performs a more exhaustive search.

Neural large neighborhood search was first introduced by [26], where a neural network was trained to learn a repair policy for the capacitated vehicle routing problem (CVRP). This concept of learning a repair operator has since been applied to other problems, such as the capacitated team orienteering problem [27] and the vehicle routing problem with time windows [17]. While these early methods relied on reinforcement learning to train the repair policy, recent approaches have incorporated the LNS framework to enhance the performance of decoder-only models trained in a supervised manner. For example, [42] propose a method called random reconstruct, where a random subset of components from a given solution is removed and then restructured to create a new candidate solution. Their approach enables a more comprehensive search capability for their original construction method, leading to significant performance improvements. More recently, Hottung et al. [30] propose to learn the destroy operator instead of the repair operator via a deep neural network. They combine the learned destroy operator with a fast, handcrafted greedy insertion algorithm at test time. This approach demonstrates strong performance, matching state-of-the-art operations research methods across three variants of the vehicle routing problem.

Transductive Methods

Transductive methods construct solutions iteratively from scratch, refining model parameters after each iteration based on observed performance. In other words, transductive methods fine-tune a model to a specific instance (or set of instances) at test time. The fine-tuning process is typically implemented using the same reinforcement learning setup employed during the method's training. In these methods, the fine-tuning process itself acts as the search procedure, allowing the model to explore the solution space and discover high-quality solutions. Figure 7 illustrates the core components of transductive methods. Importantly, the fine-tuned model produced at the end of the search phase is not intended for reuse; rather, its purpose is solely to yield a high-quality solution for the current instance.

One major advantage of transductive search is its ease of implementation for many construction methods. Because the reinforcement learning framework and setup used during the search phase closely mirror those used during training, the method requires fewer additional components compared to other approaches. This alignment between training and test-time procedures simplifies the overall development.

The first transductive method, known as *active search*, is introduced by Bello et al. [7]. In active search, all model parameters are adjusted during the search phase, enabling a comprehensive exploration of the solution space. However, this approach requires substantial memory resources when solving multiple instances in parallel, as it updates every parameter independently for each instance. Hottung et al. [28] propose an enhanced variant called *efficient active search*, which updates only a subset of model parameters during the search, keeping the rest fixed. This selective update strategy reduces memory consumption significantly by allowing shared parameters across instances, resulting in a more stable search process. Additionally, efficient active search incorporates a modified loss function that directs the model toward the best solution encountered so far. Overall, efficient active search has demonstrated considerably improved performance and memory efficiency compared to the original active search approach.

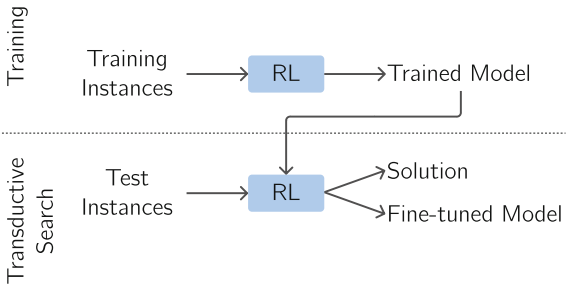

Fig. 7 Core components of transductive methods, e.g., active search [7]

Conclusion and Outlook

We have described several settings in which DNNs have been making an impact for solving OR problems. DNNs are not only capable of dynamically controlling the parameters of optimization approaches, but they can also generate solutions to a wide range of optimization problems in a multitude of ways. The approaches we present are not all competitive with state-of-the-art "traditional" OR alternatives, but the performance gap is rapidly narrowing on many applications, even in well-studied areas like vehicle routing.

We expect state-of-the-art OR methods to increasingly use DNNs in some part of their solution methodology. Hybrid methods in particular pose a promising way forward, in which the "intelligence" (high-quality heuristic abilities) of a DNN is used in conjunction with the speed of traditional OR techniques. Hybrids between the different areas of DNN usage listed in this chapter are also conceivable, e.g., solution approaches using DNNs to construct solutions with dynamically controlled parameters. Furthermore, for approaches requiring low domain knowledge (e.g., POMO), challenges remain in extending these techniques to real-world problems, especially those in which masking does not prevent infeasibility and those with complex side constraints that are not easily coded into a compact solution representation.

Abstract

Evolution strategies (ESs) are classical variants of evolutionary algorithms which are frequently used to heuristically solve optimization problems, in particular, in continuous domains. In this chapter, a description of classical and contemporary ESs will be provided. The review includes remarks on the history of ESs and how they relate to other evolutionary algorithms. Furthermore, developments of ESs for nonstandard problems and search spaces will also be summarized, including multimodal, multi-criterion, and mixed-integer optimization. Finally, selected variants of ESs are compared on a representative set of continuous benchmark functions, revealing strengths and weaknesses of the different variants.

Keywords

Evolution strategy · Evolutionary algorithms · Self-adaptation · Covariance matrix adaptation · Step size adaptation

Introduction

Evolution strategies (ESs) are a class of metaheuristics for optimization by means of (computer) experiments. They belong to the broader class of evolutionary algorithms and like other heuristics from this class mimic adaptive processes in biological evolution. The search in ESs is characterized by the alternating application of variation and selection operators. Recombination and mutation operators are the variation operators and create new individuals. The selection operator selects individuals from a population based on their corresponding fitness value, which is obtained by computing the objective function value in ESs. The selected individuals form the next population and the process is repeated. A distinguishing feature of ESs as compared to most other evolutionary algorithms is self-adaptive mutation operators, which are capable of adapting the shape of the mutation distribution according to the local topology of the landscape and thereby help ESs achieve maximal progress rates.

Before discussing technical details of the ESs, it will be worthwhile to give a brief outline of their history: The idea of mimicking evolution in order to optimize technical systems arose in Germany, where it led to the development of ESs by Ingo Rechenberg [69] and Hans-Paul Schwefel [79], and in the USA, where it led to the development of genetic algorithms [34, 50] and evolutionary programming [31]. In the mid-1990s, these strategies were unified under the common umbrella of *evolutionary algorithms* (EAs) [8]. While all these heuristics share the idea to mimic evolution in computational algorithms, researchers in genetic algorithms and ESs emphasized on different aspects of algorithm design and problem domains.

Since their invention in the 1960s by Rechenberg and Schwefel at the Technical University of Berlin, ESs have been used to optimize real-world systems, typically in engineering design. The first application of an evolution strategy was the design of optimal shapes in engineering such as nozzles and wing shape using physical

experiments. Often the evolutionary design procedure discovered high-performing structures with surprising shapes that have never been considered by engineers before [10]. Starting from sequential stochastic hill climbing strategies, soon ESs advanced to more sophisticated problem solvers, and their main application domain became the treatment of black-box continuous optimization problems on the basis of computer models.

One important development introduced adaptive step sizes or mutation distributions. Although there were some precursors to the idea of step-size adaptation in stochastic search algorithms [78], the development of flexible and efficient adaptation schemes for mutation distributions became a major point of attention in ES research. This feature distinguished them from genetic algorithms which worked commonly with constant mutation strengths.

Different variants of the adaptation of the mutation parameters were developed, and the three mainstream variants are the control of a single step size by means of a so-called $1/5$th success rule, the mutative self-adaptation which most closely resembles natural evolution [20], and the derandomized self-adaptation schemes by Hansen, Ostermeier, and Gawelczyk [42]. Their efforts to find efficient ways to control the shape of the mutation distribution culminated in the covariance matrix adaptation evolution strategy (CMA-ES) [41]. Due to its invariance properties, it is seen today by many researchers as the state-of-the-art evolution strategy when it comes to practically solving ill-conditioned optimization problems (cf. [45]).

A parallel development was the introduction of population-based (or multimembered) ESs. Here, the idea is to create an evolutionary algorithm that performs, as Hans-Paul Schwefel called it, a *collective hill climbing* [80]. To categorize different population models, the notation of (μ, λ)- and $(\mu + \lambda)$-schemes was introduced, in which μ denotes the number of individuals in the parent population and λ the number of individuals in the offspring population. These multimembered strategies are able to exploit the positive effects of recombination (crossover) and are more reliable in global optimization settings and on noisy problems than the early single-membered variants. Moreover, population-based algorithms could be executed in parallel and later could more easily be extended to advanced ESs for solving multi-objective and multimodal optimization tasks.

Nowadays, ESs are mainly used for the simulation-based optimization, i.e., computerized models that require parametric optimization. Evolution strategies are suitable for the optimization of non-smooth functions because they do not require derivatives. In general, the algorithmic paradigms of ESs can be extended to general metric search spaces, and mainstream variants of ESs address continuous optimization problems, as opposed to genetic algorithms [34], which are more typically used on binary search spaces.

Contemporary ESs have shown to be competitive to other derivative-free optimization algorithms, both in theoretical studies [18, 88] and by benchmark comparisons on a large corpus of empirical problems [81]. Furthermore, their practical utility is underpinned by a large number of successful applications in engineering and systems optimization [11].

This chapter will give a brief introduction to classical and contemporary ESs with a focus on mainstream variants of ESs. Firstly, classical $(\mu, \lambda)-$ and $(\mu + \lambda)$

ESs will be described in section "Classical Evolution Strategies." Then, in section "Derandomized Evolution Strategies," derandomization techniques will be discussed, which is the distinguishing feature in the CMA-ES. Section "Theoretical Results" addresses theoretical findings on the convergence and reliability of ESs. An overview on new developments and nonstandard ESs is provided in section "Nonstandard Evolution Strategies." Moreover, this section covers adaptations of ESs that make them more suitable for multimodal optimization. Section "Benchmarks and Empirical Study" discusses empirical benchmarks used in this field and includes a comparative study of contemporary ESs. Section "Conclusions" summarizes the main characteristics of ESs and highlights future research directions.

Classical Evolution Strategies

The typical application field of ESs is (continuous) unconstrained optimization where the optimization problem is given by

$$f(\vec{x}) \to \min, \quad \vec{x} \in \mathbb{R}^d \tag{1}$$

In the context of ESs, the function f can be a black-box function, and usually function f is assumed to be nonlinear and have a minimum. Maximization problems can be brought into the standard form of Eq. 1 by simply flipping the sign of f. Standard implementations also allow to restrict the domain of decision variables to interval domains and to introduce constraints. For the sake of brevity, the extensions of ESs for constraint handling will be widely omitted in the following discussion.

Evolution strategies can be viewed as stochastic processes on a population of individuals from the space of individuals $\mathbb{I}$. An individual in ESs typically comprises the following information:

- A d-tuple of values for the decision variables $x_1, \ldots, x_d$, representing a candidate solution for the optimization problem (see Eq. 1).
- A tuple of strategy parameters. The strategy parameters can, for instance, be the standard deviations used to generate the perturbations of variables in the mutation (step sizes) or the components of a covariance matrix used in the mutation. Strategy parameters can be adapted during evolution.
- A fitness value. The fitness value is typically based on the objective function value, and it may be altered by a penalty for constraint violations.

In some variants of ESs, the so-called (μ, κ, λ)-ESs, the individual's age is also maintained, that is, the number of generations that an individual has survived.

Another basic data structure of an evolution strategy is a population. A population is a multi-set of individuals, i.e., of elements of $\mathbb{I}$. One distinguishes between the parent populations P_t consisting of μ individuals and the offspring populations consisting of λ individuals.

The basic algorithm of a (μ, λ)-evolution strategy and a $(\mu + \lambda)$-evolution strategy is outlined in Algorithm 1. The algorithm starts with initializing a population P_0 of μ parent individuals, for instance, by uniform random sampling in the feasible intervals for the objective variables $\vec{x}$. Then, the fitness values of P_0 are determined, and the best solution found in P_0 is identified and stored in the variables $\vec{x}_0^{\text{best}}$, f_0^{best}.

Then, the following *generational loop* is executed until a termination criterion is met. Common termination criteria are stagnation of the search process or the excess of a maximally allowed duration for searching. The search process in the generational loop is governed by two (stochastic) variation operators, *recombination* and *mutation*, and a deterministic *selection* operator. The recombination operator, namely $\texttt{Recombine} : \mathbb{I}^{\mu} \times \Omega \rightarrow \mathbb{I}^{\lambda}$, generates from the μ individuals in P_t an offspring population of λ individuals which are then mutated by the mutation operator, $\texttt{Mutate} : \mathbb{I}^{\mu} \times \Omega \rightarrow \mathbb{I}^{\mu}$. The mutated individuals are evaluated, and, if necessary, the best found solution $\vec{x}_t^{\text{best}}$, f_t^{best} gets updated. Then the parent population of the next round is determined by selecting the μ best solutions from:

- In case of a (μ, λ)-ES the λ offspring individuals
- In case of a $(\mu+\lambda)$-ES the μ parents of the current generation and the λ offspring individuals, and
- In case of a (μ, κ, λ)-ES from the μ parents who have not exceeded an age of κ and the λ offspring individuals

Finally, the generation counter is increased, and the loop is continued or terminated (if the termination condition is met). After completing the loop, the best attained solution constitutes the output.

It appears to be a "*chicken-and-egg*" dilemma whether it makes more sense to start the evolution strategy with the generation of a parent population (with μ individuals), as suggested in Algorithm 1, or to do so at some other stage of the evolution, i.e., starting with an offspring population. The chosen representation has the advantage that the process that generates the subsequent parent populations $P_0, P_1, P_2, \ldots$ can be viewed as a memoryless stochastic process or more precisely a Markov process:

$$P_{t+1} = \texttt{Select}\left(\texttt{Mutate}\left(\texttt{Recombine}\left(P_t\right)\right), P_t\right) \tag{2}$$

This means that given P_t for some $t \geq 1$, the information of P_{t-1} is irrelevant in order to determine P_{t+1}; alternatively, in the terminology of stochastic processes, the state of P_{t+1} is conditionally independent of the state of P_{t-1} given P_t. This so-called Markov property makes it easier to analyze the behavior of the evolution strategy. In addition, P_t can be viewed as a checkpoint of the algorithm, and if the process stops, e.g., because of a computer crash, the process may resume by starting the loop with the last saved state of P_t.

The main loop of the evolution strategy is inspired by the principles of evolutionary adaptation in nature that were discovered in parallel by the naturalists Alfred Russel Wallace (1823–1913) and Charles Darwin (1809–1882). In brief, a popula-

tion of individuals adapt to their environment by (random) variation and selection. The reason for variability in the population was unknown to these researchers. Only much later in the so-called *modern synthesis*, it was linked to the mutation and recombination of genes. The ES presented in Algorithm 1 does however by far not provide a complete model for evolution in nature. In fact, important driving forces of natural evolutionary processes such as the development of temporally stable species and coevolution cannot be modeled with this basic evolution strategy. On the other hand, by mimicking only the variation and selection process, one can already achieve a potent and robust optimization heuristic, and the theoretical analysis of ESs can provide new insights in the dynamics of natural evolution.

Algorithm 1: Evolution strategy

input: initial population P_0 with μ evaluated individuals
$t \leftarrow 0$ {Generation counter}
$(\vec{x}_1^{\text{best}}, f_1^{\text{best}}) = \texttt{Update}(P_0)$ {Updates best found solution to best solution found in P_0.}
while termination criterion not fulfilled **do**
  $t \leftarrow t + 1$
  $R_t \leftarrow \texttt{Recombine}(P_{t-1})$ {Creates λ offspring from P_t using recombination operator.}
  $M_t \leftarrow \texttt{Mutate}(R_t)$ {Creates a mutant for each individual in R_t.}
  $C_t \leftarrow \texttt{Evaluate}_f(M_t)$ {Evaluates fitness function values.}
  $(\vec{x}_{t+1}^{\text{best}}, f_{t+1}^{\text{best}}) = \texttt{Update}(C_t, \vec{x}_t^{\text{best}}, f_t^{\text{best}})$ {Updates best found solution.}
  $P_t \leftarrow \texttt{Select}(C_t, P_{t-1})$ {Selects the μ best individuals from $C_t \cup P_{t-1}$ in case of a $(\mu+\lambda)$-selection, and from C_t in case of a (μ, λ)-selection.}
end while
return $\vec{x}^{\text{best}}, f^{\text{best}}$

There are many options to instantiate the operators of an evolution strategy, and in the literature, a certain terminology is used to refer to standard choices. Next, the most common instantiations of operators will be discussed by following the structure of Algorithm 1. The first step is the *initialization* of P_0, where the starting population is set by the user, since this allows to resume the evolution from a checkpoint. However, it is also very common to view the initialization as an integral part of the evolution strategy. Initialization procedures vary, while common choices are either constant initialization by generating μ copies of a starting (seed) point, or random initialization, i.e., to initialize the decision variables randomly within their bounds. The initialization of strategy parameters can have a significant impact on the transient behavior of an evolution strategy. In case of step-size parameters, it is often recommended to set these to 5% of the search space size.

A more complex operator is the recombination operator. In the nomenclature, the number of individuals who participate in the creation of a single vector is called ρ. The notation $(\mu/\rho, \lambda)$-ES and, respectively, $(\mu/\rho + \lambda)$-ES makes this number explicit. The ρ individuals who participate in the recombination are drawn by independent uniformly random choices from the population.

Given ρ individuals, there are two common strategies to create an offspring vector—*intermediate* recombination and *dominant* recombination. The vector to be

determined is commonly the vector of decision variables $\vec{x}$, but it can also include the vector of strategy parameters:

- *Intermediate recombination* determines the offspring by averaging the components of the parent individual. It can be applied on the object parameters and on the strategy parameters. Given a ρ-tuple of parent vectors $(\vec{q}^{(1)}, \ldots, \vec{q}^{(\rho)}) \in (\mathbb{R}^d)^\rho$, it computes the resulting vector $\vec{r}$ by means of $r_j = \frac{1}{\rho}(\sum_{i=1}^{\rho} q_j^{(i)})$ for $i = 1, \ldots, d$.
- *Discrete (or dominant) recombination* sets the ith position of the offspring vector $\vec{r}$ randomly to one of values of the parents. By drawing d uniform random numbers u_j, $j = 1, \ldots, d$, from the set $\{1, \ldots, \rho\}$, the offspring individual is set to $r_j = q_{u_j}$.

The terminology, *intermediate* and *dominant*, is lent from the theory of inheritance of biological traits by the botanist Gregor Mendel (1822–1884).

The *mutation* operator is seen as a main driving force of the evolutionary progress in ESs. Mutation adds a small random perturbation to each component of $\vec{x}$. The scaling of this perturbation is based on the strategy variables. A common case is to use the individual so-called step-size parameters $\sigma_1 \in \mathbb{R}^+, \ldots, \sigma_d \in \mathbb{R}^+$. The mutation then performs as indicated in the following equation:

$$x_i' \leftarrow x_i + \sigma_i \cdot \mathcal{N}(0, 1), \quad i = 1, \ldots, d \tag{3}$$

Here, $\mathcal{N}(0, 1)$ denotes the generation of a standard normal distributed random number. The resulting distributions of random numbers have a standard deviation of σ_i, why the σ-variables are also termed as standard deviations of the mutation.

A distinguishing feature of ESs is the *self-adaptation* of the mutation's parameters. In case of d step sizes, the mutative self-adaptation lets the step sizes themselves undergo an evolutionary process. In continuous optimization, the parameters of the multivariate Gaussian distribution can be adapted. Three levels of adaptation can be devised: Firstly, it is possible to control only a single standard deviation that is used for all decision variables (possibly with a constant scaling factor). This is called isotropic self-adaptation. Then, in the so-called individual step-size adaptation for each decision variable, a different standard deviation for the mutation is maintained and adapted. Finally, it is also possible to learn the full covariance matrix of the multivariate Gaussian distribution that is used in the mutation. The different levels of mutation distribution adaptation are indicated in Fig. 1. As a rule of thumb, it can be stated that the more mutation parameters are to be adapted the longer it takes to reach an optimal convergence behavior for a given model.

There are different strategies for controlling or adapting the mutation parameters:

- Step-size control based on the success rate. It has been shown that for the $(1 + 1)$-ES and on two important benchmark functions—sum of squares and

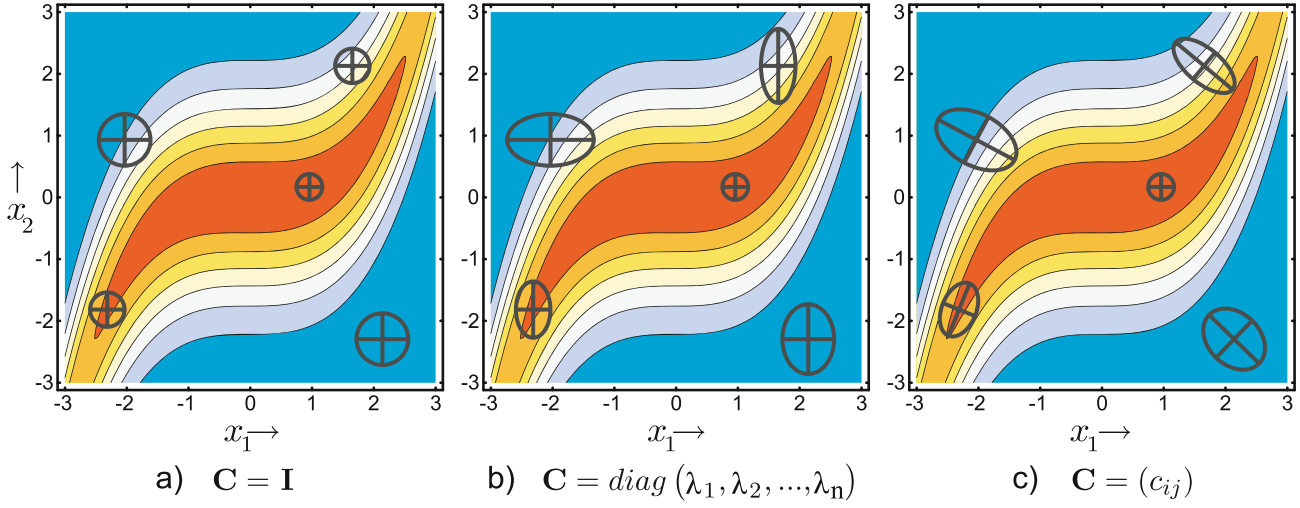

Fig. 1 Three levels of step-size control: isotropic (**a**), individual step sizes (**b**), and covariance matrix adaptation (**c**)

corridor model—among all isotropic Gaussian distributions, the optimal standard deviation is obtained at a step size that yields approximately a success probability of 1/5. Because the success probability can be assessed during execution, this allows for an effective step-size control of the $(1 + 1)$-ES.
- Mutative step-size control: The idea is to make the parameters of the mutation distribution part of the individual and let it undergo an evolutionary process itself. Details of this strategy will be elaborated in this section.
- Derandomized step-size control: Here a more efficient adaptation of the mutation distribution is derived based on cumulative information from previous successful mutation steps. Derandomized self-adaptation uses arithmetic procedures that can no longer be considered as biomimetic. For the price of losing flexibility and simplicity, they gain efficiency in particular for unconstrained continuous optimization and allow practicable schemes for adapting a full covariance matrix of a mutation distribution. The history and details of derandomized ESs will be elaborated on in the next section.

The classical self-adaptive mutation in ESs is nowadays called mutative step-size control. For adapting the standard deviations of the mutation distribution, it augments the individual by a step-size vector and mutates the standard deviations of the mutation before it mutates the decision variables using these standard deviations.

$$N_{\text{global}} \leftarrow \mathcal{N}(0, 1) \tag{4}$$

$$\sigma_i' \leftarrow \sigma_i \cdot \exp(\tau_{\text{local}}\mathcal{N}(0, 1) + \tau_{\text{global}}N_{\text{global}}), \quad i = 1, \ldots, d \tag{5}$$

$$x_i' \leftarrow x_i + \sigma_i \cdot \mathcal{N}(0, 1), \quad i = 1, \ldots, d \tag{6}$$

The parameters τ_{local} and τ_{global} are called local and global learning rates. The simplest form of the mutative step-size control exploits only a single step-size σ for all the coordinates. In this case, Eqs. 5 and 6 simplify to

$$\sigma' \leftarrow \sigma \cdot \exp(\tau_{\text{global}}N_{\text{global}}), \quad i = 1, \ldots, d \tag{7}$$

$$x_i' \leftarrow x_i + \sigma' \cdot \mathcal{N}(0, 1), \quad i = 1, \ldots, d \tag{8}$$

The utilization of mutative self-adaptation is valid when there are more offspring individuals than parent individuals. In this case, the step sizes with a greater value have a higher probability to be selected because they typically lead to better offspring individuals. Two commonly used default settings for parameters in the (μ, λ)-ES are: small population size: $\mu = 1$, $\lambda = 7$, $\tau_{\text{global}} = 1.2$, single step size, $\rho = 1$. Large population size: $\mu = 15$, $\lambda = 100$, $\tau_{\text{local}} = 1.1$, $\tau_{\text{global}} = 1.2$, $\rho = \mu$, and intermediate recombination of decision variables and step-size parameters. A larger population size is preferable if the optimization takes place on a rugged fitness function and a larger number of evaluations can be afforded.

Derandomized Evolution Strategies

Mutative step-size control tends to work well in the standard-ES for the adaptation of a single global step size but shows poor performance when it comes to the individual step sizes or arbitrary normal mutations. Schwefel claimed that the adaptation of the strategy parameters in those cases is impossible within small populations [80], and suggested larger populations as a solution to the problem. Later on, Rudolph questioned the effectiveness of ES learning upon discarding past information and claimed that ES learning would benefit from introducing memory to the individuals [71]. Indeed, due to the crucial role that the mutation operator plays within ES, its mutative step-size control was investigated intensively. Especially, the disruptive effects to which mutative step-size control is subject were studied at several levels [41, 66] and are reviewed here:

- **Indirect selection**. By definition, the goal of the mutation operator is to apply a stochastic variation to the decision variables, which will increase the individual's selection probability. The selection of the *strategy parameters* setting is indirect, i.e., the vector of a successful mutation is not utilized to adapt the step-size parameters, but rather the parameters of the distribution that led to this mutation vector.
- **Realization of parameter variation**. Due to the sampling from a random distribution, the *realization* of the parameter variation does not necessarily reflect the nature of the strategy parameters. Thus, the difference de facto between good and bad strategy settings of strategy parameters is only reflected in the difference between their probabilities to be selected—which can be rather small. Essentially, this means that the selection process of the strategy parameters is *strongly disturbed*.
- The *strategy parameter change rate* is defined as the difference between strategy parameters of two successive generations. Hansen and Ostermeier [41] argue that the change rate is an important factor, as it gives an indication concerning the adaptation speed, and thus it has a direct influence on the performance of the algorithm. The principal claim is that *this change rate basically vanishes* in the standard-ES. The *change rate* depends on the *mutation strength* to which the strategy parameters are subject. While aiming at attaining the maximal change rate, the latter is limited by an upper bound, due to the finite selection information that can be transferred between generations. Change rates that exceed the upper bound would lead to stochastic behavior. Moreover, the mutation strength that obtains an optimal change rate is typically smaller than the one that obtains good diversity among the mutants, a desired outcome of the mutation operator, often referred to as *selection difference*. Thus, the conflict between the objective of *optimal change rate* versus the objective of *optimal selection difference* cannot be resolved at the mutation strength level [66]. A possible solution to this conflict would be to *disconnect* the change rate from the mutation strength.

The so-called *derandomized mutative step-size control* aims to treat those disruptive effects, regardless of search space dimensionality, population size, or any other characteristic parameters.

The concept of derandomized ESs was originally introduced by scholars at the Technical University of Berlin at the beginning of the 1990s. It was followed by the release of a new generation of successful ES variants by Hansen, Ostermeier, and Gawelczyk [40, 42, 65, 67].

The first versions of *derandomized ES algorithms* introduced a controlled global step size to monitor the individual step sizes by decreasing the stochastic effects of the probabilistic sampling. The selection disturbance was completely removed with later versions by omitting the adaptation of strategy parameters by means of probabilistic sampling. This was combined with individual information from the last generation (the successful mutations, i.e., of selected offspring) and then adjusted to *correlated mutations*. Later, the concept of *adaptation by accumulated information* was introduced, aiming to use the information from preceding evaluations wisely for the purpose of step-size adaptation. Rather than using the information of the preceding generation alone, it was successfully generalized to a weighted average of the previous generations.

Note that the different derandomized ES variants strictly follow a $(1, \lambda)$ strategy, postponing the treatment of recombination or plus strategies for later stages. Moreover, the different variants hold different numbers of strategy parameters to be adapted, and this is an important factor in the complexity of the optimization routine and in its learning rate. The different algorithms hold a number of strategy parameters scaling either linearly ($\mathcal{O}(d)$ parameters responsible for individual step sizes) or quadratically ($\mathcal{O}(d^2)$ parameters responsible for arbitrary normal mutations) with the dimensionality d of the search space.

First Level of Derandomization

The so-called *first level of derandomization* aimed the following desired effects: (i) a degree of freedom with respect to the mutation strength of the strategy parameters, (ii) scalability of the *ratio* between the change rate and the mutation strength, and (iii) independence of population size with respect to the adaptation mechanism. The realization of the first level of derandomization can be reviewed through *three* particular derandomized ES variants:

DR1 The first derandomized attempt [65] coupled the successful mutations to the selection of decision parameters and learned the mutation step size as well as the scaling vector based on the successful variation. The mutation step is formulated for the k^{th} individual, $k = 1, \ldots, \lambda$:

$$\vec{x}^{(g+1)} = \vec{x}^{(g)} + \xi_k \delta^{(g)} \vec{\xi}^{k}_{\text{scal}} \vec{\delta}^{(g)}_{\text{scal}} \vec{z}_k \qquad \vec{z}_k \in \{-1, +1\}^d \tag{9}$$

Note that $\vec{z}_k$ is a random vector of ± 1, rather than a normally distributed random vector, while $\vec{\xi}^k_{\text{scal}} \sim \vec{\mathcal{N}}(0,1)^+$, i.e., distributed over the positive part of the normal distribution. The evaluation and selection are followed by the adaptation of the strategy parameters (subscripts *sel* refer to the selected individual):

$$\delta^{(g+1)} = \delta^{(g)} \cdot (\xi_{sel})^{\beta} \tag{10}$$

$$\vec{\delta}^{(g+1)}_{\text{scal}} = \vec{\delta}^{(g)}_{\text{scal}} \cdot \left(\vec{\xi}^{sel}_{\text{scal}} + b\right)^{\beta_{\text{scal}}} \tag{11}$$

DR2 The second derandomized ES variant [67] aimed to accumulate information about the correlation or anticorrelation of past mutation vectors in order to adapt the *global step size* as well as the *individual step sizes*—by introducing a *quasi-memory* vector. This accumulated information allowed omitting the stochastic element in the adaptation of the strategy parameters—updating them only by means of successful variations, rather than with random steps.

The mutation step for the k^{th} individual, $k = 1, \ldots, \lambda$, reads:

$$\vec{x}^{(g+1)} = \vec{x}^{(g)} + \delta^{(g)} \vec{\delta}^{(g)}_{\text{scal}} \vec{z}_k \qquad \vec{z}_k \sim \vec{\mathcal{N}}(0,1) \tag{12}$$

Introducing a quasi-memory vector $\vec{Z}$:

$$\vec{Z}^{(g)} = c\vec{z}_{sel} + (1-c)\,\vec{Z}^{(g-1)} \tag{13}$$

The adaptation of the strategy parameters according to the selected offspring:

$$\delta^{(g+1)} = \delta^{(g)} \cdot \left(\exp\left(\frac{\|\vec{Z}^{(g)}\|}{\sqrt{d}\sqrt{\frac{c}{2-c}}} - 1 + \frac{1}{5d} \right) \right)^{\beta} \tag{14}$$

$$\vec{\delta}^{(g+1)}_{\text{scal}} = \vec{\delta}^{(g)}_{\text{scal}} \cdot \left(\frac{\left|\vec{Z}^{(g)}\right|}{\sqrt{\frac{c}{2-c}}} + b \right)^{\beta_{\text{scal}}}, \qquad \left|\vec{Z}^{(g)}\right| = \left(|Z_1^{(g)}|, |Z_2^{(g)}|, ..., |Z_n^{(g)}| \right) \tag{15}$$

DR3 This third variant [42], usually referred to as the *generation set adaptation* (GSA), considered the derandomization of arbitrary normal mutations for the first time, aiming to achieve invariance with respect to the scaling of variables and the rotation of the coordinate system. This naturally came with the cost of a quasi-memory matrix, $\mathbf{B} \in \mathbb{R}^{r \times d}$, setting the dimension of the strategy parameters space to $d^2 \leq r \leq 2d^2$. The adaptation of the global step size is *mutative* with stochastic variations, just like in the **DR1**.

The mutation step is formulated for the kth individual, $k = 1, \ldots, \lambda$:

$$\vec{x}^{(g+1)} = \vec{x}^{(g)} + \delta^{(g)} \xi_k \vec{y}_k \tag{16}$$

$$\vec{y}_k = c_m \mathbf{B}^{(g)} \cdot \vec{z}_k \qquad \vec{z}_k \sim \vec{\mathcal{N}}(0, 1) \tag{17}$$

The update of the *memory matrix* is formulated as

$$\begin{aligned} &\mathbf{B}^{(g)} = \left(\vec{b}_1^{(g)}, \ldots, \vec{b}_r^{(g)}\right) \\ &\vec{b}_1^{(g+1)} = (1-c) \cdot \vec{b}_1^{(g)} + c \cdot (c_u \xi_{sel} \vec{y}_{sel}), \vec{b}_{i+1}^{(g+1)} = \vec{b}_i^{(g)} \end{aligned} \tag{18}$$

The step size is updated as follows:

$$\delta^{(g+1)} = \delta^{(g)} \, (\xi_{sel})^{\beta} \tag{19}$$

Second Level of Derandomization: CMA-ES

Following a series of successful derandomized ES variants addressing the first level of derandomization, and a continuous effort at the Technical University of Berlin, the so-called *Covariance Matrix Adaptation* (CMA) evolution strategy was released in 1996 [40], as a completely derandomized evolution strategy—the *fourth* generation of derandomized ES variants. The so-called *second level of derandomization* targeted the following effects: (i) The probability of regenerating the same mutation step is increased, (ii) *change rate* of the strategy parameters is subject to explicit control, and (iii) the strategy parameters are stationary when subject to random selection. The second level of derandomization was implemented by means of the CMA-ES.

The CMA-ES combines the robust mechanism of ES with powerful principles of *statistical learning*, and thus it is sometimes subject to informal criticism for not being a genuine biomimetic evolution strategy. In short, it aims to satisfy *maximum likelihood principle* by applying *principal components analysis* (PCA) [51] to the successful mutations and uses *cumulative global step-size adaptation*.

In the notation used here, the vector $\vec{m}$ represents the mean of the mutation distribution but is also associated with the current solution point, σ denotes the *global step size*, and the covariance matrix $\mathbf{C}$ determines the shape of the distribution ellipsoid:

$$\vec{x}^{NEW} \sim \mathcal{N}(\vec{m}, \sigma^2 \mathbf{C}) = \vec{m} + \sigma \cdot \mathcal{N}(\vec{0}, \mathbf{C}) = \vec{m} + \sigma \cdot \vec{z}$$

Two independent principles define the adaptation of the covariance matrix $\mathbf{C}$, versus the adaptation of the global step size σ:

- The mean $\vec{m}$ and the covariance matrix $\mathbf{C}$ of the normal distribution are updated according to *maximum likelihood principle*, so that good mutations are likely to appear again. $\vec{m}$ is updated such that

$$\mathcal{P}\left(\vec{x}_{sel}|\mathcal{N}\left(\vec{m}, \sigma^2\mathbf{C}\right)\right) \longrightarrow \max$$

  and $\mathbf{C}$ is updated such that

$$\mathcal{P}\left(\frac{\vec{x}_{sel} - \vec{m}_{old}}{\sigma}\middle|\mathcal{N}\left(\vec{0}, \mathbf{C}\right)\right) \longrightarrow \max$$

  considering the prior $\mathbf{C}$. This is implemented through the so-called *covariance matrix adaptation* (CMA) mechanism.
- σ is updated so that it is conjugate perpendicular to the consecutive steps of $\vec{m}$. This is implemented through the so-called *cumulative step-size adaptation* (CSA) mechanism.

Evolution Path A straightforward way to update the covariance matrix would be to construct a $d \times d$ *matrix analogue* to the **DR2** mechanism (see Eq. 13), with the *outer product* of the selected mutation vector $\vec{z}_{sel}$:

$$\mathbf{C} \longleftarrow (1 - c_{\text{cov}})\mathbf{C} + c_{\text{cov}}\vec{z}_{sel}\vec{z}_{sel}^T$$

However, to avoid discarding the sign information of $\vec{z}_{sel}$, the so-called *evolution path* is defined to accumulate the past information using an *exponentially weighted moving average*,

$$\vec{p}_c \propto \sum_{i=0}^{g}(1 - c_c)^{g-i}\vec{z}_{sel}^{(i)},$$

yielding the following update step for the covariance matrix:

$$\mathbf{C} \longleftarrow (1 - c_{\text{cov}})\mathbf{C} + c_{\text{cov}}\vec{p}_c\vec{p}_c^T$$

The Path Length Control The covariance matrix update is not likely to simultaneously increase the variance in all directions, and thus a global step-size control is much needed to operate in parallel. The basic idea of the so-called *path length control* is to measure the length of the evolution path, which also constitutes the consecutive steps of $\vec{m}$, and adapt the step size according to the following rationale: If *evolution path* is longer than expected, the steps are likely parallel, and thus the step size should be increased; alternatively, if it is shorter than expected, the steps are probably antiparallel, and the step size should be decreased accordingly. That

magnitude is defined as the expected length of a normally distributed random vector. This evaluation is explicitly carried out by the *conjugate* evolution path:

$$\vec{p}_\sigma \propto \sum_{i=0}^{g} (1 - c_\sigma)^{g-i} \mathbf{C}^{(i)\,-\frac{1}{2}}\, \vec{z}_{sel}^{\,(i)}$$

where the *eigendecomposition* of $\mathbf{C}$ is required in order to align all directions within the *rotated frame*. Then, the update of the step size depends on the comparison between $\|\vec{p}_\sigma\|$ and the expected length of a normally distributed random vector, $E\left[\|\mathcal{N}(0, \mathbf{I})\|\right]$:

$$\sigma \longleftarrow \sigma \cdot \exp\left(\frac{\|\vec{p}_\sigma\|}{E\left[\|\mathcal{N}(0, \mathbf{I})\|\right]} - 1\right)$$

The (μ_W, λ) Rank-μ CMA The Rank-μ covariance matrix adaptation [39] is an extension of the original update rule for larger population sizes. The idea is to use μ vectors ($\mu > 1$) to update the covariance matrix $\mathbf{C}$ in each generation, based on *weighted intermediate recombination*. Let $\vec{x}_{i:\lambda}$ denote the i^{th} ranked solution point, such that

$$f\left(\vec{x}_{1:\lambda}\right) \leq f\left(\vec{x}_{2:\lambda}\right) \leq \cdots \leq f\left(\vec{x}_{\lambda:\lambda}\right)$$

The updated *mean* is now defined as follows:

$$\vec{m} \leftarrow \sum_{i=1}^{\mu} w_i \vec{x}_{i:\lambda} = \vec{m} + \sigma \sum_{i=1}^{\mu} w_i \vec{z}_{i:\lambda} \equiv \langle \vec{x} \rangle_W$$

with a set of weights, $w_1 \geq w_2 \geq \cdots \geq w_\mu > 0$, $\sum_{i=1}^{\mu} w_i = 1$. The covariance matrix update is now formalized by means of rank-μ update, combined with the rank-one update:

$$\mathbf{C} \longleftarrow (1 - c_{\text{cov}})\mathbf{C} + \frac{c_{\text{cov}}}{\mu_{\text{cov}}} \vec{p}_c \vec{p}_c^{\,T} + c_{\text{cov}} \left(1 - \frac{1}{\mu_{\text{cov}}}\right) \sum_{i=1}^{\mu} w_i \vec{z}_{i:\lambda} \vec{z}_{i:\lambda}^{\,T}$$

The (μ_W, λ)-CMA-ES heuristic is summarized in Algorithm 2, with `initCMA()` referring to the parametric initialization procedure. It should be noted that a CMA-ES variant, which resembles DR2 and targets a vector of d individual step sizes (i.e., by means of a *diagonalized* covariance matrix), was released by the name of sep-CMA-ES [70]. Furthermore, the CMA-ES heuristic was simplified in the form of the so-called CMSA strategy [21] and was further improved for certain cases of global optimization [2].

Algorithm 2: (μ_W, λ)-CMA-ES

1: `initCMA()`
2: $g \leftarrow 0$
3: **repeat**
4: **for** $k = 1 \ldots \lambda$ **do**
5: $\vec{x}_k^{(g+1)} \leftarrow \langle \vec{x} \rangle_W^{(g)} + \sigma^{(g)} \cdot \vec{z}_k^{(g+1)}, \quad \vec{z}_k^{(g+1)} \sim \mathcal{N}\left(\vec{0}, \mathbf{C}^{(g)}\right)$
6: $f_k^{(g+1)} \leftarrow \texttt{Evaluate}\left(\vec{x}_k^{(g+1)}\right)$
7: **end for**
8: $\langle \vec{x} \rangle_W^{(g+1)} \leftarrow \texttt{Select}\left(\vec{f}^{(g+1)}, \vec{x}_{1\ldots\mu:\lambda}^{(g+1)}\right)$

10: $\mathbf{C}^{(g+1)} \leftarrow \texttt{UpdateCov}\left(\mathbf{C}^{(g)}, \vec{p}_c^{(g+1)}, \vec{z}_{1\ldots\mu:\lambda}^{(g+1)}\right)$
11: $\mathbf{C}^{(g+1)} := \mathbf{R}^{(g+1)} \mathbf{\Lambda}^{(g+1)} \left(\mathbf{R}^{(g+1)}\right)^T, \mathbf{\Lambda}^{(g+1)} = \text{diag}\left(\lambda_{\max}^{(g+1)}, \ldots, \lambda_{\min}^{(g+1)}\right)$
12: $\vec{p}_\sigma^{(g+1)} \leftarrow \texttt{UpdateSPath}\left(\vec{p}_\sigma^{(g)}, \vec{z}_{1\ldots\mu:\lambda}^{(g+1)}\right)$
13: $\sigma^{(g+1)} \leftarrow \texttt{UpdateStep}\left(\sigma^{(g)}, \vec{p}_\sigma^{(g)}\right)$
14: $g \leftarrow g + 1$
15: **until** stopping criterion is met
16: **return** $\langle \vec{x} \rangle_W^{(g)}$

Theoretical Results

Historically, the theory of ESs has primarily examined questions of convergence dynamics.

Under relatively mild conditions on the used mutation and recombination operators, complete global convergence for $t \to \infty$ can be proven for a certain probability [73]. Basically, for continuous objective functions, it is sufficient to ascertain that for every ϵ ball around the global minimizer, the probability that the mutation operator samples a point in this region is positive, regardless of the starting point. This is given, for instance, by bounding the standard deviations of the mutation from below by a small positive value. This can be easily generalized to ES for discrete [72] or even mixed-integer optimization problems [59].

Of more practical relevance are results on the convergence dynamics that is the speed of convergence to the optimum and on local progress rates. Different approaches for analysis have been used, based on dynamical systems theory [18], stochastic process theory [73], and techniques from the asymptotic analysis of randomized algorithms [49]. It is a well-established result that the most self-adaptive ES variants, if parameterized correctly, achieve a linear convergence rate in convex-quadratic problems, where the matrix condition number and the type of adaptation of step size determine the linear factor [20,62]. The same can be found for problems with proportional noise of fitness [4]. On the other hand, on sharp ridges, plateaus, and at the boundary of constraints, the classical step-size adaptation tends to fail

[54]. Also, for problems with additive noise, the accuracy of the results found will be limited by the standard deviation of the noise [55]. The theory of ESs also revealed some insights regarding the manner in which different parameters are correlated with each other and devised guidelines concerning optimal parameter settings. Most prominently, the $1/5$th success rule for step-size control in $(1+1)$-ES with isotropic mutation was developed based on theoretical studies on the sphere and the corridor model [69].

Also results on the effect of genetic drift and recombination in population-based ESs are available: Beyer highlighted the so-called genetic repair effect that recombination has in ESs. When using recombination, convergent behavior and optimal convergence rates can be achieved with higher mutation step sizes. This increases the robustness in global optimization settings as it is more likely to escape from local optima. The genetic repair effect is stronger when intermediate recombination is used, as compared to discrete recombination. Dynamical systems analysis and Markov chain analysis on simple search landscapes revealed that it is rather impossible to simultaneously explore different local optima by means of a single population [16]. Even if the recombination operator is disabled, when different attractor basins share exactly the same geometry, the population tends to quickly concentrate on a single attractor only [77]. For the global convergence on multimodal landscapes, analytical results have been derived for the progress rate and the success probability of hitting the global optimum [64, 75, 76]. Remarkably, on the Rastrigin function, it is shown that to maintain a high success probability, one must scale the population size μ with respect to the dimension $d \mid \mu \in \mathcal{O}(\sqrt{d} \ln d) \mid$ for both mutative step-size control and cumulative step-size adaptation [76]. These findings gave incentive to the development of niching [82] and restart methods [6, 26] that counteract this effect and prove to perform better on multimodal landscapes.

The Link to Statistical Learning and the Covariance-Hessian Relation The pragmatic motivation to obtain the landscape Hessian will become evident in the next section when we discuss noise handling and robust optimization (section "Noise Handling and Robust Optimization with ESs"). Here, as another important theoretical pillar, we elaborate on the inherent relation of the ESs' covariance matrix to the landscape Hessian. Attempts to formally characterize this relation originated in the release of the so-called natural ESs [94], and the consequent compilation of the information geometry optimization (IGO) philosophy [63] in parallel to the formulation of the natural gradient (NGD) algorithm [1]. In short, the building block of this class of algorithms is the *natural gradient method* [3], which features steepest ascent moves on the Riemannian manifold of the strategy distribution function using Fisher information. Importantly, in the context of landscape learning, modern ESs were proven to achieve such learning under certain adaptation mechanisms. Akimoto proved that the NGD algorithm adapts its covariance matrix so it becomes proportional to the inverse landscape Hessian of any monotonic convex-quadratic composite function in the limit of a large population size [1]. In a broader perspective, Beyer showed that upon implementing

the IGO philosophy in the same population-size limit, the self-adapted covariance matrix necessarily becomes proportional to the inverse Hessian [19]. Finally, a recent study proved a more fundamental result, stating that the covariance matrix over $(1, \lambda)$-selected decision vectors becomes proportional to the inverse of the landscape Hessian as the population size λ increases [85]. Explicitly, it showed that the statistically constructed covariance matrix over *single-winning* decision vectors converges to the inverse of the landscape Hessian, up to a scalar factor, when the population size tends to infinity for any quadratic objective function. Importantly, this kind of learning does not require the NGD mechanism or any derandomization (for adaptation) nor the IGO (as a proof tool)—i.e., remarkably, it is an inherent property of standard ESs which simply rely on Gaussian mutations and rank-based selection. This result constitutes a mathematical rigor to support a long-standing hypothesis on the behavior of ESs. The precise estimation of the local Hessian has been the topic of further, subsequent studies, such as [33], which propose an approach motivated by machine learning theory.

Nonstandard Evolution Strategies

The broad success of the family of ESs provided the motivation to devise extended heuristics for treating problem instances that are beyond the canonical unconstrained single-objective, unimodal optimization formulation. Indeed, ESs' extensions to mixed-integer search spaces [9, 58, 84, 95], uncertainty handling [43], multimodal domains [82] and to multi-objective Pareto optimization [47] were introduced in recent years. The goal of the current section is to provide an overview of those extensions.

ESs for Nonstandard Search Spaces Mixed-integer (MI) optimization [59] targets an objective function subject to constraints that include both continuous and discrete variables. MI optimization problems are NP-hard already in the linear case, and obtaining optimality in either white- or black-box scenarios is often challenging. MI ESs (MIESs) were originally investigated in the 1990s [9, 72] and have been enjoying a growing interest three decades later (see, e.g., [46, 90, 95]), including two successful MI variants of the CMA-ES [36, 61].

At a broader level, a general framework for ESs on nonstandard search spaces, termed metric-based evolutionary algorithms, was developed by Droste and Wiesmann [28]. They specified guidelines for instantiating of a mutation operator and recombination operators and exemplified the design method for the optimization of ordinary binary decision diagrams. By using similar guidelines, ESs for integer programming [72], mixed-integer programming [59], and graph-based optimization [29] were developed. Common guidelines for the design of ESs for new types of solution spaces are:

1. Causal Representation: Solutions should be represented in some metric search space such that relatively small changes with respect to the distance in the search

space result on average in only relatively small changes of the objective function value.
2. Unimodal Mutation Distributions: Small mutations should occur more likely than large mutations.
3. Scalability of Mutation: In order to implement self-adaptive mutation operators, it is essential that mutations can be scaled in terms of the average distance between parents and offspring.
4. Accessibility of Points by Mutation: By applying one (or a chain of many) mutation, it should be possible to reach every point in the search space, regardless of the starting point.
5. Unbiasedness of Mutation: Mutations should not introduce a bias in the search. They should be symmetric, and probability distributions with maximal entropy should be preferred.
6. Similarity to Parents in Recombination: The distance of an offspring to its parents should not exceed the distance of the parents to each other. Moreover, on average, the distance to all parents should be the same.

Following these design principles, one can expect generalized ESs to possess similar properties in comparison to standard ESs for continuous search spaces. However, a warning should be placed here regarding the functioning of step-size adaptation. In the theoretical derivation of optimal schemes of ESs, it is often assumed that differentiable problems locally resemble quadratic or linear functions. This property is lost when it comes to discrete optimization, and therefore, the generalization of such results requires some caution. On the other hand, it has been found that mutative self-adaptation of step sizes also works in nonstandard search spaces such as for the adaptation of mutation probabilities for binary vectors or for parameters of geometric distributions in MIESs.

Niching and Multi-population ESs

Given multimodal search landscapes with multiple basins of attraction that are of interest, targeting the simultaneous identification of several optima constitutes a challenge at both the theoretical and practical levels [60, 68, 82]. In such a scenario, the aim is to obtain the top optima of the landscape, yet in practical applications it may translate to locating a diverse set of high-quality solutions, optimal or suboptimal. Within the domain of evolutionary computation, this challenge is typically treated by extending a given search heuristic into subpopulations of trial solutions that evolve in parallel to various solutions of the problem. This idea stems from the evolutionary concept of *organic speciation*, and the so-called *niching* techniques are the extension of EAs to speciation forming multiple subpopulations. The computational challenge in niching may be formulated as achieving an effective interplay between partitioning the search space into niches occupied by stable subpopulations, by means of population diversity preservation, and exploiting the search in each niche by means of a highly efficient optimizer with local-search capabilities [82]. A niching framework utilizing derandomized ES

was introduced in [82], proposing the CMA-ES as a niching optimizer for the first time. The underpinning of that framework was the selection of a peak individual per subpopulation in each generation, followed by its sampling according to DES principles to produce the consecutive dispersion of search points. The *biological analogy* of this machinery is an *alpha-male winning all the imposed competitions and dominating thereafter its ecological niche*, which then obtains all the sexual resources therein to generate its offspring.

A common utility for defining the landscape subdomain of each subpopulation is a so-called niche radius. A radius-based framework for niching, which employs derandomized ES heuristics, has been formulated and investigated [83] and has shown a broad success in tackling both synthetic and real-world multimodal optimization problems. In practice, this framework holds multiple derandomized ES populations, which conduct heuristic search in their radii-defined subdomains and independently update their mutation distributions and step sizes. Since the partitioning is enforced per each generation according to the niche-radius parameter, and since no a priori knowledge is available on the global structure of the search landscape and the spatial distribution of its basins of attraction, an adaptive niche-radius approach was devised to remedy this so-called niche-radius presumption [86]. The main idea of ES niching with self-adaptive niche-shape approaches is to exploit learned landscape information, as reflected by the evolving mutation distribution, to define the niches in a more accurate manner. Especially, a Mahalanobis CMA-ES niching heuristic was formulated, which carries out the distance calculations among the individuals based upon the Mahalanobis distance metric, by utilizing the evolving covariance matrices of the CMA mechanism. Such heuristic operation resulted in successful niching on landscapes with unevenly shaped optima, on which the fixed-radii approaches performed poorly [86].

In scenarios where obtaining the *global* optimum is the paramount target in multimodal landscapes, niching may not necessarily be the most suitable approach to treat it. Rather, restart schemes can be effective in such scenarios. A multi-restart with increasing population-size approach was developed with the CMA algorithm, namely IPOP-CMA-ES [5]. This heuristic aims at attaining the global optimum, while possibly visiting local optima along the process and restarting the algorithm with a larger population size and a modified initial step size. The question of redundant restarts, when optimizing multimodal landscapes using ESs and particularly the CMA-ES, has been recently addressed [26]. That study proposed a metaheuristic to avoid such restarts while utilizing the CMA-ES.

Noise Handling and Robust Optimization with ESs

Robust optimization is concerned with identifying solvers that can also perform well when the input parameters and/or the values of the objective function are slightly perturbed [14]. Most variants of ESs are inherently suited to deal with noisy environments, and larger population size and the use of recombination were shown to be beneficial in noisy settings [4, 17]. Various techniques have

been shown to further improve the performance of noisy objective functions. One technique is the so-called thresholding operator, which considers search points as an improvement only when they introduce objective function improvements that exceed a certain threshold [13]. Moreover, it has been suggested to use the sample mean of multiple evaluations of the same individual (effective fitness) for evaluation. This increases the computation time, and therefore, more efficient sampling schemes have been developed subsequently. In [27], an adaptive sampling method is devised to determine the evaluation number based on the eigenspectrum of the covariance matrix, the step size, population size, and the local Lipschitz constant. Furthermore, a rank-stability scheme was suggested to treat noise, exploiting the fact that ESs rather require a correct ranking rather than a correct objective function value [43].

Knowledge of second-order Hessian information at the optimum is desirable not only as a measure of system robustness to noise in the decision variables but also as a means for dimensionality reduction and for landscape characterization. Experimental optimization of quantum systems motivated the compilation of an automated method to efficiently retrieve the Hessian matrix about the global optimum *without derivative evaluations* from experimental measurements [87]. The study designed a heuristic to learn the Hessian matrix based on the CMA-ES machinery, with necessary modifications, by exploiting an inherent relation between the covariance matrix and the inverse Hessian matrix. It then corroborated this newly proposed technique, entitled forced optimal covariance adaptive learning (FOCAL), on noisy simulation-based optimization as well as on laboratory experimental quantum systems. For a comprehensive overview of contemporary noise handling and robust optimization in ESs, the reader is referred to the PhD dissertation of Kruisselbrink, which was also complemented by an empirical study of the most common variants. In addition, theoretical limits in the precision of multievaluation schemes in the presence of additive noise are derived therein [55].

Multi-criterion and Constraint-Handling ESs

In practical settings, the scenario of unconstrained optimization is not very common. Rather, problems with multiple constraint functions and conflicting objective functions need to be solved.

In optimization with constraints, it is mandatory to use alternative schemes for step-size adaptation for reasons that are explained in detail by Kramer and Schwefel [54]. They also suggested alternative schemes that can better deal with the constraints.

Adaptations of the ESs are also required for optimization with multiple objective functions. In this case, it is common to search for a set of nondominated solutions, the so-called Pareto set. A first proposal on using ESs to approximate a Pareto front was made by Kursawe [56], a long time before the nowadays flourishing research field of evolutionary multi-criterion optimization was established. Today, three variants of the evolution strategy are used for optimization with multiple objectives:

- Pareto-archiving evolution strategy [53]: This classical multi-criterion optimization strategy uses an archive to maintain nondominated points. The archive is updated based on the nondominance and density of points.
- Predator-prey evolution strategy [35,57]: In this biomimetic strategy, individuals are distributed on a grid, and a population of predator individuals is performing a random walk on the grid and triggers local selection. The predators select their prey based on different objective functions or combination strategies.
- Multi-objective CMA-ES [47]: This strategy seeks to improve contributions of individuals to the hypervolume indicator, which measures the size of the Pareto-dominated space. Consequently, this strategy is well adapted to locate precise and regular representations of Pareto fronts for objective functions with complex shapes and correlated input variables. Another self-adaptation method, using local tournaments on hypervolume contributions, was suggested in [52] but so far received little attention.

Mirrored Orthogonal Sampling

The mirrored sampling technique is a derandomized mutation method. It was firstly introduced in [24] for non-elitist $(1, \lambda)$-ES and then extended to the (μ, λ)-ES [7]. The idea of mirrored sampling is to generate part (normally half) of the offspring population in a derandomized way. More specifically, a single mutation vector $\mathbf{z}$ is utilized to generate two offspring (rather than one in the standard ES)—one by adding $\mathbf{z}$ to the parent $\mathbf{x}$: $\mathbf{x} + \mathbf{z}$, and another by subtracting $\mathbf{z}$ from $\mathbf{x}$: $\mathbf{x} - \mathbf{z}$. The two offspring generated are *symmetric* or *mirrored* to the parental point. Mirrored sampling helps accelerating the convergence rate of ESs, which is theoretically proven in [24].

When applied in (μ, λ)-CMA-ES with cumulative step-size adaptation, the mirrored sampling leads to a reduction of recombined mutation variance. Consequently, the step size is more than desirably reduced and a premature convergence would occur. In order to solve this, the concept of pairwise selection is introduced [7], in which only the better offspring among the mirrored pair is allowed to possibly contribute to the weighted recombination. Then, it is assured that recombination will not use both elements of a mirrored pair at the same time. Mirrored sampling can be enhanced by incorporating orthogonal samples [93], where the generated samples form an orthogonal basis. This approach minimizes redundancy in sampling directions and further reduces sampling error, leading to more efficient exploration of the search space. For a comprehensive overview of classical and more advanced sampling strategies and variants of evolutionary strategies, the reader is referred to [12]. Studies such as Biedrzycki's work on CMA-ES involving bound constraints [22] address challenges in sampling strategies that occur when solving real-world problems but are underrepresented in the research of ES which mainly focused on unconstrained continuous optimization.

Algorithm Configurators and Hyperparameter Optimization

Hyperparameter optimization and automated algorithm configuration can be crucial to improving the performance of the covariance matrix adaptation evolution strategy (CMA-ES). This includes tuning parameters such as step size, learning rates, population size, and choosing sampling strategies and covariance matrix update algorithms. Van Rijn et al. [91] explored data mining approaches to identify links between algorithm configurations and performance, advancing automated parameter tuning. In a follow-up work, Van Rijn et al. [92] proposed a method to dynamically adjust CMA-ES configurations during runtime based on problem-specific data.

Recent advancements include the use of meta-optimization, where CMA-ES optimizes its own parameters. Thomaser et al. [89] demonstrated this approach, further advancing self-optimization strategies. In addition to these works that are specific to ES, it is also common to use general-purpose hyperparameter optimization methods in the context of ES tuning.

Benchmarks and Empirical Study

Besides a detailed description of ESs and their theoretical aspects, it would be intuitive and helpful to look at the empirical ability of ESs in solving the black-box problems. In the ESs benchmarking, two difficulties arise. On one hand, it is hard to design a set of test functions that captures the problem characteristics encountered in the real-world applications. On the other hand, summarizing ESs ability over a set of test functions would not be straightforward due to the fact that performance of ESs largely varies on problems with different characteristics (e.g., separability). The black-box optimization benchmark [44] (BBOB) is devised to tackle these difficulties. The noiseless BBOB encompasses 24 noise-free real-parameter single-objective functions that are either separable, ill-conditioned, or multimodal. All the test functions are defined over $\mathbb{R}^d$, while the global optima for all the test functions are initialized in $[-5, 5]^d$ [30]. In addition, BBOB also introduces a proper measure to represent the performance of ESs for global optimization—the empirical cumulative distribution function (ECDF). ECDFs can be summarized over multiple test functions and represented graphically, increasing the accessibility of the benchmark results.

As opposed to the earlier work, in this empirical study, ESs with different step-size adaptation strategies are considered, including the classical $1/5^{\text{th}}$ success rule and mutative self-adaptation. Moreover, the benchmark also covers a broad range of classical and contemporary strategies with derandomized self-adaptation. The ESs tested are listed in the following:

- $(1 + 1)$-ES: one plus one elitist evolution strategy with $1/5^{\text{th}}$ success rule
- $(15, 100)$-MSC-ES: mutative self-adaptation of individual step sizes

- (1, 7)-MSC-ES: mutative self-adaptation of individual step sizes
- DR2-ES: The derandomized evolution strategy using accumulated success mutation vector for step-size adaptation
- $(\mu/\mu_{\mathrm{w}}, \lambda)$-CMA-ES: covariance matrix adaptation evolution strategy with weighted intermediate recombination
- $(\mu/\mu_{\mathrm{w}}, \lambda_{\mathrm{m}})$-CMA-ES: CMA-ES with mirrored sampling and pairwise selection
- IPOP-CMA-ES: a restart CMA-ES with increasing population size
- $(1, \lambda)$-DR2-Niching: the niching approach based on the second derandomized ES variants
- $(1, \lambda)$-CMA-Niching: CMA-ES niching with fixed niche radius
- $(1 + \lambda)$-CMA-Niching: the elitist version
- $(1, \lambda)$-Mahalanobis-CMA-Niching: niche-shape adaptation using Mahalanobis distance

Experimental Settings

The BBOB parameter settings of the experiment are the same for all the tested ES variants. The initial global step size σ is set to 1. The maximum number of function evaluations is set to $10^4 \times d$. The initial solution vector (initial parent) is a uniformly distributed random vector restricted to the hyper-box $[-4, 4]^d$. The algorithms are tested for problems of a different number of input variables d. These are $d \in \{2, 3, 5, 10, 20\}$.

The parameter settings for CMA-ES variants follow the suggested values in [37]; the reader is referred to it for details. For all the niching ES variants, the setting $\lambda = 10$ is used throughout all the test. The fixed niche radius calculation can be found in [82].

Results

BBOB automatically records the history of the fitness values found by the tested algorithm. The time is measured in numbers of function evaluations. The benchmark provides a postprocessing procedure to statistically estimate the empirical cumulative distribution function (ECDF) of running length (function evaluations) to reach the global optimum from the data. The ECDF of running length describes the distribution of necessary function evaluations a specific optimization algorithm follows in order to reach the global optimum in an experiment. An ECDF curve that inclines to distribute running length over smaller values indicates good performance of its corresponding algorithm. Thus, ECDFs characterize the performance of optimization algorithms and are used to present the benchmark results.

In contrast to the standard way of generating ECDFs in BBOB, which is to aggregate ECDFs over function groups (separable, ill-conditioned, multimodal),

in each group, representative functions in BBOB are selected, which are listed as follows:

1. f_1 sphere function
2. f_2 ellipsoidal function
3. f_{10} rotated ellipsoidal function
4. f_8 Rosenbrock function
5. f_{13} sharp ridge function
6. f_7 step ellipsoidal function
7. $f_{15} - f_{19}$ multimodal function having weakly global structure
8. $f_{20} - f_{24}$ multimodal function having adequate global structure

By aggregating the selected functions in functions groups, it is possible to illustrate which ES variants perform better given a specific property (e.g., separable, isotropic, multimodal) by identifying functions with distinct properties. Rather than making a thorough competition, we aim for providing insights into the algorithms' strengths and weaknesses.

The results are presented in two parts. In the first part, all the ESs except IPOP-CMA-ES and the niching ES variants are compared on the aforementioned test functions are excluded from the comparison. The purpose is to compare all the ESs which are inclining to local search. The results are depicted in Figs. 2, 3, 4, and 5. In 5D, the comparisons on the first six functions show that the standard CMA-ES and its mirrored sampling variant outperform the others in most functions. In general, the mutative self-adaptation ESs perform worse than the derandomized ES variants. The reason is that the MSC-ES normally exploits a much larger population size in order to adapt the covariance and thus consumes much more function evaluations. On the simple sphere function, the winner is $(1 + 1)$-ES, as expected from theory. In addition, the DR2-ES is equally good as CMA-ES. On the separable ellipsoid function, DR2-ES even outperforms CMA-ES because it efficiently adapts the uncorrelated mutations. On the non-separable functions (ellipsoid, Rosenbrock, sharp ridge, and step ellipsoid), CMA-ES and mirrored sampling significantly outperform the other ES variants. This is because CMA-ES is capable of adapting arbitrary mutations by means of the covariance matrix, while the other ES variants exploit either isotropic or axis-parallel mutation distributions. In 20D, the comparison roughly shows the same results as in 5D. Note that on separable ellipsoid and step-ellipsoid function, $(15, 100)$-MSC-ES could catch the convergence speed of CMA-ES variants.

In the second part, all the niching ES variants are compared, IPOP-CMA-ES, restart $(1 + 1)$-ES and $(15, 100)$-MSC-ES only on the multimodal functions. These algorithms are grouped for this comparison because they are better equipped for global search. The results are depicted in Figs. 6 (5D) and 7 (20D). On the weakly structured multimodal functions ($f_{15} - f_{19}$), IPOP-CMA-ES outperforms all the niching ES variants, $(1 + 1)$-ES with restart and $(15, 100)$-MSC-ES. $(1+\lambda)$-CMA-Niching shows the best performance among all the niching ES variants

tested. Surprisingly, (μ, λ)-MSC-ES performs well even compared to niching ES variants, which may be a consequence of its large population size. On the weakly structured multimodal functions, $(1 + \lambda)$-CMA-Niching could catch up with the performance of IPOP-CMA-ES in both 5D and 20D. (μ, λ)-MSC-ES performs quite poorly in this case. In addition, although it is a simple strategy, $(1 + 1)$-restart shows good results compared to IPOP-CMA-ES and niching ES. Evidently, the niching ES variants spend many function evaluations for maintaining the local optima and thus exhibit altogether poorer performance in terms of global convergence speed when compared to, e.g., IPOP-CMA-ES, which targets the

accurate approximation of a single optimum and exploits much of its resources to achieve this.

Conclusions

It has been shown in this chapter that ESs are a versatile class of stochastic search heuristics for optimization. There exists a rich body of theoretical results on ESs, including global convergence conditions, results showing linear convergence rates on high-dimensional functions, and findings on the stability of subpopulations and the impact of recombination on global convergence reliability. Moreover, ESs are rank-based (order-invariant) and invariant to changes of the coordinate system. The self-adaptation of the stochastic distribution is an important feature, too, as it frees the user from the burden of choosing the right parameters for mutation and it also makes highly precise approximation of optima possible.

This chapter highlighted mainstream variants of ESs for continuous optimization, including the $(1+1)$-ES with $1/5$th success rule, the $(\mu, \lambda)-$ES with mutative step-size adaptation and common variants of ES with different levels of derandomized step-size adaptation, namely DR1, DR2, DR3, and CMA-ES. Moreover, common concepts of ESs for multimodal optimization were discussed.

All these strategies have been compared on different categories of functions. The empirical studies confirmed the superiority of covariance matrix adaptation techniques on ill-conditioned problems with correlated variables. However, if these problems do not govern the search difficulty, other ESs can be highly competitive as well. Moreover, it was confirmed that multimodal optimization requires special adaptations to ESs in order to achieve maximal performance.

Our literature review has shown that the algorithmic techniques developed for ESs are not only fruitful in the domain of continuous optimization but can be applied to other problem classes as well. Here, the key lies in defining a metric representation of the search space and following a set of guidelines for the design of mutation and recombination operators—which have been reviewed herein rather informally. Importantly, ESs operating in the area of MI optimization have the potential to obtain high impact in comparison to mathematical programming solvers in either single- [95] or multi-objective [84] problem domains. Yet, the compliance of MIESs is still underexplored and calls for further research.

Some prevalent topics for future research will be the integration of multiple criteria and constraints, although some first promising results are already available in this direction. Moreover, for nonstandard ES, the theoretical analysis needs to be advanced, in particular the study of convergence dynamics when the available time is limited. Finally, looking back at the original biological inspiration of ESs, one might conjecture that nature still has many "tricks" in store that, when well understood, could lead to a further enhancement of ES-like search strategies. In this context, it will be interesting to follow recent trends in biological evolution theories [48], showing that a much broader set of mechanisms seems to govern organic evolution than those captured in modern synthesis.

Table 1 Source code packages with ES-related implementations

Package	Language	License	Reference
Pytorch ES	`Python`	MIT	[32]
Nevergrad (by Meta)	`Python`	MIT	[15]
Distributed ES (by OpenAI)	`Python`	MIT	[74]
modcma (ModularCMAES)	`Python`	MIT	[25]
ecr	`R`	GPL3 (GNU)	[23]
CMA-ES	Various	GNU	[38]

Available Code Packages

Table 1 provides an overview of various source code packages that implement ESs. The table includes implementations predominantly in `Python`, with one in `R`, reflecting the accessibility of ES frameworks across programming ecosystems. Each entry specifies the package name, programming language, license type, and reference to its source or documentation. Examples include well-known projects like *Nevergrad* by Meta and *Distributed ES* by OpenAI, both of which use the permissive MIT license. The table also features additional frameworks, such as *Pytorch ES* and *modcma* (ModularCMAES), which are customized for advanced ES experimentation, and allows to assemble different ES variants from modular components. An R-based package, *ecr*, is also listed, expanding the scope of users in statistical computing environments. Additionally, implementations of covariance matrix adaptation evolution strategy (CMA-ES) across a wide range of problems can be found on the homepage of Nikolaus Hansen. The homepage provides source code for CMA-ES in several programming languages, including C (ANSI), C++, Fortran, Java, Matlab and Octave, Python, R, and Scilab. It also contains practical hints and remarks about using the CMA-ES. Note that this list of references is merely a small selection of more recent implementations.

Abstract

Evolutionary algorithms (EAs) are population-based metaheuristics, originally inspired by aspects of natural evolution. Modern varieties incorporate a broad mixture of search mechanisms, and tend to blend inspiration from nature with pragmatic engineering concerns; however, all EAs essentially operate by maintaining a population of potential solutions and in some way artificially 'evolving' that population over time. Particularly well-known categories of EAs include genetic algorithms (GAs), Genetic Programming (GP), and Evolution Strategies (ES). EAs have proven very successful in practical applications, particularly those requiring solutions to combinatorial problems. EAs are highly flexible and can be configured to address any optimization task, without the requirements for reformulation and/or simplification that would be needed for other techniques. However, this flexibility goes hand in hand with a cost: the tailoring of an EA's configuration and parameters, so as to provide robust performance for a given class of tasks, is often a complex and time-consuming process. This tailoring process is one of the many ongoing research areas associated with EAs.

Keywords

Population-based · Genetic algorithms · Evolutionary programming · Evolution strategies

Introduction

Evolutionary algorithms (EAs) are population-based metaheuristics. Historically, the design of EAs was motivated by observations about natural evolution in biological populations. Recent varieties of EA tend to include a broad mixture of influences in their design, although biological terminology is still in common use. The term "EA" is also sometimes extended to algorithms that are motivated by population-based aspects of EAs but which are not directly descended from traditional EAs, such as scatter search. The term evolutionary computation is also used to refer to EAs but usually as a generic term that includes optimization algorithms motivated by other processes but which generally involve a population of potential solutions adapting and improving over time. This includes algorithms inspired by other natural processes, such as ant colony optimization (ACO—inspired by the collective problem-solving behavior of social insects) and artificial immune systems (AIS—inspired by the adaptive molecular processes involved in the human immune system's ability to recognize and destroy harmful agents). It also includes algorithms inspired by social behavior, such as particle swarm optimization (PSO); however, in recent years, the convention has shifted toward using the term "swarm intelligence" to describe PSO, ACO, and other algorithms inspired more by interaction than evolution. Although these algorithms often resemble EAs, this is

not always the case, and they will not generally be discussed in this chapter. For a discussion of their commonalities and differences, the reader is referred to [1].

Over the years, EAs have become an extremely rich and diverse field of study. In part this arises from their inherent design flexibility—there are innumerable ways to specify an algorithm that operates according to the core concepts of evolution. In part this also arises from the fact that their performance tends to be highly problem dependent—an EA that works well on one task may well perform poorly on another, even quite similar, task. Arising from these factors and others, the sheer number of publications in this area is challenging for people new to the field. To address this, this chapter aims to give a concise overview of EAs and their application, with an emphasis on contemporary rather than historical usage.

The main classes of EA in contemporary usage are (in order of popularity) genetic algorithms (GAs), evolution strategies (ESs), differential evolution (DE), and estimation of distribution algorithms (EDAs). Multi-objective evolutionary algorithms (MOEAs), which generalize EAs to the multiple objective case, and memetic algorithms (MAs), which hybridize EAs with local search, are also popular, particularly within applied work. Special-purpose EAs, such as genetic programming (GP) and learning classifier systems (LCS), are also widely used. These are all discussed in this chapter.

Although these algorithms differ from each other in a number of respects, they are all based around the same core process. Each of them maintains a population of search points (known variously as candidate solutions, individuals, chromosomes, or agents). These are typically generated at random and are then iteratively evolved over a series of generations by applying variation operators and selection. Variation operators generate changes to members of the population, i.e., they carry out moves through the search space. After each generation, the objective value (or *fitness*) of each search point is calculated. Selection then removes the search points with the lowest objective values, meaning that only the best search points are maintained, and new search points are always derived from these. It is this combination of maintaining a population of search points and carrying out selection between search points that differentiates EAs from most other metaheuristics.

Each EA uses its own distinctive set of variation operators, which are sometimes inspired by the mutative and recombinative processes that generate diversity in biological evolution. The mutation operator resembles the generation of "moves" in other optimization algorithms and involves sampling the neighborhood around an existing search point in some fashion. A typical approach would be to randomly change one component of a solution, though a particular EA may use more than one kind of mutation operator. The recombination (or *crossover*) operator explores the region between two or more search points, for example, by randomly reassembling the components that make up two existing solutions. This process of searching the region between existing search points is also a distinctive feature of EAs, though its practical utility depends upon the structure of the search space. Some EAs, particularly "evolutionary programming" and older varieties of evolution strategy, do not use recombination at all.

Principal Algorithms

All EAs share certain common features, including in particular the broad concepts of *variation* and *selection*, as introduced in section "Introduction", operating over a series of *generations*. More fundamentally, all EAs work by seeking the "best" (in some sense) solutions they can find to a given optimization task. Put in another way, an EA is almost always used to find the solution data-structure x which optimizes a given function $f(x)$. For example, the task at hand may be straightforward numerical function optimization, where the candidate solution data-structure is a binary string that is interpreted as a list of real-valued parameters, and $f(x)$ is a mathematical function over those parameters whose result is a scalar value. Alternatively, the task at hand may be to find an ideal schedule for a collection of manufacturing tasks at a factory; in this case, the candidate solution data-structure might be an ordered sequence of task identifiers, and $f(x)$ would be a program that simulates the schedule from the sequence, returning a vector of quality indicators including cost, time, and risk. Whatever the nature of the underlying data-structure being "evolved" and whatever the nature of $f(x)$, we can express a "canonical" EA in pseudocode as follows:

Preliminaries: determine a suitable way to represent solutions as data-structures, prepare the fitness function, and set $g = 0$.

Step 1:	set $g = 0$, and generate and evaluate an initial population Sg of candidate solutions;
Step 2:	apply *selection* operators to produce a set of "parent" solutions P;
Step 3:	apply variation operators to P to produce a set of "chil" solutions C, and evaluate the fitness of each one;
Step 4:	apply population update operations to the union of Sg and C to produce $S_{g+}1$, and increment g
Step 5:	if a termination criterion has not been reached, go to Step 2; otherwise, finish and return the fittest member of the population.

In the above pseudocode, steps 2–5 constitute a "generation," whose major components are selection, variation, and then the "population update" step that leads to renewal of the population, now ready to enter the next generation. Individual EAs vary greatly in each of these steps, including the "preliminaries" step. In the remainder of this section, we provide brief introductions to the principal classes of EA that are in current use and then discuss existing understanding of their performance and applicability.

Genetic Algorithms

Genetic algorithms, or GAs, are one of the earliest forms of EAs and remain widely used. Candidate solutions, often referred to as *chromosomes* in the GA literature, comprise a vector of decision variables. Nowadays, these variables tend to have a

direct mapping to an optimization domain, with each decision variable (or *gene*) in the GA chromosome representing a value (or *allele*) that is to be optimized. However, it should be noted that historically GAs worked with binary strings, with real values encoded by multiple binary symbols, and that this practice is still sometimes used. GA solution vectors are either fixed-length or variable-length, with the former the more common of the two.

Given their long history, genetic algorithm implementations vary considerably. However, it is fairly common to use a mutation operator that changes each decision variable with a certain probability (values of 4–8% are typical, depending upon the problem domain). When the solution vector is a binary string, the effect of the mutation operator is simply to flip the value. More generally, if the solution vector is a "$k-$ary" string, in which each position can take any of a discrete set of k possible values, then the mutation operator is usually designed to choose a random new value from the available alphabet. If the solution vector is a string of real-valued parameters within a set range, the new value may be sampled from a uniform distribution in that range, or it may be sampled from a nonuniform (e.g., Gaussian) probability distribution centered around the current value. The latter is generally the preferred approach, since it leads to less disruptive change on average. Recombination is typically implemented using two-point or uniform crossover. Recombination tends to be applied at a high rate (e.g., 0.7, typically called the *crossover rate*); this means, for example, that when a variation operator is to be applied, the chance of this operator being a crossover operator will be 0.7; otherwise (depending on the algorithm), the operator may be the application of mutation to a single parent or simply copying a single parent. Two-point crossover chooses two *parent* solutions and two *crossover points* within the solutions. The values of the decision variables lying between these two points are then swapped to form two *child* solutions. Historically, "one-point" crossover was popular, which produced the first (second) child by copying the first (second) parent up to a randomly chosen point and then copied the second (first) parent thereafter. However, though more convenient for theoretical analyses, one-point crossover is rarely used in practice these days. Meanwhile, in uniform crossover, crossover points are created at each decision variable with a given probability. Other forms of crossover have also been used in GAs. Examples include line crossover and multi-parent crossover. Other variation operators, such as inversion, have been found useful for some problems.

Various forms of selection are used with GAs. Rank-based or tournament selection are generally preferred, since they maintain exploration better than the more traditional fitness-proportionate selection (e.g., roulette-wheel selection). Note, however, that the latter is still widely used. Rank-based selection involves ranking the population in terms of objective value. Population members are then chosen to become parents with a probability proportional to their rank. In tournament selection, a small group of solutions (typically three or four) are uniformly sampled from the population, and those with the highest objective value(s) become the parent(s) of the next child solution that is created. Tournament selection allows selective pressure to be easily varied by adjusting the tournament size.

Evolution Strategies and Evolutionary Programming

Evolutionary programming (EP) and evolution strategies (ES) also have a long history, starting earlier than the development of GAs. First described in the 1960s and 1970s, respectively (see [2] for a comprehensive account of the historical development), early ES and EP used only single-parent operators in the variation step (i.e., mutation). Meanwhile, EP was singular in focusing on using finite-state machines as the evolving data-structures, while ES soon introduced a recombination operator and championed the exploration of so-called "$m + n$" schemes, whereby a population of m parents would generate n children and the best n of the combined parents and children becomes the next generation of parents. In current research and practice, modern formulations of EP focus on numerical optimization over real-valued parameters and still eschew multi-parent operators in favor of paying attention to careful design of the mutation operator(s). Of the two styles, however, ES is more widely researched and deployed in practice, and particular variants of ES have shown particular prowess in numerical function optimization. Modern ESs incorporate strategies that carefully guide how the mutation operator is applied to each decision variable. Unlike GAs, ESs mutate every decision variable at each application of the operator and do so according to a set of *strategy parameters* that determine the magnitude of these changes. Strategy parameters Strategy parameters usually control characteristics of probability distributions from which the new values of decision variables are drawn.

It is standard practice to adapt strategy parameters over the course of an ES run, the basic idea being that different types of move will be beneficial at different stages of search. Various techniques have been used to achieve this adaptation. Some of these involve applying a simple formula, e.g., the 1/5th rule, which involves increasing or decreasing the magnitude of changes based on the number of successful mutations that have recently been observed. Others are based around the idea of self-adaptation, which involves encoding the strategy parameters as additional decision variables and hence allowing evolution to come up with appropriate values. However, the most widely used contemporary approach is covariance matrix adaptation (CMA-ES), which uses a mechanism for estimating the directions of productive gradients within the search space and then applying moves in those directions. In this respect, CMA-ES has similarities with gradient-based optimization methods.

ESs use different recombination operators to GAs and often use more than two parents to create each child solution. For example, intermediate recombination gives a child solution the average values of each decision variable in each of the parent solutions. Weighted multi-recombination is similar but uses a weighted average, based on the fitness of each parent. Also unlike GAs, ESs tend to use deterministic rather than probabilistic selection mechanisms, whereby the best solutions in the population are always used as parents of the next generation.

Estimation of Distribution Algorithms

Like ESs, estimation of distribution algorithms [3], or EDAs, make use of probability distributions. However, rather than using them to describe a distribution of next moves, as an ES does, EDAs use them to describe a distribution of next sample solutions. The basic mechanism is quite simple. As for most EAs, the initial population of solutions is (typically) sampled from a uniform distribution. Selection is then used to remove the poorer members of this population, and a probability distribution is then constructed that attempts to model the statistics of the relatively high-fitness sample solutions that remain in the population. Importantly, this distribution is constructed in such a way that it "generalizes" the population members suitably well. The next generation of solutions is then constructed by sampling from this distribution. So, if the distribution was highly peaked around the existing samples, for example, the next generation would explore very little beyond the previous one. This pattern of building a distribution, sampling, and selection is then iterated in the usual generational fashion, with the hope that the final probability distribution will characterize solutions that are, or are close to, globally optimal.

While an EDA may be used with any kind of probability distribution, in practice, it is necessary to choose a distribution that induces an appropriate trade-off between efficiency and expressiveness. More expressive models, such as Bayesian networks and Markov models, can capture dependencies between decision variables but can be expensive to construct and sample from. Simple univariate distributions, by comparison, are cheap to build and sample from but are unable to capture dependencies between variables. This trade-off is reflected in the range of EDAs in common use. Population-based incremental learning (PBIL) and the compact genetic algorithm (CGA) are both examples of computationally efficient EDAs that build simple univariate models based on discrete variables. Because of their simplicity, they can be applied to large problem instances. Bayesian optimization algorithms (BOAs) lie at the other end of the spectrum: these can express dependencies between variables, and certain varieties can be applied to both discrete and continuous variables, but they are far more demanding of computational resources.

Differential Evolution

Differential evolution [4, 5], or DE, is a relatively recent EA formulation which uses a mechanism for adaptive search that does not make use of probability distributions. While its basic mechanism is similar to a GA, its mutation operator is quite different, using a geometric approach that is motivated by the moves performed in the Nelder-Mead simplex search method. This involves selecting two existing search points from the population, taking their vector difference, scaling this by a constant F, and then adding this to a third search point, again sampled randomly from the

population. Following mutation, DE's crossover operator recombines the mutated search point (the *mutant vector*) with another existing search point (the *target vector*), replacing it if the child solution (known as a *trial vector*) is of equal or greater objective value. There are two standard forms of crossover [6]: exponential crossover and binomial crossover, which closely resemble GA two-point crossover and uniform crossover, respectively. The comparisons between target vector and trial vector play the same role as the selection mechanism in a GA or ES. Since DE requires each existing solution to be used once as a target vector, the whole population is replaced in the course of applying crossover.

An advantage of using simplex-like mutations in DE is that the algorithm is largely self-adapting, with moves automatically becoming smaller in each dimension as the population converges. More generally, the authors of the method have claimed that this sort of self-adaptation means that the size and direction of moves are automatically matched to the search landscape, a phenomenon they term *contour matching*. When compared to CMA-ES, for example, this means that the algorithm has few parameters and is relatively easy to implement.

Performance Comparisons

Fair comparisons of optimization algorithms are inherently challenging [7] and arguably unachievable. Nevertheless, there have been some attempts to understand the comparative performance of different EAs, particularly within the domain of continuous optimization. In particular, a series of workshops held at two of the largest annual EA conferences, CEC and GECCO, have sought to define benchmark suites of real-valued function optimization problems suitable for comparing EAs (and other optimizers) [8–10]. Using these benchmarks, a number of authors have shown their algorithms to perform better than others, including variants of CMA-ES and DE (see [4]). It should be borne in mind that these are not exhaustive studies, either in terms of problems or approaches. The "no free lunch theorem" (NFLT) [11] may also be considered when attempting to generalize these results to a wider spectrum of problems, although, in itself, the NFLT does not apply in the case of comparisons based on the standard suites of test problems (since those suites are not closed under permutation [12]). A nice example of the perils of comparison study in this field is shown by a recent study that showed how quite different conclusions could be drawn from a comparative study by changing minimization problems into maximization problems [13].

Common Variants

The general purpose EAs introduced in the last section are applicable to a wide range of problems. However, over the course of EA history, algorithmic variants have been developed to deal with the characteristics of particular categories of problem. Some

of these categories are quite broad, for example, problems with multiple solutions. Others are more specific, such as discrete optimization problems. In this section, we discuss a number of these EA variants, focusing on those which are commonly used to solve real-world optimization problems.

Alternative Representations

In common with other optimization algorithms, most EAs are designed to work with and optimize vectors (or, equivalently, lists or arrays) of decision variables. Solutions to many kinds of problems can be represented, either directly or indirectly, in this form. However, EAs are not limited to working with vectors, and there are often advantages to working directly with representations that are more natural for the problem domain: for example, matrices [14], trees [15], graphs [16], rule sets, etc. The general approach is the same as for the EAs discussed in the previous section, except that specialized initialization routines and variation operators are used to randomly create, mutate, and recombine instances of the appropriate solution representation. These variants are typically based around GAs or ESs, since these two classes of EA can be readily adapted to use alternative solution representations. Nevertheless, DE [17] and EDA [18] have also been used successfully with other representations.

Genetic programming (GP) [15] is a well-known GA variant in which each candidate solution is a *program*; in early GP this was invariably achieved by encoding programs as tree-structures, in which each "node" in the tree corresponds to a function whose input parameters are the results returned by its child-nodes and which itself returns a result to its parent nodes (if any). GP is still mostly used to optimize computer programs or mathematical expressions, often expressed as tree-structures. However alternative ways to encode programs are now often explored in GP, such as so-called linear GP, in which programs are represented as a sequence of parameterized instructions interacting via registers. A particularly common current use of GP is *symbolic regression*, which involves finding a mathematical expression that fits a particular data set. Unlike standard mathematical approaches to regression, such as curve fitting, GP makes relatively few assumptions about the function that generated the data, allowing a wide exploration of the space of possible solutions. GP is also widely used for solving classification problems. More generally, the GP community is interested in automatic programming, i.e., finding computer programs that solve a particular task, and there are many variants of GP that use particular forms of program representation. See [19] and [20] for overviews.

Some EAs work with two different solution representations, using one of these when creating and manipulating search points, the other when evaluating search points, and a mapping process that converts the former into the latter [21]. Many of these approaches are motivated by biology, and hence this process is known as a *genotype-phenotype* mapping, with the representation used during search termed the *genotype* and the representation used for evaluation termed the

phenotype. This approach can be used when the natural representation for a domain is not well suited to being evolved, i.e., where mutation and recombination do not lead to productive solutions. This approach has also been widely used for generating complex structures, such as large neural networks [22], where a genotype representation can be chosen that compresses repetitive features such as symmetry and modularity. This is arguably an area in which EAs benefit from their relationship to biology, since biology provides a ready source of information on how to represent complex structures in an evolvable way.

Hybridization with Local Search

EAs are often considered to be global search algorithms, since they explore a relatively wide region of the search space and are relatively good at escaping local optima. However, their convergence to optimal solutions can be relatively slow when compared to local search algorithms. For this reason, EAs are often hybridized with local search, using it to locally optimize members of the population at regular intervals, hence speeding up convergence. Although the resulting hybrid algorithms are known by various names, the term *memetic algorithm* [23] (MA) has become popular in recent years. Memetic, in this case, refers to an analogy between the role of local search in these algorithms and the role of within-generation learning in biological systems, though the majority of memetic algorithms have no particular biological justification beyond this. In principle, these algorithms may involve hybridizing an EA with any or with multiple local search algorithms and consequently are very diverse. For a recent review, see [24].

Beyond hastening convergence, MAs are also seen as a means of introducing domain knowledge into EAs. This is done through the use of specialized local search operators that are relevant to a particular domain. For example, this approach underlies the success of MAs in the area of discrete optimization [25]. Related to the idea of problem specialization in memetic algorithms is the concept of hyper-heuristics in EAs, which has developed some traction in recent years [26]. Generally speaking, hyper-heuristics are applicable to domains in which a variety of so-called low-level heuristics exist (or can be invented) to build quick, good solutions. In the job shop scheduling problem, for example, "shortest-process-time" and "earliest-available-machine" are two examples of low-level "dispatch" heuristics that, when iterated, can build a single solution quickly. Hyper-heuristics are essentially mechanisms used to explore *combinations* of such lower-level heuristic strategies. The term hyper-heuristics is also used to describe the cases in which an EA (often GP) both creates anew and combines such low-level heuristics. In a nutshell, the broad idea of hyper-heuristics is to search a space of algorithms that can solve a class of problems, rather than search the space of solutions directly for a single problem instance.

Multimodal Optimization

An advantage of maintaining a population of search points is that EAs can be readily applied to multimodal optimization problems in which there is more than one solution of interest. However, effective multimodal optimization generally requires some modification to the EA's underlying behavior, since, although EAs explore diverse areas of the search space, they eventually converge to fairly small areas. This behavior can be mitigated, to an extent, by varying the global selection pressure used when choosing parents; for example, in the case of tournament selection, the tournament size can be made small, increasing the likelihood that less fit members of the population will contribute to the next generation of search points. While this increases exploration, it decreases exploitation: meaning that multiple solutions may be found, but they are less likely to be optimal. Since EAs are stochastic, and there is the potential for them to converge on different optima during different runs, another simple approach to finding multiple solutions is to run an EA multiple times. However, there is no guarantee that all optima will be explored, and algorithmic biases (such as the manner in which the initial population is generated) may favor some solutions over others.

A more effective approach is to use some kind of *niching* technique [27]. These aim to preserve global diversity in the population, but without lowering local selective pressure. Niching approaches are motivated by the biological concept of evolutionary niches, in which species compete within a niche but not between niches. In optimization terms, a niche is a local region within the search space that contains a solution of interest, and the aim is for the population to be distributed across all the relevant niches. Niching has been studied for some time in GAs, and techniques include crowding [28], fitness sharing [29], spatial segregation [30], and clustering [14]. For comparative studies, see [6] and [8]. A simple but effective example of niching is probabilistic crowding [28]. This works at the operator level and always replaces parent solutions with their children, meaning that search points are usually replaced with nearby search points and the population remains spread across the search space. Similar techniques have also been developed for use in DE. Niching is less commonly used in ESs, in part due to their use of smaller populations, though examples do exist [31]. It is also common to use multi-objective evolutionary algorithms (see below) to solve multimodal problems, since these algorithms often have effective mechanisms for preserving population diversity.

Multi-objective Optimization

Multi-objective EAs, or MOEAs, are used to solve problems which have multiple and often conflicting objectives. A central concept for MOEAs, and multi-objective optimization in general, is that of a non-dominated solution. This is a solution

which is no worse than any of the other solutions within the population when all objectives are taken into account, and the aim of an MOEA is to build and maintain a population of non-dominated solutions that cover all trade-offs between the objectives. This is known as the Pareto optimal front Pareto optimal front. Exactly how this is achieved varies between MOEAs. However, a well-known example is NSGA-II (non-dominating sorting genetic algorithm) [32]. Prior to selection, NSGA-II ranks all solutions in terms of dominance: those which are non-dominated are assigned rank 1, those which are only dominated by rank 1 solutions are assigned rank 2, etc. The population is then ordered by rank, and by a measure of crowding distance within ranks, and the first half of the ordered population is copied directly into the next generation. The remainder of the population is then filled by breeding, with parents selected from the higher ranks. Hence, non-dominated solutions are preserved between generations, and new solutions are explored via interbreeding, resulting in a diverse set of non-dominated solutions that approximate the Pareto optimal front.

The core challenge faced by multi-objective optimization (and absent from single-objective optimization) is how to rank candidate solutions in a way that leads to effective selection pressure, especially when the entire population (or most of it) may be non-dominated. Another way in which multi-objective optimization differs from single-objective optimization is in the nature of the "best-so-far solution." In single-objective optimization, the "best-so-far" solution is trivial to define and to keep track of; in multi-objective optimization, the situation is vastly different: the solution is, technically, the entire Pareto front, which is usually a set of solutions, whose cardinality may vary from one to the entire search space. For MOEAs, this leads to certain technical issues which are invariably addressed by maintaining an *archive* of non-dominated solutions; this archive simply keeps track of the "best-so-far" approximation to the Pareto front but is also often used as a reservoir for selection of parents. Approaches to the main challenge—how to apply effective selection pressure among the current population—are far more varied. While the approach taken by NSGA-II, as detailed above, is a common and quite successful one, many other styles of MOEA exist, which take different approaches to this central question. In PAES [33], for example, there is only a single "current" population member. Selection is consequently simplified; however, the challenge shifts to the question of whether or not to update the current solution with a newly generated one when the two are non-dominated; PAES makes this decision with the aid of its archive, preferring to explore new areas of the search space than to stay close to solutions already in the archive. Meanwhile, a different breed of MOEAs in this respect is represented by MOEA/D [34]; bypassing the need to distinguish between non-dominated solutions for selection purposes, MOEA/D "decomposes" a multi-objective problem into many single-objective simplifications of it, each involving a different weighting of the objectives. MOEA/D conducts these single-objective searches in parallel (typically using a local search mechanism) and organizes occasional communication between them, as well as bookkeeping activities that build and maintain the archive. Effectively, each of MOEA/D's single-objective searches explores a different area of the Pareto front. There are many other approaches, and MOEAs are becoming increasingly used as it becomes recognized

that real-world problems are almost invariably multi-objective in nature. Further discussion of the latter point, as well as a first introduction to MOEAs, may be found in [35], while an example of a fairly recent review of MOEAs may be found in [36].

Dynamic Optimization

So far, our discussion of optimization has only considered problems in which the search space remains fixed. In many real-world problems, this is not the case, and various EA approaches are used to handle these situations. Dynamic optimization is an area in which EAs might be expected to perform relatively well, since the natural diversity present in their populations provides a recovery mechanism that can respond to slow changes in the optimization landscape. This is especially the case when diversity maintenance techniques are implemented, such as those already discussed in the sections on multimodal and multi-objective optimization. However, this diversity may be insufficient when the optimization targets change rapidly or abruptly. A simple solution in this situation is to inject extra diversity into the population when a change is detected, for instance, by adapting the variation operators so that larger moves are made. Detection of change can be done by reevaluating a proportion of the population, looking for significant changes in fitness.

A variety of more elaborate approaches have been developed to handle dynamic optimization in EAs. An approach inspired by biological systems is to use redundancy in the encoding of a solution. Rather than replacing components of a solution when variation operators are applied, this allows old components to become recessive, i.e., to remain present within the solution but not be expressed during evaluation. Later in the evolutionary process, these components can become reactivated, in effect providing a mechanism to backtrack to previous search points. This is particularly useful when changes in the search space are cyclic. A well-known example is the use of *multiploidy* in GAs [37], where each solution has multiple chromosomes (only one of which is dominant) and variation operators are able to move information between chromosomes. Other approaches to handling dynamic search spaces include predicting change and using multiple populations; see [38] for a recent review.

Coevolving Solutions

Coevolutionary algorithms [39] are motivated by the interactions that occur between species during the course of biological evolution and the roles these interactions are thought to play in the evolution of complex organisms. Most coevolutionary algorithms use multiple populations, one per *species*. Coevolutionary relationships in biology can be cooperative or competitive. The latter class are particularly well known and are encapsulated in the idea of predator-prey patterns of evolution, where an arms race between two species can lead to the rapid emergence of complex

adaptations. Similar ideas have been explored in EAs, the classic example being the coevolution of sorting networks and sorting algorithms [40]: the discovery of harder problems (the sorting networks in the first population) leads to selective pressure to discover better solutions (the sorting algorithms in the second population), which leads to selective pressure to discover harder problems and so on. Competitive coevolution can be used to solve hard problems and is also useful in circumstances where a fitness function cannot be defined. However, competitive coevolution is known to be difficult to control, and pathological situations can lead to ineffective search. See [39] for a review.

Cooperative coevolution, by comparison, is seen as a useful mechanism for breaking down large problems into more tractable chunks [41]. The idea is that a solution to a problem is divided into sub-components. Each of these sub-components is then evolved in a separate population, with its objective value dependent upon how compatible it is with sub-components being evolved in other populations. Following this, the coadapted sub-components are then assembled to form a complete solution. In [42], for example, the authors describe how a cooperative coevolutionary variant of DE can be used to solve numerical optimization problems with up to 1000 variables. Cooperative coevolution can also take place within a single population. An example of this is a Michigan-style learning classifier system (LCS), a form of EA that coevolves a population of rules that can collectively solve difficult problems in classification and machine learning [43].

Applying Evolutionary Algorithms

Choosing a Methodology

It can be difficult to choose which EA to use for a particular task, since there are many different EAs in common use and relatively little in the way of objective comparative guidance. In practice, it may be necessary to try out different EAs to find out which is the best match to a problem, especially when the problem is poorly understood. However, given whatever is known about the problem at hand, it might be possible to leverage existing understanding of the strengths and weaknesses of particular algorithm frameworks. Some guidance on this matter is available in studies of comparative performance mentioned at the end of section "Introduction". It is hoped that section "Principal Algorithms" also provides useful pointers if the problem is multimodal, multi-objective, dynamic, or unusually large and complex. It is also notable that multi-objective and memetic algorithms, in particular, have become popular for solving difficult real-world problems.

Choosing Parameters

EAs invariably have many parameters, and once an algorithm has been selected, it is normal to carry out parameter tuning in order to obtain a better fit between the algorithm and the problem. It can be challenging to obtain optimal parameter

settings, since parameters are typically both numerous and not independent of one another. DE, for instance, is notable for having relatively few parameters, and this is often portrayed as a strength of the method. However, EAs are relatively forgiving, and good performance is likely to be possible with nonoptimal parameter settings. Nevertheless, guidance is available for choosing the settings of certain parameters [44], and a number of techniques have been developed for automating the choice of parameter settings [45].

Software Tools

Tools support is an important issue for many practitioners, and a particular EA methodology is likely to be more appealing if it has a mature supported implementation. Tools support is also important if it is necessary to handcraft a new algorithm to solve a particular problem, and in this situation the language used by the tool may also be a significant concern. Table 1 summarizes the features of some of the better known EA tools. GAs are widely supported by all of these. ES support is also widely available, though EvA2 stands out in this regard, with implementations of a wide range of ES variants. DE and EDAs are more recent algorithms, and this is reflected by fewer mature tools. However, EvA2 is again notable for having an implementation of BOA and other EDAs. GP support is offered by a number of these tools, with ECJ implementing a particularly wide range of GP variants. Most also offer support for multimodal and multi-objective approaches, though MOEA Framework stands out for the latter. All of these tools allow custom code to be written. Most use Java or C++, though DEAP is notable as a mature Python implementation and HeuristicLab is available for C# users.

Case Studies

Evolutionary Algorithms at Large

Now more than half a century since the first appearance of "EA"-style algorithms in the research literature (widely considered to be [46]), EAs have penetrated almost every area of science and industry and are regularly used in solving an immense range of optimization problems.

In terms of broad classes of problem, EAs have enabled practitioners and researchers to make particular headway in *combinatorial optimization* which, unlike *numerical optimization*, for example, was hitherto poorly served by classical algorithms. In combinatorial optimization, the task is typically to find an ideal permutation (or otherwise constrained arrangement) of a set of entities—such as a sequence of customer visits for a delivery vehicle or a sequence of production tasks for each of a set of machines in a factory. Before EAs, the primary approach used to solve such problems was integer programming and constraint programming (and variations thereon), which tend to require a complex (and often tortuous) problem reformulation step. EAs, however, provide a far more accessible and

Table 1 Open-source EA frameworks

Tool	Language	Summary
DEAP https://code.google.com/p/deap/	Python	Distributed Evolutionary Algorithms in Python offers good support for GAs and ESs. Also implements GP and MOEAs
ECJ http://cs.gmu.edu/~eclab/projects/ecj/	Java	Continuously developed since 1998, Evolutionary Computation in Java has particular strength in GP but also implements GAs, DE, and MOEAs
EO http://eodev.sourceforge.net	C++	Evolving Objects is an established general-purpose EA library with implementations of GAs, GP, ESs, and EDAs
EvA2 http://www.ra.cs.uni-tuebingen.de/software/JavaEvA/	Java	EvA2 is a general-purpose EA framework but has particular strengths in ESs and EDAs, including BOA
HeuristicLab http://dev.heuristiclab.com/	C#	HeuristicLab implements many of the common EA varieties and also has support for other population-based and local search metaheuristics
MOEA framework http://www.moeaframework.org/	Java	A relatively new EA framework with considerable strength in MOEAs and multi-objective variants of DE and GP
OpenBEAGLE https://code.google.com/p/beagle/	C++	A long established EA framework with good support for GAs and ESs. Also implements GP and NSGA-II

flexible approach to addressing such problems and are now commonly used in practice for combinatorial tasks such as vehicle routing, job shop scheduling, and facility allocation [47].

Meanwhile, beyond combinatorial optimization, the inherent flexibility of EAs has led to their use, to at least some extent, in every conceivable area of science, enterprise, and industry in which one or more important tasks can be formulated in terms of optimization and/or design. To name just a few of the areas in which EAs have had much impact, we can list aeronautical and automotive design [48], bioinformatics and biotechnology [49], chemical engineering [50], creative pursuits [51], finance and investment [52], manufacturing [53], and structural design [54]. To select a small number of case studies could not serve to characterize the true diversity of applied EAs. We therefore duck that challenge and take the liberty of concluding this chapter by providing two case studies from the authors' recent work, illustrating how some EA approaches are being applied to diverse and challenging optimization problems in just one corner of science.

Using Niching and Coevolution to Understand Gene Regulation

Understanding gene expression is fundamental to understanding living processes. The expression of each gene in an organism is determined by the binding of special proteins, called transcription factors, within a region of DNA upstream of its coding region. In higher organisms, such as humans, this regulatory region

typically contains around 5–10 transcription factor binding sites. Characterizing these bindings sites, both individually and in combination, is a fundamental part of reconstructing (and ultimately controlling) the genetic networks that underlie biological function.

Identifying binding sites is often reduced to an optimization problem that involves constructing a matrix model of the occurrence of each DNA base at each position within a short region of DNA. Candidate solutions to this problem can be evaluated by scanning them along the regulatory regions of groups of genes which are known to be expressed at a certain time or within a certain cell type, looking for matches to patterns embedded in the sequences. In most cases, this is a multimodal problem, since multiple binding sites are likely to be relevant to a particular regulatory context, and it is important to be able to identify these different optima. However, these binding sites can vary quite considerably in their degree of conservation, meaning that the objective values of different optima also vary considerably.

Identifying and preserving different modes within a multimodal search space is a challenging problem, especially when they have different relative finesses. In section "Common Variants", we discussed the idea of niching within the populations of EAs as a means of addressing multimodal problems. In [14] we used an EA furnished with a particular form of niching, termed population clustering, that uses a clustering algorithm to identify and preserve the different modes present within an evolving population of solutions. This allowed a number of different binding sites to be characterized and preserved during a single run. Compared to other forms of niching, it also had the benefit of explicitly identifying these different groups of solutions, allowing the progress of search to be visualized and for clustering parameters to be dynamically modified by an expert user. Even in the absence of dynamic modification, however, this was effective at identifying the clusters of binding sites within comparatively long regions of DNA.

Identifying binding sites is only one part of the problem. Another important aim is to understand the interactions between different binding sites during gene regulation. In [55], we used coevolution to explore solutions to this problem. This involved coevolving two populations, the first containing matrix models of binding sites and the second containing Boolean expressions describing their co-occurrence within binding regions. Members of the binding site population were used as leaves within the Boolean expressions. In essence, the problem of identifying binding sites and their co-expression was decomposed into two problems which were then solved in parallel, using coevolution to provide feedback between the populations. In comparison to a more traditional approach, which would involve sequentially learning binding sites and then learning their interactions, this allows search to be directed toward solutions that interact well with other solutions during the course of search. Such solutions, in turn, are more likely to be meaningful. This approach proved effective for reverse engineering the regulatory rules underlying differential gene expression within tissues. More surprisingly, it also provided a mechanism for solving harder instances of the single binding site optimization problem, with coevolution provided a means of implicitly decomposing the matrices associated with these harder problems.

Evolving Classifiers for Parkinson's Disease Diagnosis

This second case study concerns a problem in which the optimal representation for solutions is not clear in advance, requiring experimentation with different kinds of solution representation. As discussed earlier, EAs are entirely flexible in this regard. The problem involves building diagnostic classifiers for Parkinson's disease. These are required to reach their decision based on time series movement data recorded while patients and age-matched control were undergoing clinical assessments of motor function. Motor aspects of Parkinson's are incompletely understood, making it unclear what kind of features of the data are important.

To address this, we used EAs to explore two different relatively unconstrained classifier models. Initially we considered a GP-based approach, using it to discover mathematical expressions that describe overrepresented patterns of movement embedded in short segments of the time series data, i.e., a form of symbolic regression [56]. An advantage of this approach is that the resulting expressions were relatively interpretable, allowing us to gain insight into the basis of classifications and then pass this information on to our clinical partners. In particular, analysis of the evolved expressions identified specific aspects of the closing phase of a "finger tap" movement as highly discriminatory of Parkinson's disease patients versus control. These factors alone were indeed more discriminatory than standard metrics; however, overall classification performance was not quite as good as that of trained clinicians.

We then considered a more unusual method of representing programs, artificial biochemical networks [57]. These are abstract executable models of the networks of biochemical interactions that underlie the function of biological cells. In a nutshell, they attempt to capture the representation which biological evolution has selected to optimize complex behaviors, with the hypothesis that this makes them particularly suitable for use with EAs. Meanwhile, the use of an EA to search through the space of possible artificial biochemical network classifiers represents, in itself, a major and commonly understood strength of EAs: they can be tailored and deployed effectively with relative ease despite the complexity and diversity of the structure they are being used to evolve. By using this approach, we were now able to find classifiers that produced comparable performance to that of trained clinicians [58]; with accuracy at around 90% overall, accuracy was comparable to the diagnostic accuracies found in clinical diagnosis, and significantly higher than those found in primary and non-expert secondary care.

Conclusion

In this chapter we have provided a broad introduction to and overview of evolutionary algorithms, and the many varieties of them that appear in modern research and practice. We have seen that there are a handful of key EA 'families', such as 'genetic algorithms' and 'differential evolution'; meanwhile, to some extent cutting across

the principal types of EAs, there are several algorithm features and variants (such as co-evolution, or hybridisation with local search) that are often 'grafted' into an EA, in order to boost performance on a particular class of problems (or perhaps just for research purposes). Towards the end, we considered the real-world application of EAs, reporting that they are generally highly successful, and are growing to be common tools used for optimisation tasks in science and industry. However, for someone new to EAs, an early question might well be: "There are so many types and variants of EAs – which should I use?" In this chapter, we have effectively promised that EAs are likely to be a successful approach to any given optimization task—particularly if that task is not well served by other available schemes or heuristics. However, we have not necessarily made it easy for a novice to deliver on that promise. A common theme has been the very wide variety of EA designs that have been developed, and this great variety can be a barrier for those new to the field, who aim to understand the key aspects of EAs and how best to apply them to any given task. In closing, we attempt to provide some support for the novice via the following perspective: EAs should not be seen as a collection of algorithms; instead, they are far more fruitfully viewed as an approach to the engineering of problem-specific (or problem-class specific) optimization algorithms. The key lesson for practitioners, from half a century of research and practice in EAs, is, broadly speaking, that concepts from evolution (population, selection, variation) can be very powerful tools in optimization; but to achieve ideal performance on a given task, one must be pragmatic, and often creative, about the details.

Abstract

The optimization of hyperparameters and the learning process associated with supervised machine learning models, including artificial neural networks and deep learning architectures, are viewed as among the most formidable challenges in machine learning. Several prior investigations have applied gradient-based backpropagation approaches in the training of deep learning architectures. However, gradient-based methods exhibit notable disadvantages, such as the tendency to become trapped in local minima when dealing with multi-objective cost functions, extensive calculations of gradient information with numerous iterations, and requiring the cost functions to maintain continuity. Given that the training process for a diverse array of supervised machine learning techniques is identified as an *NP-hard optimization* problem, there has been a considerable surge in the adoption of heuristic or metaheuristic algorithms aimed at optimizing the structures and parameters of these approaches. In the context of optimization, metaheuristic optimizers are designed to identify the optimal estimations for different components of supervised machine learning (e.g., weights, hyperparameters, the number of layers or neurons, and the learning rate in case of deep learning models, or hyperparameters for Gaussian processes in Gaussian process regression (GPR), etc.). Many researchers are inclined to extend innovative hybrid algorithms by integrating metaheuristic algorithms to optimize the hyperparameters of supervised machine learning models. The evolution of hybrid metaheuristics aids in boosting algorithm performance and is proficient in addressing complex optimization problems. In general, the optimal functioning of the metaheuristics ought to attain a favorable compromise between the exploration and exploitation characteristics. This chapter has comprehensively reviewed two recent advancements in the application of metaheuristic optimizers in supervised machine learning approaches, which are distinctly diverse in their characteristics. To begin with, this chapter offers a detailed review of a modern hybrid intrusion detection technique that employs a black widow-optimized convolutional long short-term memory neural network. Following this, the authors provide an in-depth analysis of a recent investigation focused on the metaheuristic optimization of hyperparameters for the GPR model associated with FEREBUS, a GPR engine embedded within the extensive framework of FFLUX, which is recognized as an innovative machine-learned force field. The integration of metaheuristics with supervised machine learning models is projected to expedite the training process in the forthcoming years. However, the concept of evolutionary hybrid architecture remains underutilized in the existing literature, with relevant publications being relatively uncommon.

Introduction

Introduction to Supervised Machine Learning

In the era of big data, sectors such as marketing, finance, health care, and telecommunications are persistently seeking innovative methods to derive valuable insights and facilitate informed decision-making. In this respect, a prominent technique that has garnered considerable attention in recent years is *data mining* [1]. Data mining is the *process* of extracting and discovering interesting patterns and knowledge from *large*-scale data collections. As a domain that prioritizes practical applications, data mining has assimilated a variety of methods from several other domains, including statistics, machine learning, pattern recognition, database and data warehousing systems, high-performance computing, etc. [1]. The interdisciplinary aspects of research and development in data mining play a crucial role in the overall success and diverse applications of data mining.

Therefore, *machine learning* represents one of the key disciplines that significantly impacts the advancement of data mining strategies. Despite their inherent differences, both these fields are closely associated and yield synergistic benefits when combined. Machine learning (ML) is considered a subdomain of *artificial intelligence* (AI) that enables computers to acquire knowledge and improve their performance autonomously, without the need for explicit programming [1]. One of the central areas of research is the ability of computer programs to learn independently to recognize complex patterns and to derive intelligent decisions from the data they process. For example, a standard ML problem within the field of medical imaging is to design a computer program that learns from a labeled dataset of medical images, where each image is accompanied by annotations indicating the relevant diagnosis or condition, enabling the algorithm to classify new *unseen* images based on the patterns it recognizes in the labeled examples. This technology is typically employed in tasks such as tumor detection, identification of abnormalities in imaging scans, or diagnosis of illnesses through medical imaging modalities like X-ray, magnetic resonance imaging (MRI), or computed tomography (CT) scan.

The name itself suggests that it endows the computer with a characteristic akin to that of humans: the capacity to learn. ML is currently being employed in a variety of applications, likely in more areas than one might anticipate. There are several varieties of ML, each with unique characteristics and applications. The following are a few of the primary categories of ML algorithms [1–4]: (i) supervised ML, (ii) unsupervised ML, (iii) semi-supervised ML, and (iv) reinforcement learning. The position of different types of ML techniques in the taxonomy of ML is depicted in Fig. 1.

Supervised ML is often more accurate than other ML methods, because it uses labeled training datasets. This provides the model with a foundational comprehension of what the appropriate output ought to be. These datasets are intended to train or "supervise" algorithms in accurately classifying data or predicting outcomes.

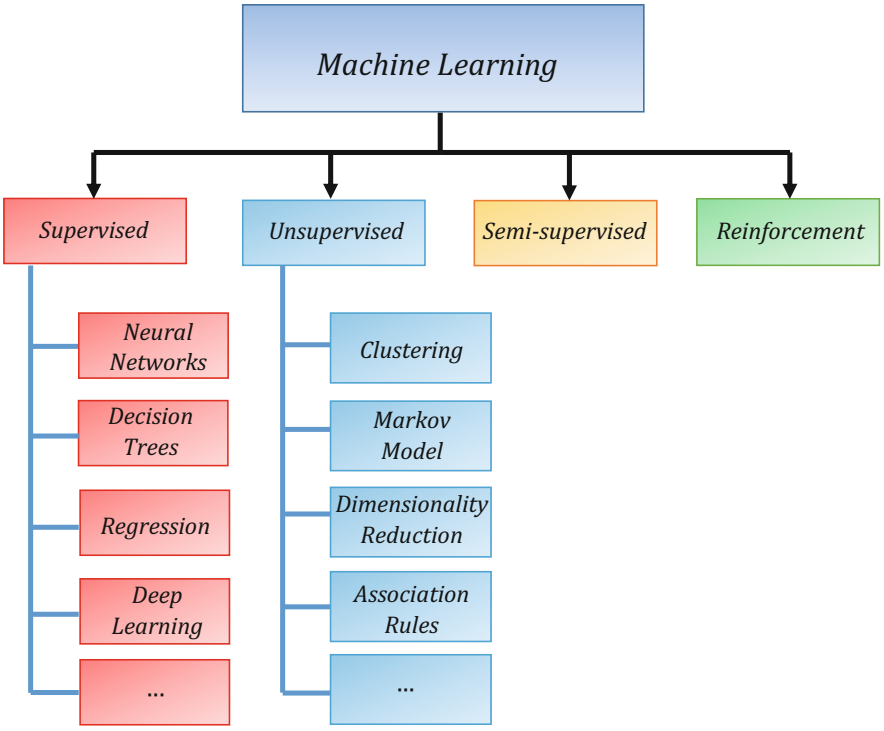

Fig. 1 Taxonomy of ML approaches

Through the application of labeled inputs and outputs, the model is capable of measuring its accuracy and evolving its learning process over time. In the context of data mining, supervised ML can be categorized into two distinct types of problems: *classification* and regression.

- *Classification* problems employ algorithms to effectively categorize test data into distinct groups, such as differentiating between apples and oranges. Or, in practical applications, supervised ML algorithms are employed to sort spam emails into a designated folder, thereby isolating them from your inbox. Commonly employed classification algorithms include linear classifiers, decision trees, support vector machines, random forest, etc.
- *Regression* is classified as another type of supervised ML approach that applies algorithms to elucidate the relationship between dependent and independent variables. Regression models serve as valuable tools for forecasting numerical outcomes by analyzing various data points, including projections of sales revenue for a specific enterprise. Linear regression, logistic regression, polynomial regression, GPR [5, 6], etc. are examples of popular regression algorithms.

Learning Aspects of the Supervised Methods and the Existing Challenges

The significance of employing supervised ML techniques across diverse applications underscores the necessity of recognizing their limitations and enhancing these algorithms, which remains a pressing concern in the field of ML. The process of learning different supervised ML techniques, including artificial neural networks (ANNs), deep learning (DL) architectures, and GPR, is viewed as one of the most formidable challenges in the field of ML. Throughout the previous two decades, one of the key areas of research has been the optimization of the structure and parameters associated with different supervised ML approaches. For example, optimization of ANNs and DL architectures, two of the most popular classes of supervised ML algorithms, is frequently approached from various perspectives, including the optimization of weights, biases, hyperparameters, activation nodes, network architecture, learning algorithms, learning parameters, learning environment, among others [7].

A variety of earlier research efforts have utilized gradient-based methods in the training of architectures. Nevertheless, the constraints associated with gradient-based algorithms have highlighted the importance of utilizing optimization algorithms. For instance, within the framework of the backpropagation (BP) learning algorithm, the primary objective of learning is to optimize the weights and thresholds of the network in order to reduce the cost function to its minimum. In gradient-based learning algorithms, it is essential for the cost function to be differentiable in order to utilize backpropagation. This aspect also highlights a significant drawback of gradient-based learning algorithms, because, in various cases, the activation and cost functions are non-derivable. In these algorithms, sigmoid activation functions are commonly employed. In the literature, a number of gradient-based techniques, including Levenberg Marquardt (LM) and backpropagation (BP) methods, have been established to facilitate the training of neural network-based systems. However, gradient-based methods exhibit several critical shortcomings as follows [7]:

- In the case of multi-objective cost functions, there is a possibility of being stuck at local minima.
- The time required to execute these algorithms is considerably costly, largely because of the extensive calculations of gradient information that involve thousands of iterations.
- In scenarios where multiple local minima exist within the problem search space, the learning algorithm attains an error of 0 at the first local minimum encountered. Consequently, the algorithm converges at this initial local minimum, preventing it from reaching the optimal solution.
- Gradient-based learning algorithms necessitate that the cost function be differentiable. Therefore, continuity of the cost function is a prerequisite. This characteristic highlights a significant drawback of gradient-based learning algorithms, particularly since, in various situations, the activation function may not be differentiable.

Initially, the Conjugate Gradient Algorithm, Stochastic Gradient Descent (SGD), Newton's Method, and Adaptive Moment Estimation (Adam) were introduced to enhance gradient-based learning algorithms, which exhibit superior generalizability and convergence compared to the BP algorithm. Nevertheless, the neural networks and DL architectures associated with these methods are often regarded as "black boxes," due to the fact that human intuition cannot interpret them [7].

Metaheuristic Optimization: A Potential Solution to the Local Minima Problem in Supervised ML

Given that the training of a broad spectrum of supervised ML techniques is classified as an *NP-hard optimization problem*, there has been a notable rise in the utilization of heuristic or metaheuristic algorithms for the optimization of the structures and parameters of those methods. As an optimization problem, metaheuristic optimizers aim to derive the optimal estimations for various supervised ML components (e.g., Gaussian process (GP) hyperparameters for GPR, or in case of DL models, weights, hyperparameters, the number of layers or neurons, the learning rate, etc.) [7]. The necessity for multi-objective metaheuristics has grown due to the existence of multiple objectives in the optimization of ANNs and DL models, such as minimizing errors, improving network generalization, and simplifying models. Recent literature indicates that the application of metaheuristic search (MHS) algorithms in training DL models enhances the overall learning process [7]. For example, evolutionary and swarm intelligence algorithms have contributed to the development of a generalized and optimal network [8–10]. This improves the model's accuracy and shortens the time required for its execution. The application of MHS algorithms to enhance supervised techniques, particularly in the realm of neural networks and DL architectures, remains a complex endeavor, necessitating further investigation.

What Are Metaheuristics?

Heuristic algorithm is a term that describes the implementation of systematic approaches which often compromise solution quality in favor of enhanced processing speed [11]. Many heuristics originate from straightforward, intuitive concepts aimed at problem-solving; however, they do not guarantee the attainment of an optimal solution. In certain cases, heuristics can yield solutions that are provably optimal. Heuristics can be described as a framework consisting of a series of permissible operations or transformations that convert an existing solution, labeled Q, into a new solution, Q*, which is usually an improved version. The domain encompassing all feasible solutions for a given problem is termed the search space, S, whereas the space of solutions that can be reached by applying a single transformation to an existing solution is known as the neighborhood space, N.

On the other hand, the term *metaheuristic* refers to the evolution of heuristic strategies that surpass local search (LS) methods in the pursuit of a global optimum [12, 13]. This concept is frequently drawn from analogies with natural processes, including both physical and biological phenomena. A metaheuristic is an advanced strategy or heuristic designed to identify, create, or choose a heuristic that can yield a sufficiently good solution to an optimization problem. These newer techniques were introduced aim to resolve challenges such as nonlinearity, multi-objective scenarios, uncertainty, and various other issues. Examples of metaheuristics include simulated annealing, tabu search, particle swarm optimization, genetic algorithms, artificial bee colony, etc. [12].

Metaheuristic optimization strategies can be classified into two categories—*population-based algorithms* and *trajectory-based algorithms*—based on the number of tentative solutions [12]. Trajectory-based algorithms, often referred to as single-solution metaheuristics, focus on a singular solution which they aim to enhance through iterative refinement employing a diverse array of stochastic operators. This pertains to the simulated annealing algorithm. The fundamental concept of simulated annealing involves creating a solution within the vicinity of the existing solution by making suitable moves in the search space. Subsequently, an acceptance probability is calculated to ascertain whether the new solution should be accepted or discarded. On the other hand, a set of agents is used by population-based MHS algorithms (e.g., particle swarm optimization, gravitational search algorithm, etc.) to examine the search space. The location of each agent is represented as a vector that matches the dimensions of the search space, thereby forming a potential solution. Population-based MHS algorithms facilitate the navigation of agents within the search space by enabling them to exchange information regarding their current locations and/or their best positions encountered thus far, utilizing well-structured communication rules.

The ability of population-based metaheuristic optimizers to deal with a particular optimization problem might differ greatly between techniques, since they use a wide variety of search strategies to update agents' positions. Generally speaking, metaheuristic-based optimization algorithms need to exhibit a decent balance between search space *exploration* and *exploitation* in order to produce the desired performance on a particular objective function [14]. It is commonly acknowledged that the optimizers that prioritize exploration (diversification) overexploitation (intensification) are more likely to explore search space regions where better solutions are located, leading to an overall improvement in performance. It has been demonstrated, meanwhile, that algorithms with comparable exploration-exploitation patterns can nevertheless behave completely differently. This finding implies that the specific ability of metaheuristic optimizers to produce promising solutions is just as important to their success as the trade-off between exploration and exploitation. The complexity of the search space affects an algorithm's ability to produce promising results, and we must remember that no MHS algorithm is intrinsically (by design) able to outperform all of its equivalents on *every* optimization task.

Therefore, comparing the effectiveness of several algorithms seems to be the most trustworthy approach of determining the best search mechanism for each unique optimization problem.

The Remainder of the Chapter

This study discusses two characteristically diverse verticals of application of metaheuristics in the realm of supervised ML in sections "Black Widow-Optimized Convolutional Long Short-Term Memory Network for Hybrid Intrusion Detection" and "Metaheuristic Optimization of Hyperparameters of GPR Model: Application to FEREBUS," respectively. In section "Black Widow-Optimized Convolutional Long Short-Term Memory Network for Hybrid Intrusion Detection," a recent approach to hybrid intrusion detection, which incorporates a black widow-optimized convolutional long short-term memory neural network, is reviewed in detail. Section "Metaheuristic Optimization of Hyperparameters of GPR Model: Application to FEREBUS" conducts a comprehensive review of a recent study that examines the metaheuristic optimization of hyperparameters for the GPR model linked to FEREBUS, a GPR engine integrated within the extensive framework of FFLUX, which is an innovative machine-learned force field. Section "Conclusion" concludes the study.

Black Widow-Optimized Convolutional Long Short-Term Memory Network for Hybrid Intrusion Detection

Background and Overview

Network traffic data has increased dramatically in the contemporary era due to developments in communication protocols and information technologies. Since practically every computer has an Internet connection, internet applications rely on different networks to provide services like social media, email, and surfing. But it has also left a security gap, opening the door for severe cyber threats including *network intrusions*. Unauthorized network traffic activities that are malevolent and damaging to computer networks are known as network intrusions. The results of these malicious invasions make a system susceptible to numerous attacks. It can cause system degradation or termination through identity theft attacks, *Denial of Service* (DoS) attacks, spam emails, or phishing attempts to gain sensitive user data by impersonating a trustworthy website. Additionally, it compromises user privacy in a shared environment [15] and raises security concerns with cloud storage. The intruders may initiate these attacks by executing a malware or malicious code to infect a host computer. This malware gives intruders the ability to take over infected hosts in order to obtain information or interfere with network services for illicit purposes.

Malevolent cyberattacks lead to serious security issues that need for an advanced, dependable, and adaptable *intrusion detection system* (IDS) [16]. An intelligent intrusion detection mechanism proactively identifies and classifies harmful activities or intrusions at both the system and host levels. IDS models are divided into *two* categories depending on the intrusion behaviors and architectures of the IDSs: *host-based IDS* (HIDS) and *network-based IDS* (NIDS). The HIDS models identify attacks using log files on the local host machines, whereas the NIDS do so based on network behavior [17]. To fully protect a network system and offer greater reliability and flexibility, both HIDS and NIDS are necessary. Therefore, a hybrid strategy that combines both HIDS and NIDS is preferred by the majority of organizations.

According to recent research, ML algorithms have been used in many studies to enhance intrusion detection in place of traditional technologies. The majority of ML algorithms, however, are not capable of analyzing all widely used benchmark datasets that are accessible in the public domain. The ML methods fail to adapt to modern datasets that include new attack classes having features incompatible with ML. Additionally, depending on the size of the dataset and optimization parameters, they offer sluggish training process, as well as high false-positive rates. To identify intrusions as fast as possible, computing performance must be enhanced as intrusion data quantity increases. Together with the ML classifiers for choosing the optimal features, statistical techniques and metaheuristic-based optimizers have been used to shorten the computation time. However, the limited learning and classification capabilities of the ML algorithms prevent them from identifying attacks, especially in case of varying feature dimensions or complex new feature characteristics of attacks. Therefore, intelligent assessment and the forecasting principles of high-dimensional learning with massive amounts of data are not compatible with ML algorithms.

The sluggish training problem is resolved by a class of ML techniques called DL. The advancement of DL algorithms has improved computing and processing power across a range of applications in different research fields. Convolutional neural networks (CNN), recurrent neural networks (RNN), long short-term memory (LSTM) neural networks, and other efficient DL techniques have served as the foundation for recent IDS models [18]. DL algorithms are more efficient and faster compared to ML for detecting intrusions in vast, diverse, and high-dimensional network traffic. Additionally, it makes it possible to train nonlinear models on big datasets in a scalable manner and accurately identify novel attack types. However, there are certain restrictions. Both the temporal and spatial features cannot be learnt simultaneously by CNN, RNN, LSTM, etc. CNN learns spatial features very well, whereas RNN and LSTM effectively deal with temporal information. While CNN has higher accuracy and a shorter training period, LSTM takes longer to train but produces fewer false positives than CNN. LSTM and CNN are both needed for developing a hybrid IDS model in order to learn all features and enhance overall performance. However, it will lead to increased processing and architectural complexity. Hybrid models complicate the integration of multiple classifiers by increasing computation time for each method. Additionally, the class imbalance

issue is more prevalent in the majority of publicly accessible IDS datasets and cannot be successfully addressed by CNN or LSTM alone. Modern solutions cannot keep up with the high-speed network traffic that is growing at an accelerated rate.

These difficulties inspired Kanna and Santhi to combine CNN and LSTM to develop a unified DL model that incorporates the advantages of both models while minimizing the effects of their drawbacks [19]. This fully integrated hybrid model called Conv-LSTM performed as a single powerful classifier. Its hyperparameters are optimized to cut down on computation time, because parameter tuning can be a useful in resolving this problem. However, rather than tuning the CNN and LSTM parameters separately, the parameters of the combined Conv-LSTM are learned by making use of black widow optimizer (BWO) [19], forming a new BWO-Conv-LSTM network-based IDS solution that significantly reduces the training time, as well as the computational cost [19]. BWO is chosen over other contemporary optimization methods due to its rapid convergence and ability to find global optimal solutions with minimal iterations. BWO-Conv-LSTM solves the class imbalance problem in network traffic datasets with simple oversampling, whereas the advanced DL classifier overcomes overfitting by utilizing *structural stabilization* strategy, which involves varying the values and number of weights with the BWO algorithm.

Model and Methodology

The IDS model based on BWO-Conv-LSTM aims at addressing the problem of intrusion classification in the big data context. The study [19] used four datasets, NSL-KDD, ISCX-IDS 2012, UNSW-NB15, and CSE-CIC-IDS 2018, which are mostly classified as big data on the basis of their volume aspect. These datasets are difficult to process, because the typical classifier models lack time or space to handle such problems. The processing of these datasets necessitates a massive and growing volume of resources, and additionally, advanced computing facilities and durable power sources are required to support learning and classification. These difficulties are lessened by the BWO-Conv-LSTM network model, which uses the characteristics of LSTM and CNN to extract the spatiotemporal features of network traffic data, resulting in accurate intrusion detection with reduced processing complexity. An overview of the design model for the hybrid IDS model developed in [19] is illustrated in Fig. 2.

The BWO-Conv-LSTM network-based intrusion detection system model consists of *four* major modules [19]:

(i) Oversampling,
(ii) Preprocessing,
(iii) Feature extraction and selection,
(iv) Classification

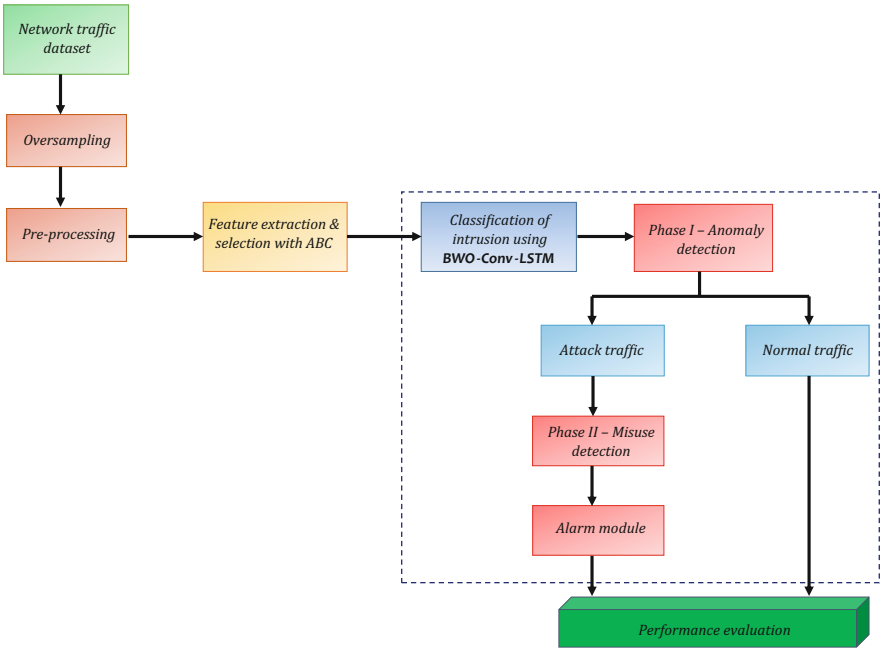

Fig. 2 A comprehensive outline of the hybrid IDS model presented in [19]

(i) **Oversampling**: Inadequate data distribution causes class imbalance problems in the input datasets; one class has the majority of the samples, whereas others have relatively less. Such imbalanced datasets will significantly impair the classifier performance. To address the imbalance issue, the majority of current approaches make use of statistical and ML techniques, such as data augmentation. However, those models solely use data samples from the majority class to fill the minority class samples, handling the minority class minimal. This leads to better data distribution across all minority classes without having regular minority class samples. High-dimensional imbalance problems with the evaluation datasets include potentially noisy, erroneous, and outlying cumulative data in addition to missing features and missing feature values. In order to overcome this problem, *oversampling* is carried out, which entails arbitrary replication of the minority class instances to expand the number of minority class samples. Despite the possibility of overfitting in the classifier, this method often produces no information loss and performs better than the other sampling and augmentation strategies. In order to prevent the potential overfitting problem, the BWO accomplishes the *structural stabilization* by changing the values and number of weights in the convolutional layers of the developed BWO-Conv-LSTM network. Since BWO finds these weights and their values in the best possible way, they can be changed within the optimal range without causing the classifier performance to deteriorate.

(ii) **Preprocessing**: The preprocessing phase carries out the label transformation, redundancy elimination, and data normalization operations following the oversampling procedure. Subsequently, the datasets are divided into 7 : 3 training and testing sets. For rapid evaluation, the training set was used for training, and the testing set was used to conduct the final assessment of the model.
(iii) **Feature Extraction and Selection**: After that, features are extracted from each dataset, and following the feature extraction, the artificial bee colony (ABC) algorithm [20] chooses the optimal feature subsets to enhance the performance of the classifier. Because ABC has proven to be incredibly effective at feature selection in large size datasets, it is used in this investigation.
(iv) **Classification**: The developed BWO-Conv-LSTM model-based classifier is incorporated in the final phase, which is *classification*. There are two components in the BWO-Conv-LSTM classifier: one for feature learning and one for classification. Two layers, namely, the *convolution* and *pooling* layers, make up the feature learner. While they pick up the spatial features, the convolutional layers miss the temporal information. Consequently, recurrent layers of LSTM are added after the CNN layers in order to more robustly capture both spatial and temporal features. The vanishing and exploding gradient problems will be stated properly by this procedure, improving the ability to capture temporal and spatial relationships and learn effectively. The CNN layers in the BWO-Conv-LSTM network handle the input mainly, while the LSTM layers process the output of the CNN layers to generate sequences at each time step. After passing through a fully connected layer, the sequence vector is then input into a Softmax layer to determine the probability distribution across the classes. In particular, this CNN and LSTM integration is carried out with the least amount of architectural complexity.

Optimization of Hyperparameters Using BWO

Using the BWO, the weights and biases are suitably learned, allowing for the optimal hyperparameter values. The life activities of black widow spiders are the source of BWO. It imitates mating behaviors, including procreation (reproduction), cannibalism, and mutation. These spiders reproduce by an unusual mating behavior, in which the females consume the conspecific males, and the young spiders undergo mutations after evading cannibalism by the mothers. The BWO algorithm was developed in light of these behaviors. The BWO begins by initializing the population of spiders. After that, these original spiders are coupled off in an attempt to reproduce a new generation. During mating, the female spiders consume the male. Following mating, the sperm is carried by the female and released toward eggs. Eleven days after the sperm-induced eggs are laid, the new baby spiders will emerge. On the maternal web, these young spiders live together, and the mothers cannibalize the weaker spiderlings to get rid of them and preserve the stronger spiders that are given priority. Young spiders undergo an enhanced mutation process as a result of this mechanism, and the winds subsequently carry the spiderlings to different regions. The methodology for implementing BWO in Conv-LSTM is outlined in Algorithm 1.

Algorithm 1: BWO algorithm [19]

Initialize population of spiders using a D-dimensional array, represented by *pop*.
Initialize Iteration = 0
Determine the count of reproductions (solutions nrp) by utilizing the procreation rate
Select the most effective solutions within the population and store them in *sub-pop-I*
/*Carry out procreation and cannibalism*/
for $i = 1$ to nrp **do**
    Selecting a pair of solutions (w_1, w_2) from *sub-pop-I* to serve as parents.
    Generate D offspring (z_1, z_2), which are new achieved solutions utilizing

$$\begin{cases} z_1 = \beta \times w_1 + (1 - \beta) \times w_2 \\ z_2 = \beta \times w_2 + (1 - \beta) \times w_1, \ \beta : \text{a } D\text{-dimensional array of random numbers from [0, 1]} \end{cases}$$

    Eliminate the paternal solution
    Evaluate the fitness function $f(z)$
    Annihilate several fragile children (new solutions) in light of the cannibalism rate
    Preserve the leftover solutions in *sub-pop-II*
end for
/*Carry out mutation*/
Calculate the count of mutated offspring (nmu) in accordance with the mutation rate
for $i = 1$ to nmu **do**
    Opt for a solution from *sub-pop-II*
    Implement a process of random mutation to create a new solution
    Save the new solution in *sub-pop-III*
end for
Update *pop* = *sub-pop-II*+*sub-pop-III*
Until maximum iteration
Return the most favorable solution from *pop*
end

This algorithm is used to tune the biases and weights of Conv-LSTM, resulting in the optimal values for the hyperparameters. The fitness function of Conv-LSTM is substituted for the original one, as $f(z) = f(\upsilon, \kappa)$, with υ and κ representing the sets of weights and biases of the optimized Conv-LSTM. This fitness function is associated with the convolution, pooling, fully connected layers, and activation function of the CNN, as well as the LSTM's learning rate and activation function. The optimal setup is achieved by tuning the parameters. The tuning procedure finds numerous configurations for the optimized Conv-LSTM, but BWO chooses the one with the *lowest error rate*. In this work, the initial values of three different parameters of BWO, i.e., procreation rate, cannibalism rate, and mutation rate are set as 0.6, 0.44, and 0.4, respectively.

Table 1 presents the best configuration for Conv-LSTM that is achieved with BWO. As can be observed in Table 1, the Conv-LSTM needed two LSTM layers and five layers of fully convoluted arrangement for optimal construction. With this setup, CNN can learn deep spatial features, and LSTM can learn temporal information. The convolution and pooling layers' sizes are determined by the results of prior experiments. There are three components that represent the dimensions, as shown in the table. For the input dimension (1, 256, 24), 1 represents the input

Table 1 Superior configuration featuring optimal hyperparameters achieved for Conv-LSTM through the application of BWO [19]

Layer	Name	Dimensions	Parameters
0	Input	(1, 256, 24)	–
1	Convolution	(16, 256, 24)	{16, 3, 3}
	Pooling	(16, 128, 12)	{2, 2}
	Activation (sigmoid)	–	–
2	Convolution	(32, 128, 12)	{32, 3, 3}
	Pooling	(32, 64, 6)	{2, 2}
	Activation (sigmoid)	–	–
3	Convolution	(64, 64, 6)	{64, 3, 3}
	Pooling	(64, 32, 3)	{2, 2}
	Activation (sigmoid)	–	–
4	Convolution	(128, 32, 3)	{128, 3, 3}
	Pooling	(128, 16, 1)	{2, 2}
	Activation (sigmoid)	–	–
5	Convolution	(256, 16, 1)	{256, 3, 3}
	Pooling	(256, 8, 1)	{2, 2}
	Activation (sigmoid)	–	–

8	LSTM	–	{200}
	Activation (tanh)	–	–
	Learning rate	–	{0.7}
9	LSTM	–	{200}
	Activation (tanh)	–	–
	Learning rate	–	{0.7}
10	Fully connected	(278,)	{278}

data channel, 256 the total number of data, and 24 the processing time steps. The convolution layer parameter (16, 3, 3) indicates that layer 1 has 16 filters of size (3, 3). Depending on the requirements of the dataset, the structural stabilization mechanism is implemented based on these parameter value ranges. To address the over-fitting issue, the nodes in the layers are either enhanced or decreased when the weights are readjusted.

As previously stated, the Adam is chosen as the Conv-LSTM optimizer, and the error rate is selected as the optimization function. Comparing the optimal setup presented in Table 1 to other potential choices, it has an effective architecture with the lowest error rate. Therefore, the BWO-Conv-LSTM is designed with a great deal of efficiency. This classifier's performance is assessed using four IDS datasets.

Results and Discussions

The performance evaluation of the BWO-Conv-LSTM with ABC-based feature selection (hereafter referred to as BWO-Conv-LSTM (ABC)) is carried out on the *four*

datasets based on *four* quantitative performance metrics, i.e., Accuracy, Precision, Recall, and F-Measure [19]. For performance comparison, *five* recent state-of-the-art models for IDS are implemented, namely, support vector machines (SVM) with improved binary grey wolf optimizer-based feature selection (referred to as IGWO-SVM) [21], ANN with correlation-based feature selection (referred to as ANN-CFS) [22], genetic algorithm (GA)-optimized CNN (referred to as GA-CNN) [23], hybrid convolutional RNN-based NIDS model (referred to as HCRNNIDS) [24], and optimized CNN and Hierarchical Multi-scale LSTM (referred to as OCNN-HMLSTM) previously developed by Kanna and Santhi [25]. These contemporary models are chosen for evaluation comparison, because they demonstrated superior performance, as pointed in the literature. The study [19] evaluated these established models under the same platform, despite the fact that they were actually tested in different experimental configurations in the literature.

Tables 2, 3, 4 and 5 report the comparison of the BWO-Conv-LSTM (ABC)-based IDS model against the five competing models over the four datasets, in terms of Accuracy, Precision, Recall, and F-Measure, respectively. The results in Tables 2 and 5, respectively, demonstrated that the BWO-Conv-LSTM (ABC) achieved higher accuracy values and F-scores than the other methods of comparison uniformly for all the four datasets. Table 3 reveals that BWO-Conv-LSTM (ABC) clearly outperforms its competitors in terms of precision over the NSL-KDD and CSE-CIC-IDS 2018 datasets, whereas all the six competing models achieved a precision of 100% for ISCX-IDS and UNSW-NB15 datasets. Likewise, as can be observed from Table 4, BWO-Conv-LSTM (ABC) achieved better recall results

BWO-Conv-LSTM (ABC)	**25,717.68**	**604.32**

compared to five competing models for the ISCX-IDS, UNSW-NB15, and CSE-CIC-IDS 2018 datasets, while BWO-Conv-LSTM (ABC), as well as IGWO-SVM and HCRNNIDS, produced a 100% recall for NSL-KDD dataset. In a nutshell, as evidenced by the results of Tables 2, 3, 4 and 5, BWO-Conv-LSTM (ABC) emerged as the overall superior to the five competing state-of-the-art models for IDS. These findings demonstrate how the BWO-Conv-LSTM (ABC) ensures better intrusion detection than the majority of current models through the use of more sophisticated DL of both temporal and spatial characteristics of network traffic data. The overall performance has also been greatly impacted by the use of ABC and BWO for feature selection and parameter optimization, respectively. The assessment of four datasets further shows that this model supports various types of network traffic data. Additionally, Table 6 reports the average training and detection time consumed by the six IDS models of comparison over the four datasets. It can be observed

from Table 6 that the training and detection time of BWO-Conv-LSTM (ABC) is noticeably less than the other models. This is because CNN requires less training time, which is why the overall detection and training time is justified.

Metaheuristic Optimization of Hyperparameters of GPR Model: Application to FEREBUS

Background and Overview

The cost-versus-accuracy trade-off has long plagued molecular dynamics (MD) simulations of macromolecules, encouraging low-cost approaches—more especially, classical force field (CFF) methodologies—despite their obvious inability to produce quantitatively reliable and consistent outcomes [26]. On the other hand, as the size of the system grows, *ab initio* quantum mechanics (QM) techniques, which offer a more plausible description of molecular systems by explicitly treating the electrons (neglected in CFFs), become unaffordable. The development of a new class of unconventional potentials known as machine learning force fields (MLFFs) is presently being pursued in an attempt to resolve this dilemma. The potential to combine the predictive effectiveness of ML regression models with the accuracy of QM observables is what drives MLFFs. The goal of MLFFs is to attain the accuracy of ab initio QM techniques at a significantly lower cost that is on par with CFFs.

FFLUX is an innovative yet well-established MLFF that was created from the scratch using proof-of-concept research [27]. It makes use of pretrained GPR models to forecast multipole moments and atomic energies, which are both necessary to estimate the physical interactions that occur within and between molecules during MD simulations. FFLUX does not define atom types or rely on any predetermined bonding arrangement like CFFs do. Rather, it works with quantum topological atoms, which are the identical space-filling atoms in molecules arising from a thorough division of molecular spaces in the framework of quantum chemical topology.

FEREBUS [28], a Fortran90 package, forms the core of FFLUX. It is in charge of constructing GPR models for multipole moments and atomic energies. FEREBUS builds as many models as quantum observables for each atom in the system. Every model associates the relevant input features, which encapsulate structural details about the system under consideration, with a specific target attribute (QM observable). Three major architectural changes have been made to the FEREBUS package in its current version (9.2): (i) multiple metaheuristic optimizers have been implemented; (ii) STELLA, a software module that can validate models on the fly, has been integrated; and (iii) a different, straightforward but effective protocol for optimizing model hyperparameters has been developed [29].

The performance of the latent GPR models determines the results of FFLUX simulations. Finding the factor that determines the quality of a GPR model is a valid question at this stage. The prediction ability of a GPR model is determined by the set of model hyperparameters, represented by $\boldsymbol{\phi}$, for a particular training dataset ($\mathbf{U}$, $\mathbf{v}$),

mean function $\mu(\mathbf{u})$, and covariance function $c(\mathbf{u}, \mathbf{u}')$. As $\boldsymbol{\phi}$ values are never known beforehand, the process of training a GPR model mostly involves determining the optimal combination of these hyperparameters. In general, the log marginal likelihood function $\mathcal{L}(\mathbf{v}|\mathbf{U}, \boldsymbol{\phi})$ of a GP is maximized to derive the hyperparameters of the GPR model; this approach is also known as the *Type-II maximum likelihood* (ML-II) method. One of its advantages is the computational ease provided by the analytical tractability of its gradient and the cost function, which enables the use of any standard gradient-based technique for model hyperparameter optimization. Nevertheless, the ML-II protocol has certain shortcomings in spite of its popularity. For example, it is well known that the existence of outliers in the dataset can significantly impair the performance of ML-II-based models. Several approaches have been put forth to address this problem, including (i) using an outlier-resistant observation model, like the student-t distribution, in place of the Gaussian-like likelihood of the observations, and (ii) applying a Gaussian mixture noise model to account for regular as well as irregular noises [29]. Sadly, neither solution maintains the intended analytical tractability of the marginal likelihood, therefore in order to access the model hyperparameters, the practitioner must either (i) rely on approximation techniques or (ii) just think of a different protocol.

Using the same justification, it was recently found that the propagation of numerical errors may have a significant impact on the $\mathcal{L}(\mathbf{v}|\mathbf{U}, \boldsymbol{\phi})$ cost function, potentially producing inconsistent findings. Thankfully, an alternative protocol for optimizing the hyperparameters of the GPR model is now incorporated in FEREBUS. In comparison to ML-II, this straightforward and user-friendly method known as *iterative hold-out cross-validation* (IHOCV) can significantly increase the quality of the trained models. Additionally, unlike the commonly used, yet occasionally contentious, k-fold cross-validation [30], IHOCV attempts to improve the same model by performing minimization of the predictive root-mean-square error (RMSE) RMSE($\boldsymbol{\phi}$) of intermediate models over a significantly large and consistent internal validation set rather than computing the average performance of multiple models constructed from different segments of the same dataset. Particularly in the noise-free regime, the ML-II technique cannot guarantee that the optimization process will continuously improve the performance of intermediary models, while the IHOCV protocol does.

Whichever training protocol—ML-II or IHOCV—an individual chooses, he/she still needs to select a method for optimizing the related cost functions. Finding the global optimum of the RMSE($\boldsymbol{\phi}$) and $\mathcal{L}(\mathbf{v}|\mathbf{U}, \boldsymbol{\phi})$ functions is extremely difficult because to their multimodal nature and complex landscape, particularly for large dimensional search spaces. This calls for a search method that can jump out of local optima. Gradient-based methods, which require the availability of the analytical gradient of the cost function, are often highly sensitive to initial guesses and converge to the closest optimum without escape mechanisms. On the contrary, the stochastic nature of MHS algorithms allows them to avoid repeated traps of local extrema, while they do not need any analytical gradient. Even though MHS algorithms are incredibly good at solving a wide range of complex optimization problems, they have not yet gotten the consideration they deserve in the context of

GPR-based atomistic potentials, where gradient-based approaches are prioritized for optimizing model hyperparameters. In contrast to this well-liked option, FEREBUS provides its users with a number of (population-based) MHS algorithms, all of which are able to optimize model hyperparameters globally.

In [29], Isamura and Popelier examined the performance of ten distinct population-based MHS algorithms to find the optimal set of hyperparameters of the GPR model following the two protocols (i.e., ML-II and IHOCV) as implemented in FEREBUS. The effectiveness of each combination of hyperparameters was assessed based on the corresponding model's predictive accuracy on data points that had not been seen before. Four of the most well-known families of population-based MHS algorithms, namely, (i) particle swarm optimization (PSO), (ii) bat algorithms (BA), (iii) firefly techniques (FFA), and (iv) gray wolf optimizer (GWO), were used to choose the optimizers investigated in [29]. All the GPR models were developed to estimate the total electronic energy of individual atoms across different conformations of capped alanine. It should be noted that the reference atomic energies were meticulously calculated using the Interacting Quantum Atoms (IQA) method [31]. As demonstrated by Isamura and Popelier, GWOs outperform the other three families. In particular, atomic models produced by the standard GWO have the lowest average prediction errors.

Fundamentals of GPR

Bayesian statistics serves as the foundation for GPR, often referred to as kriging, a nonparametric ML technique [32]. GPR has four key benefits over alternative regression techniques: (i) Being a nonparametric method, GPR does not specifically assume how the function to be learnt should be expressed analytically; (ii) even when trained on small datasets, GPR models can achieve high predictive accuracy, something that naturally "greedy" ANNs typically find difficult to do; (iii) there is less chance of overfitting; and (iv) alongside each point estimate (prediction), there is an estimate of the degree of uncertainty around the predicted (mean) value [29].

To train a GPR model, a dataset $\mathbf{D} = \{\mathbf{U}, \mathbf{v}\}$ comprising n observations is necessary, with $\mathbf{U}$ representing a rectangular matrix of input features and $\mathbf{v}$ denoting the vector of target values (which, in this context, are atomic energies). It is presumed that a function f exists such that for each observation $(\mathbf{u}_k, v_k)$, $v_k = f(\mathbf{u}_k) + \epsilon_k$, where ϵ_k indicates the noise corrupting the k-th measurement. The noise $\boldsymbol{\epsilon} = \{\epsilon_1, \epsilon_2, \ldots, \epsilon_n\}$ is assumed to follow a zero-mean Gaussian distribution with a standard deviation σ_n^2. The regression problem involves determining the most likely function f that associates each input vector $\mathbf{u}_k$ with the corresponding target value v_k. This task is performed in two steps from a Bayesian perspective: (i) defining a Gaussian process prior over the unknown distribution of functions f and (ii) updating the initial belief about f using the Bayes' theorem in light of the observations in $\mathbf{D}$. This results in a posterior distribution over f that provides a predictive Gaussian distribution for each new point, with its mean value being the point estimate of the prediction (expected value).

Assuming that a GPR model is already trained on **D**, the following formulas can be used to determine the expected value corresponding to any new point $\mathbf{u}^*$ [29]:

$$f(\mathbf{u}^*) = \mu(\mathbf{u}) + \mathbf{c}_*^T \mathbf{C}^{-1} \mathbf{v}_{\boldsymbol{\mu}} \tag{1}$$

$$\mathbf{c}_* = \begin{bmatrix} c(\mathbf{u}_1,\ \mathbf{u}^*|\boldsymbol{\phi_k}) \\ c(\mathbf{u}_2,\ \mathbf{u}^*|\boldsymbol{\phi_k}) \\ \vdots \\ c(\mathbf{u}_n,\ \mathbf{u}^*|\boldsymbol{\phi_k}) \end{bmatrix} \tag{2}$$

$$C_{ij} = cov(\mathbf{u}_i,\ \mathbf{u}_j) = c(\mathbf{u}_i,\ \mathbf{u}_j|\hat{\boldsymbol{\phi}}_k) + \sigma_n^2 \delta_{ij} \tag{3}$$

$$\mathbf{v}_{\boldsymbol{\mu}} = \mathbf{v} - \mathbf{1}\mu(\mathbf{u}) \tag{4}$$

where $\mu(\mathbf{u})$ and $c(\mathbf{u}_i,\ \mathbf{u}_j|\boldsymbol{\phi_k})$ are the prior mean and covariance functions, respectively, determining the GP prior over f, and **C** represents the covariance matrix. The superscript T represents the transposition of a column vector into a row vector. In addition to measuring the noise dispersion of the dataset, the parameter σ_n^2 also acts as a regularization factor meant to keep the matrix **C** from becoming ill-conditioned. Lastly, δ_{ij} represents the Kronecker delta.

There are several different approaches to define the prior mean function $\mu(\mathbf{u})$. However, this study chose to maintain it constant and have it match the arithmetic mean of the output attributes (atomic energies) in **D**. This decision guarantees that even in the atypical extrapolation regime where predictions converge toward $\mu(\mathbf{u})$, they maintain their physical significance. The covariance function $c(\mathbf{u}_i,\ \mathbf{u}_j|\boldsymbol{\phi_k})$, however, is often called as the *kernel*. This function evaluates the distance required between two points in the input space for them to be deemed uncorrelated. The strength of these correlations is governed by a specific set of parameters $\boldsymbol{\phi}_k$, which, when paired with σ_n^2, form the hyperparameters ($\boldsymbol{\phi}$) of the GP. The composite kernel described in Eq. (5) was used throughout the study [29], where N_{ft} represents the dimension of each feature (input) vector [29]. This kernel integrates periodic covariance functions with the radial basis function (RBF) and utilizes them across various dimensions of the input space.

$$c_{\text{RBF}}\left(\mathbf{u}, \mathbf{u}'|\phi_k = \{\sigma_f^2,\ \gamma_{d,1},\ \gamma_{d,2}, \ldots,\ \gamma_{d,N_{ft}}\}\right) = \sigma_f^2 \exp\left[-\sum_{d=1}^{N_{ft}} \Omega(\mathbf{u},\ \mathbf{u}')\right] \tag{5}$$

with

$$\Omega(\mathbf{u},\ \mathbf{u}') = \begin{cases} \dfrac{1 - \cos(\mathbf{u}_d - \mathbf{u}'_d)}{\gamma_d^2} & d > 3 \quad \text{and} \quad \text{mod}\ (d, 3) = 0 \\ \dfrac{(\mathbf{u}_d - \mathbf{u}'_d)^2}{2\gamma_d^2} & \text{otherwise} \end{cases}$$

It is important to mention that FEREBUS computes ϕ_d hyperparameters that are linked to the parameters of characteristic length scale γ_d via $\phi_d = 1/2\gamma_d^2$. It is assumed in Eqs. (1)–(4) that the GP hyperparameters ($\boldsymbol{\phi}$) are known. But these $\boldsymbol{\phi}$ values are never known in advance, and determining the best combination of them is the key to training a GPR model. In order to access the model hyperparameters, the study [29] took into consideration two distinct protocols: ML-II and IHOCV.

In the ML-II protocol, the hyperparameters $\boldsymbol{\phi}$ are derived by maximizing the LML function as described in Eq. (6)

$$\mathcal{L}(\mathbf{v}|\mathbf{U}, \boldsymbol{\phi}) = -\frac{1}{2}\sigma^2 - \frac{1}{2}\log|\mathbf{C}| - \frac{n}{2}\log(2\pi) \tag{6}$$

$$\sigma^2 = (\mathbf{v} - \boldsymbol{\mu}_\mathbf{v})^T \mathbf{C}^{-1}(\mathbf{v} - \boldsymbol{\mu}_\mathbf{v}) \tag{7}$$

$$\boldsymbol{\mu}_\mathbf{v} = \mathbf{1}\mu(\mathbf{u}) \tag{8}$$

where, in Eq. (6), the first two terms are, respectively, referred to as the *data-fit* and *complexity penalty components*.

The IHOCV protocol attains $\boldsymbol{\phi}$ values by minimizing the predictive RMSE of intermediary models across a sufficiently extensive internal validation dataset. The RMSE objective function is computed by making use of Eq. (9), with m representing the count of internal validation points and v_k^{pred} being the prediction corresponding to the kth validation point,

$$\text{RMSE}(\boldsymbol{\phi}) = \left(\frac{1}{m}\sum_{k=1}^{m}|v_k - v_k^{pred}|^2\right)^{1/2} \tag{9}$$

The tuning of model hyperparameters in the IHOCV protocol necessitates assessing the expected values for each unseen point in the internal validation dataset. Because FEREBUS uses MHS algorithms, the $\boldsymbol{\phi}$ vector in Eq. (9) actually represents a temporary combination of hyperparameters ($\boldsymbol{\phi}^{tmp}$) that corresponds to the best agent's location in the RMSE function landscape during the current iteration. To calculate v_p^{pred} for a new data point p that is not in $\mathbf{D}$, plug $\boldsymbol{\phi}^{tmp}$ in Eqs. (1)–(4)

Metaheuristic Optimizers Under Investigation

In a population-based MHS algorithm, all the search agents should gradually converge toward the same optimal solution under ideal conditions. That being said, this is not always the case. At times, due to a variety of factors, one or more agents may find it challenging to synchronize with the group's collective movement, leading them to diverge or exit the search space. This behavior can adversely affect the overall search process, and if not managed properly, it may result in unforeseen and potentially unfeasible solutions. To prevent this unfavorable scenario, FEREBUS employs a control strategy that involves reinitializing the position of any agent that exceeds the limits of the search space.

As previously mentioned, the optimizers investigated in the study [29] were chosen from four of the most widely recognized categories of population-based MHS algorithms: (i) PSO, (ii) GWO, (iii) BA, and (iv) FFA. Within the genre of PSO, a canonical version of PSO (i.e., CPSO) [33] and three noncanonical PSO algorithms, namely, the (i) global-best fully informed PSO (FIPSO-Gb) [34], (ii) randomized PSO (RPSO) [35], and (iii) bare bone PSO (BBPSO) [36], were considered. From the family of GWO, the standard GWO [37] and "random-walk" GWO (RW-GWO) [38] were selected, whereas the basic BA [39] and "directional" BA (dBA) [40] were chosen from the family of BA. In the realm of FFA, the standard FFA [41] and chaotic FFA (CFFA) [42] were chosen.

Details of Computation

Generation of Dataset

The datasets utilized in the research [29] to evaluate the effectiveness of metaheuristic optimizers across different optimization tasks were produced through a protocol executed in the proprietary task management software ICHOR. Consistent with the protocol, the potential energy surface (PES) of capped alanine was examined using classical molecular dynamics simulations, employing the GAFF2 [43] force field as featured in the AMBER18 software package [29]. This decision was motivated by the necessity to achieve a balanced compromise between computational time and the feasibility of the sampled conformations. The simulation was conducted over a duration of 1,000,000 steps, utilizing a timestep of 1 femtosecond, with the Langevin thermostat selected to regulate the temperature at approximately 300 K. Geometries were gathered at intervals of 100 steps, resulting in an initial population of 10,000 geometries. Each of the 10,000 geometries sampled underwent a single point calculation at the B3LYP/6–31+G(d,p) level to obtain the electron density, which is the sole physical quantity necessary for AIMAll [29] to conduct topological analyses. Gaussian16 was utilized to conduct single-point computations.

The atomic IQA energy for each atom across all sampled geometries was computed utilizing the AIMAll program, which employs the IQA methodology. Simultaneously, the structural information present in each geometry was represented through fixed-length vectors that comprised geometrical features specified within the *atomic local frame* (ALF) [27].

The datasets, comprising 22 files corresponding to each atom, were generated by concatenating the input features with the atomic energies. A filtering process was then applied to eliminate any geometries in which at least one atomic energy exhibited an absolute integration error exceeding 0.0004 a.u. It should be noted that the integration error $I(\delta)$, associated with the Laplacian of the electron density integrated over an atomic basin δ, serves as an indicator of the numerical accuracy of atomic integrations [29]. Typical values of 0.001 a.u. for elements in the second and third rows, and 0.0001 a.u. for hydrogen, are regarded as a reasonable compromise for medium-sized molecules, as they ensure the reconstruction of the total electronic energy within an accuracy of 1 kcal/mol. In the research [29], reducing the initial

population to $I(\delta) = 0.0004$ a.u. enabled the retention of approximately 74% of the geometries, specifically 7412 conformations, while attaining a satisfactory mean absolute recovery error of 4.2 kJ/mol, which is roughly equivalent to 1 kcal/mol. After filtering, the reference datasets were subsequently employed to sample the training, validation, and test sets.

ALF Feature Calculation

The input space was delineated through the concept of ALF [27], which is a molecular representation that integrates both *two-body* (noncyclic) and *three-body* (cyclic) interactions. Each local frame is defined by three atoms: the atom of interest (α_0) acting as the origin and two additional atoms arranged in descending order of importance in accordance with *Cahn-Ingold-Prelog* principles [44]. The atom given the highest priority, designated α_x, is positioned along the X axis, whereas the other atom α_y describes the XY plane. The Z axis is positioned at a right angle to the XY plane, thereby forming a right-handed (orthogonal) local coordinate system. Since every ALF is based around a particular atom, describing the entire system necessitates having as many local frames as there are atoms present.

For a system comprising M atoms, every input vector consists of $3M-6$ features. The initial three features of the input vector related to the local frame of α_0 include the two Euclidean distances from atom α_0 to the α_x and α_y atoms ($\Lambda^{\alpha x}$ and $\Lambda^{\alpha xy}$), in addition to the angle ψ^{α} formed by the three ALF atoms (refer to Eqs. (10)–(12)). Moreover, for each non-ALF atom α_n, where n is greater than or equal to 4, the input vector is augmented by incorporating three additional features that represent the spherical coordinates ($\Lambda^{\alpha n}$, $\omega^{\alpha n}$, $\varphi^{\alpha n}$) of atom α_n within the ALF. Equations (13)–(15) define these features.

$$\Lambda^{\alpha x} = \left[\left(\boldsymbol{\Lambda}^{\alpha x} - \boldsymbol{\Lambda}^{\alpha 0}\right)^2\right]^{1/2} \tag{10}$$

$$\Lambda^{\alpha xy} = \left[\left(\boldsymbol{\Lambda}^{\alpha xy} - \boldsymbol{\Lambda}^{\alpha 0}\right)^2\right]^{1/2} \tag{11}$$

$$\psi^{\alpha} = \cos^{-1}\left(\frac{\boldsymbol{\Lambda}^{\alpha x} \cdot \boldsymbol{\Lambda}^{\alpha xy}}{|\boldsymbol{\Lambda}^{\alpha x}||\boldsymbol{\Lambda}^{\alpha xy}|}\right) \tag{12}$$

$$\Lambda^{\alpha n} = \left[\left(\boldsymbol{\Lambda}^{\alpha n} - \boldsymbol{\Lambda}^{\alpha 0}\right)^2\right]^{1/2} \tag{13}$$

$$\omega^{\alpha n} = \cos^{-1}\left(\frac{\xi_3^{\alpha n}}{|\boldsymbol{\Lambda}^{\alpha n}|}\right) \tag{14}$$

$$\varphi^{\alpha n} = \tan^{-1}\left(\frac{\xi_2^{\alpha n}}{\xi_1^{\alpha n}}\right) \tag{15}$$

where $n \geq 4$. The term $\xi_i^{\alpha n}$ is defined as a Cartesian coordinate within the ALF, whereas $\boldsymbol{\Lambda}^{\alpha x}$, $\boldsymbol{\Lambda}^{\alpha xy}$, $\boldsymbol{\Lambda}^{\alpha 0}$, and $\boldsymbol{\Lambda}^{\alpha n}$ represent position vectors in the global frame.

The ALF representation is among a variety of molecular descriptors being utilized for the advancement of machine-learned potentials. Indeed, the features of ALF are (i) invariant to both translation and/or rotation of the system; (ii) distinctive in that a one-to-one correspondence can always be established between a specific atomic arrangement and the resulting features for all atoms; (iii) continuous, meaning that even the smallest alteration in a molecule's structure leads to corresponding changes in the features; (iv) compact, or ideally even minimalistic, ensuring that no extraneous features are included in the feature vector; and (v) feasible in terms of computational resources [29]. Additionally, the computation of ALF features is automated and does not necessitate human involvement. Nonetheless, because the ALF descriptor is characterized by its extensive nature (meaning that the number of features grows in direct proportion to the number of atoms), its practical application may be restricted to medium- and small-sized systems. Additionally, it appears reasonable to establish a local frame for each atom within a system and to utilize ML to realize the physical characteristics of a specific atom within its unique coordinate framework. However, this design decision neither promotes nor makes it easier to take into account ALF features in relation to (i) the representation of big systems, and (ii) the handling of nonlocal properties, including delocalization indices, molecular observables, etc.

Details of the Optimization Mechanisms

In [29], after being trained on 3000 points, all atomic models were assessed on 2000 different points without any prior standardization of ALF features. For IHOCV-based models, a 100-point internal validation set was used. The upper limit for iterations was established at a substantial figure of 10,000 to ensure that each optimization run consistently converged to solutions of equivalent quality across various randomly initialized successive runs (preliminary tests conducted with the CPSO algorithm confirmed this assumption). For the hyperparameters σ_f^2, ϕ_d, and σ_n^2, the search space was selected as [0, 10], [0, 3], and $[10^{-14}, 10^{-13}]$, respectively. The spectrum of σ_n^2 values may be considered as the noise-free domain. As highlighted by Isamura and Popelier, the earlier search space enabled them to achieve an effective equilibrium between the models' predictive accuracy and their anticipated capacity to replicate the training data. In relation to population size, groups consisting of 24 agents (each representing a potential solution) were assigned the responsibility of examining the search space. All optimization processes were conducted simultaneously utilizing eight cores on compute nodes equipped with Cascade Lake Xeon Gold 6230 CPUs, each operating at a frequency of 2.10 GHz.

Results and Discussions

This research primarily focuses on the performance of a chosen set of ten MHS algorithms in the training of GPR models for atomic energies. It is reasonable to assess the efficacy of MHS algorithms by considering the optimal or best value

obtained for the objective (cost) function. In the present context of regression, where the cost function optimization serves to inform the choice of the most suitable model, it is more logical to focus on the ability of the resulting models to generalize to previously unseen data points. Here, this is accomplished by calculating each trained model's predictive mean absolute error (MAE) across the identical external validation/test sets. The predictive MAE of the trained models will be used here to describe the performance of the selected MHS algorithms in the discussion that follows [29].

Unlike the majority of benchmark studies on MHS algorithms, which typically have a known exact solution to the optimization problem, the training of atomic GPR models involves a *blind search*. In this context, the analytical solution to the problem remains unknown and varies with the dataset. Consequently, it is impossible to ascertain the convergence rate of an algorithm, as it is not feasible to determine the distance of each solution provided by the algorithm from the exact solution. Additionally, because of the multimodal characteristics of the $\mathcal{L}(\mathbf{v}|\mathbf{U}, \boldsymbol{\phi})$ and RMSE($\boldsymbol{\phi}$) cost functions, it is common for various solutions (combinations of hyperparameters) to result in models that exhibit comparable or nearly indistinguishable performance levels. As per Rasmussen and Williams [32], this frequently indicates the presence of distinct yet comparable interpretations of the same dataset. In the interest of conciseness, the designation Pr-Al-El (such as ML-II-GWO-N) is adopted to signify the atomic models associated with an element El that has undergone training through an optimization algorithm Al, adhering to the protocol Pr. The atom numbering for capped alanine is illustrated in Fig. 3.

Optimization of the $\mathcal{L}(\mathbf{v}|\mathbf{U}, \boldsymbol{\phi})$ Cost Function

All atomic GPR models were initially trained in accordance with the ML-II protocol. Table 7 illustrates the average predictive MAEs per element over 22 at. models, achieved through the application of all ten optimizers.

Table 7 demonstrates that ML-II models display satisfactory, though not exceptional, predictive accuracies, with average predictive MAEs of 2.658, 3.754, 3.879, and 2.921 kJ/mol for the models corresponding to hydrogen (H), carbon (C),

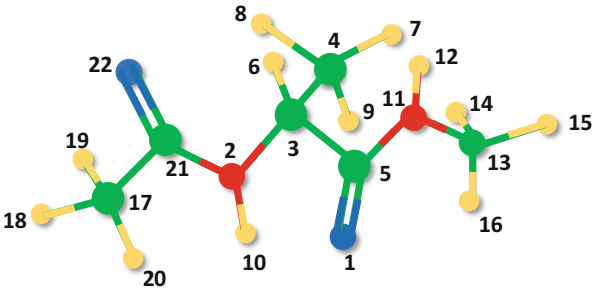

Fig. 3 Numbering of atoms of capped alanine. The yellowish, red, blue, and green spheres, respectively, represent the H, N, O, and C atoms [29]

Table 7 The average predictive MAEs in kJ/mol for atomic GPR models based on ML-II, which were trained utilizing ten distinct optimization algorithms. Each model underwent training using a dataset of 3000 points and was subsequently evaluated on a separate set of 2000 points. Each optimization run was allowed to proceed for a maximum of 10,000 iterations, a limit established to avoid premature convergence. The values highlighted in bold represent the algorithm that demonstrates the highest performance [29]

Optimizer/datasets	H	C	N	O

RW-GWO	2.831	3.665	**3.879**	3.172

nitrogen (N), and oxygen (O), respectively, as attained by the most effective optimizers. The generalization error associated with each of these ML-II-based GPR models could indeed have been minimized by increasing the size of the training dataset. In the context of the study [29], the data augmentation process could be structured to ensure that the supplementary points are gathered from areas of the PES that appear to be underrepresented in the initial training datasets. But expanding the training set's size isn't always feasible, particularly when the target values need to be derived from costly QM computations. It has been demonstrated in [29] that, with the same size of the training set, significantly improved models can be achieved by choosing the most suitable training protocol, i.e., the optimizer and cost function.

As Table 7 shows, the performance patterns of the ten MHS methods across the four elements are not consistent. This observation demonstrates that the training of atomic GPR models constitutes a distinct optimization challenge, tailored to individual atoms of an element, and corresponds with the reality that the cost function's landscape changes depending on the dataset. Understanding the function of an effective optimizer is already made easier by a close examination of the ML-II-RW-GWO-N and ML-II-BA-N models. Despite the fact that both were trained by maximizing the LML function (ML-II protocol), the accuracy of the first model is around 2.4 times higher than that of the second. The same finding holds true for further models, namely, ML-II-GWO-C and ML-II-dBA-C, which showed corresponding average predictive MAEs of 3.754 and 5.636 kJ/mol. The significance of selecting an appropriate cost function will be more evident in the following section, where the outcomes for models based on IHOCV will be presented.

Table 8 The average predictive MAEs in kJ/mol for atomic GPR models based on IHOCV, which were trained utilizing ten distinct optimization algorithms. Each model underwent training using a dataset of 3000 points and was subsequently evaluated on a separate set of 2000 points. Each optimization run was allowed to proceed for a maximum of 10,000 iterations, a limit established to avoid premature convergence. The values highlighted in bold represent the algorithm that demonstrates the highest performance [29]

Optimization of RMSE(ϕ) Cost Function

The effectiveness of the selected metaheuristic optimizers was subsequently assessed in accordance with the IHOCV protocol. In this alternative protocol, the hyperparameters of the model are derived through the minimization of the predictive RMSE of intermediate models across an internal validation set. The aforementioned dataset should be sufficiently large to enable a dependable assessment of the generalization error of intermediate models. The internal validation set should also be kept at a reasonable size, as an excessively large set may compromise the model's flexibility and unnecessarily extend the training duration.

Table 8 provides a comprehensive list of average MAEs. The same table demonstrates that, similar to ML-II-based models, the performance of the ten optimizers across the four elements lacks consistency. IHOCV-based models demonstrate a significantly higher level of accuracy compared to their ML-II-based counterparts. For example, the average MAEs presented in Table 8 are calculated to be 0.922, 1.586, 1.962, and 1.145 kJ/mol for the models of H, C, N, and O, respectively, utilizing the most effective optimizers. Compared to the data gathered in Table 7 for ML-II-based models, these values are 1.5–2.3 times lower.

Conclusion

In this chapter, the authors have explored the most recent progressions in the implementation of MHS algorithms in the context of supervised ML techniques. Evidence indicates that the application of MHS algorithms in training supervised models significantly improves the learning process. This reportedly enhances the

accuracy of the algorithm while simultaneously decreasing its execution duration. The synergy between metaheuristics and supervised methods establishes a solid basis for the supervised ML process, thereby augmenting their performance. Nonetheless, there is still opportunity to utilize these hybrid techniques in diverse applications and assess their effectiveness against various challenging real-world datasets.

It is challenging to determine if supervised techniques (especially the likes of ANN or DL models) will maintain their position at the cutting edge of academia without the incorporation of metaheuristics. In the forthcoming years, it is anticipated that the integration of supervised ML with MHS algorithm will enhance the training process and sustain elevated performance levels. It has been observed that the evolutionary hybrid architecture remains somewhat restricted in its applicability within the existing literature and an analysis of the current studies reveals that the application of MHS algorithms for the optimization of supervised ML models continues to pose significant challenges, highlighting the need for additional research in this domain. There is an expectation that the application of metaheuristics will grow in the years ahead, contributing to the improvement of the performance of different supervised architectures. Yet, there is still a lack of sufficient relevant publications in this area.

Abstract

As its name suggests, a matheuristic is the hybridization of mathematical programming with metaheuristics. The hallmark of matheuristics is the central role played by the mathematical programming model, around which the overall heuristic is built. As such, matheuristic is not a rigid paradigm but rather a concept framework for the design of mathematically sound heuristics. The aim of this chapter is to introduce the main matheuristic ideas. Three specific applications in the fields of wind farm, packing, and vehicle routing optimization, respectively, are addressed and used to illustrate the main features of the method.

Heuristics · Large scale neighborhood search · Local branching · Mathematical programming · Matheuristics

Introduction

The design of heuristics for difficult optimization problems is itself a heuristic process that often involves the following main steps.

After a clever analysis of the problem at hand and of the acceptable simplifications in its definition, one tries to set up an effective **mathematical programming** (MP) model and to solve it by a general-purpose piece of software—often a mixed-integer linear programming (MIP) solver. Due to the impressive improvement of general-purpose solvers in recent years, this approach can actually solve the instances of interest to proven optimality (or with an acceptable approximation) within a reasonable computing time, in which case of course no further effort is needed.

If this is not the case, one can insist on the MP approach and try to obtain better and better results by improving the model and/or by enhancing the solver with specialized features (cutting planes, branching, etc.). Or one can forget about MP and resort to ad hoc heuristics not based on the MP model. In this latter case, the MP model is completely disregarded or just used for illustrating the problem characteristics and/or for getting an offline indication of the typical approximation error on a set of sample instances.

A third approach is however possible that consists in using the MP solver as a basic tool *within* the heuristic framework. This hybridization of MP with *metaheuristics* leads to the *matheuristic* approach, where the heuristic is built around the MP model. Matheuristics became popular in recent years, as witnessed by the publication of dedicated volumes and journal special issues [8, 19, 24] and by the dedicated sessions on MP and metaheuristic conferences.

Designing an effective heuristic is an art that cannot be framed into strict rules. This is particularly true when addressing a matheuristic, which is not a

rigid paradigm but a concept framework for the design of mathematically sound heuristics. In this chapter, we will therefore try to illustrate some main matheuristic features with the help of different examples of application.

Section "General-Purpose MIP-Based Heuristics" describes powerful general-purpose MIP heuristics that can be used within the matheuristic framework. Interestingly, these heuristics can themselves be viewed as the first successful applications of the matheuristic idea of hybridizing MP and metaheuristics. Indeed, as noticed in [8], one of the very first illustrations of the power of the matheuristic idea is the general-purpose local branching [7] paradigm, where a black-box MIP solver is used to explore a solution neighborhood defined by invalid constraints added to the MIP model for the sake of easing its solution.

Section "Application 1: Wind Farm Layout Optimization" addresses the design of a matheuristic for wind farm optimization. This application is used to illustrate the importance of the choice of the MIP model: models that are weak in polyhedral terms can be preferred to tighter—but computationally much harder—models when heuristic (as opposed to exact) solutions are required.

Section "Application 2: Prepack Optimization" addresses a packing problem where the model is nonlinear, and the matheuristic is based on various ways to linearize it after a heuristic fixing of some variables.

Finally, section "Application 3: Vehicle Routing" is used to illustrate an advanced feature of matheuristics, namely, the solution of auxiliary MP models that describe a subproblem in the solution process. In particular, we address a vehicle routing problem and derive a matheuristic based on a set-partitioning MIP model asking for the reallocation of a subset of customer sequences subject to capacity and distance constraints.

The present chapter is based on previously published work; in particular, sections "General-Purpose MIP-Based Heuristics," "Application 1: Wind Farm Layout Optimization," "Application 2: Prepack Optimization," and "Application 3: Vehicle Routing" are based on [8, 11, 13, 15], respectively.

General-Purpose MIP-Based Heuristics

Heuristics for general-purpose MIP solvers form the basis of the matheuristic's toolkit. Their relevance to our chapter is twofold. On the one hand, they are invaluable tools for the solution of the subproblems tailored by the matheuristic when applied to a specific problem. On the other hand, they illustrate the benefits for a general-purpose MIP solver deriving from the use of metaheuristic concepts such as local search and evolutionary methods.

Modern MIP solvers exploit a rich arsenal of tools to attack hard problems. It is widely accepted that the solution of hard MIPs can take advantage from the solution of a series of auxiliary linear programs (LPs) intended to enhance the performance of the overall MIP solver. For example, auxiliary LPs may be solved to generate powerful disjunctive cuts or to implement a strong branching policy. On the other

hand, it is a common experience that finding good-quality heuristic MIP solutions often requires a computing time that is just comparable to that needed to solve the LP relaxation. So, it makes sense to think of exact/heuristic MIP solvers where auxiliary MIPs (as opposed to LPs) are heuristically solved on the fly, with the aim of bringing the MIP technology under the chest of the MIP solver itself. This leads to the idea of "translating into a MIP model" (*MIPping* in the jargon of [9]) some crucial decisions to be taken when designing a MIP-based algorithm.

We next describe the new generation of MIP heuristics that emerged in the late 1990s, which are based on the idea of systematically using a "black-box" external MIP solver to explore a solution neighborhood defined by invalid linear constraints. We address a generic MIP of the form

$$\text{(MIP)} \qquad \min c^T x \tag{1}$$

$$Ax \geq b, \tag{2}$$

$$x_j \in \{0, 1\}, \quad \forall j \in \mathcal{B}, \tag{3}$$

$$x_j \text{ integer}, \quad \forall j \in \mathcal{G}, \tag{4}$$

$$x_j \text{ continuous}, \quad \forall j \in \mathcal{C}, \tag{5}$$

where A is an $m \times n$ input matrix and b and c are input vectors of dimension m and n, respectively. Here, the variable index set $\mathcal{N} := \{1, \ldots, n\}$ is partitioned into $(\mathscr{B}, \mathcal{G}, \mathcal{C})$, where $\mathscr{B}$ is the index set of the 0–1 variables (if any), while sets $\mathcal{G}$ and $\mathcal{C}$ index the general integer and the continuous variables, respectively. Removing the integrality requirement on variables indexed by $\mathcal{I} := \mathcal{B} \cup \mathcal{G}$ leads to the so-called *LP relaxation*.

Local Branching

The *local branching* (LB) scheme of Fischetti and Lodi [7] appears to be one of the first general-purpose heuristics using a black-box MIP solver applied to sub-MIPs, and it can be viewed as a precursor of matheuristics. Given a *reference solution* $\overline{x}$ of a MIP with $\mathcal{B} \neq \emptyset$, one aims at finding an improved solution that is "not too far" from $\overline{x}$, in the sense that not too many binary variables need be flipped. To this end, one can define the k-opt neighborhood $\mathcal{N}(\overline{x}, k)$ of $\overline{x}$ as the set of the MIP solutions satisfying the invalid *local branching constraint*

$$\Delta(x, \overline{x}) := \sum_{j \in \mathcal{B}: \overline{x}_j = 0} x_j + \sum_{j \in \mathcal{B}: \overline{x}_j = 1} \left(1 - x_j\right) \leq k, \tag{6}$$

for a small neighborhood radius k—an integer parameter typically set to 10 or 20. The neighborhood is then explored (possibly heuristically, i.e., with some small node or time limit) by means of a black-box MIP solver. Experimental results [10] show that the introduction of the local branching constraint typically has the positive effect of driving to integrality many component of the optimal solution of the LP relaxation, improving the so-called relaxation grip and hence the capability of the MIP solver to find (almost) optimal integer solutions within short computing times. Of course, this effect is lost if parameter k is set to a large value—a mistake that would make local branching completely ineffective.

LB is in the spirit of local search metaheuristics and, in particular, of *large-neighborhood search* (LNS) [29], with the novelty that neighborhoods are obtained through "soft fixing," that is, through invalid cuts to be added to the original MIP model. Diversification cuts can be defined in a similar way, thus leading to a flexible toolkit for the definition of metaheuristics for general MIPs.

Relaxation-Induced Neighborhood Search

The *relaxation-induced neighborhood search* (RINS) heuristic of Danna, Rothberg, and Le Pape [4] also uses a black-box MIP solver to explore a neighborhood of a given solution $\overline{x}$ and was originally designed to be integrated in a branch-and-bound solution scheme. At specified nodes of the branch-and-bound tree, the current LP relaxation solution x^* and the incumbent $\overline{x}$ are compared, and all integer-constrained variables that agree in value are fixed. The resulting MIP is typically easy to solve, as fixing reduces its size considerably, and often provides improved solutions with respect to $\overline{x}$.

Polishing a Feasible Solution

The *polishing* algorithm of Rothberg [27] implements an evolutionary MIP heuristic which is invoked at selected nodes of a branch-and-bound tree and includes all classical ingredients of genetic computation, namely:

- *Population*: A fixed-size population of feasible solutions is maintained. These solutions are either obtained within the branch-and-bound tree (by other heuristics) or computed by the polishing algorithm itself.
- *Combination*: Two or more solutions (the parents) are combined with the aim of creating a new member of the population (the child) with improved characteristics. The RINS scheme is adopted, that is, all variables whose value coincides in the parents are fixed, and the reduced MIP is heuristically solved by a black-box MIP solver within a limited number of branch-and-bound nodes. This scheme is clearly much more time-consuming than a classical combination step in evolutionary algorithms, but it guarantees the feasibility of the child solution.

- *Mutation*: Diversification is obtained by performing a classical mutation step that (i) randomly selects a "seed" solution in the population, (ii) randomly fixes some of its variables, and (iii) heuristically solves the resulting reduced MIP.
- *Selection*: Selection of the two parents to be combined is performed by randomly picking a solution in the population and then choosing, again at random, the second parent among those solutions with a better objective value.

Proximity Search

Proximity search [10] is a "dual version" of local branching that tries to overcome the issues related to the choice of the neighborhood radius k. Instead of hard-fixing the radius, proximity search fixes the minimum improvement of the solution value and changes the objective function to favor the search of solutions at small Hamming distance with respect to the reference one.

The approach works in stages, each aimed at producing an improved feasible solution. As in LB or RINS, at each stage a reference solution $\overline{x}$ is given, and one aims at improving it. To this end, an explicit cutoff constraint

$$c^T x \leq c^T \overline{x} - \theta \tag{7}$$

is added to the original MIP, where $\theta > 0$ is a given tolerance that specifies the minimum improvement required. The objective function of the problem can then be replaced by the proximity function $\Delta(x, \overline{x})$ defined in (6), to be minimized. One then applies the MIP solver, as a black box, to the modified problem in the hope of finding a solution better than $\overline{x}$. Computational experience confirms that this approach is quite successful (at least, on some classes of problems), due to the action of the proximity objective function that improves the "relaxation grip" of the model.

A simple variant of the above scheme, called "proximity search with incumbent," is based on the idea of providing $\overline{x}$ to the MIP solver as a starting solution. To avoid $\overline{x}$ be rejected because of the cutoff constraint (7), the latter is weakened to its "soft" version:

$$c^T x \leq c^T \overline{x} - \theta\,(1 - \xi) \tag{8}$$

while minimizing $\Delta(x, \overline{x}) + M\xi$ instead of just $\Delta(x, \overline{x})$, where $\xi \geq 0$ is a continuous slack variable and $M \gg 0$ is a large penalty.

Application 1: Wind Farm Layout Optimization

Green energy became a topic of great interest in recent years, as environmental sustainability asks for a considerable reduction in the use of fossil fuels. The *wind*

farm layout optimization problem aims at finding an allocation of turbines in a given site so as to maximize power output. This strategic problem is extremely hard in practice, both for the size of the instances in real applications and for the presence of several nonlinearities to be taken into account. A typical nonlinear feature of this problem is the interaction among turbines, also known as wake effect. The wake effect is the interference phenomenon for which, if two turbines are located one close to another, the upwind one creates a shadow on the one behind. Interference is therefore of great importance in the design of the layout as it results into a loss of power production for the turbine downstream.

We next outline the main steps in the design of a sound matheuristic scheme for wind farm layout optimization that is able to address the large-size instances arising in practical applications.

Choice of the MIP Model

Different models have been proposed in the literature to describe interference. We will consider first a simplified model from the literature [5], where the overall interference is the sum of pairwise interferences between turbine pairs. The model addresses the following constraints:

(a) A minimum and maximum number of turbines that can be built is given;
(b) There should be a minimal separation distance between two turbines to ensure that the blades do not physically clash (turbine distance constraints);
(c) If two turbines are installed, their interference will cause a loss in the power production that depends on their relative position and on wind conditions.

Let V denote the set of possible positions for a turbine, called "sites" in what follows, and let:

- N_{MIN} and N_{MAX} be the minimum and maximum number of turbines that can be built, respectively.
- D_{MIN} be the minimum distance between two turbines.
- $\text{dist}(i, j)$ be the Euclidean distance between sites i and j.
- I_{ij} be the interference (loss of power) experienced by site j when a turbine is installed at site i, with $I_{jj} = 0$ for all $j \in V$.
- P_i be the power that a turbine would produce if built (alone) at site i.

In addition, let $G_I = (V, E_I)$ denote the incompatibility graph with

$$E_I = \{[i, j] \in V \times V:\ \text{dist}(i, j) < D_{\text{MIN}},\ i < j\} \text{ let } n := |V|$$

denote the total number of sites. Two sets of binary variables are defined:

$$x_i = \begin{cases} 1 & \text{if a turbine is built at site } i; \\ 0 & \text{otherwise} \end{cases} \qquad (i \in V)$$

$$z_{ij} = \begin{cases} 1 & \text{if two turbines are built at both sites } i \text{ and } j; \\ 0 & \text{otherwise} \end{cases} \qquad (i, j \in V, i < j)$$

The model then reads

$$\max \sum_{i \in V} P_i x_i - \sum_{i \in V} \sum_{j \in V, i < j} \left(I_{ij} + I_{ji} \right) z_{ij} \tag{9}$$

$$\text{s.t.} \qquad N_{\text{MIN}} \leq \sum_{i \in V} x_i \leq N_{\text{MAX}} \tag{10}$$

$$x_i + x_j \leq 1 \qquad \forall [i, j] \in E_I \tag{11}$$

$$x_i + x_j - 1 \leq z_{ij} \qquad \forall i, j \in V, i < j \tag{12}$$

$$x_i \in \{0, 1\} \qquad \forall i \in V \tag{13}$$

$$z_{ij} \in \{0, 1\} \qquad \forall i, j \in V, i < j \tag{14}$$

Objective function (9) maximizes the total power production by taking interference losses I_{ij} into account. Constraints (11) model pairwise site incompatibility. Constraints (12) force $z_{ij} = 1$ whenever $x_i = x_j = 1$; because of the objective function, this is in fact equivalent to imposing $z_{ij} = x_i x_j$.

The definition of the turbine power vector (P_i) and of interference matrix (I_{ij}) depends on the wind scenario considered, which greatly varies in time. Using statistical data, one can in fact collect a large number K of wind scenarios k, each associated with a pair (P^k, I^k) with a probability π_k, and define the average power and interference to be used in the model as:

$$P_i := \sum_{k=1}^{K} \pi_k P_i^k \qquad \forall i \in V \tag{15}$$

$$I_{ij} := \sum_{k=1}^{K} \pi_k I_{ij}^k \qquad \forall i, j \in V \tag{16}$$

While (9), (10), (11), (12), (13), and (14) turn out to be a reasonable model when just a few sites have to be considered (say $n \approx 100$), it becomes hopeless when

$n \geq 1000$ because of the huge number of variables and constraints involved, which grow quadratically with n. Therefore, when facing instances with several thousand sites, an alternative (possibly weaker) model is required, where interference can be handled by a number of variables and constraints that grow just linearly with n. The model below is a compact reformulation of model (9), (10), (11), (12), (13), and (14) that follows a recipe of Glover [17] that is widely used, for example, in the quadratic assignment problem [12, 32]. The original objective function (to be maximized), rewritten as:

$$\sum_{i \in V} P_i x_i - \sum_{i \in V} \left(\sum_{j \in V} I_{ij} x_j \right) x_i \tag{17}$$

is restated as:

$$\sum_{i \in V} (P_i x_i - w_i) \tag{18}$$

where

$$w_i := \left(\sum_{j \in V} I_{ij}\, x_j \right) x_i = \begin{cases} \sum_{j \in V} I_{ij} x_j & \text{if } x_i = 1 \\ 0 & \text{if } x_i = 0 \end{cases}$$

$$\max z = \sum_{i \in V} (P_i x_i - w_i) \tag{19}$$

$$\text{s.t.} \qquad N_{\text{MIN}} \leq \sum_{i \in V} x_i \leq N_{\text{MAX}} \tag{20}$$

$$x_i + x_j \leq 1 \qquad \forall [i, j] \in E_I \tag{21}$$

$$\sum_{j \in V} I_{ij}\, x_j \leq w_i + M_i\, (1 - x_i) \qquad \forall i \in V \tag{22}$$

$$x_i \in \{0, 1\} \qquad \forall i \in V \tag{23}$$

$$w_i \geq 0 \qquad \forall i \in V \tag{24}$$

where the big-M term $M_i = \sum_{j \in V : [i,j] \notin E_I} I_{ij}$ is used to deactivate constraint (22) in case $x_i = 0$, in which case $w_i = 0$ because of the objective function.

Choice of Ad Hoc Heuristics

A simple 1-opt heuristic can be designed along the following lines. At each step, we have an incumbent solution, say $\tilde{x}$, that describes the best-known turbine allocation ($\tilde{x}_i = 1$ if a turbine is built at site i, 0 otherwise), and a current solution x. Let

$$z = \sum_{i \in V} P_i x_i - \sum_{i \in V} \sum_{j \in V} I_{ij}\, x_i\, x_j$$

be the profit of the current solution, $\gamma = \sum_{i \in V} x_i$ be its cardinality, and define for each $j \in V$ the extra-profit δ_j incurred when flipping x_j, namely:

$$\delta_j = \begin{cases} P_j - \sum\limits_{i \in V : x_i = 1} \left(I_{ij} + I_{ji}\right) & \text{if } x_j = 0; \\ -P_j + \sum\limits_{i \in V : x_i = 1} \left(I_{ij} + I_{ji}\right) & \text{if } x_j = 1 \end{cases}$$

where we assume $I_{ij} = BIG$ for all incompatible pairs $[i,j] \in E_I$, and BIG $> \sum_{i \in V} P_i$ is a large penalty value, while $I_{ii} = 0$ as usual.

We start with $x = 0$, $z = 0$, and $\gamma = 0$ and initialize $\delta_j = P_j$ for all $j \in V$. Then, we iteratively improve x by a sequence of 1-opt moves, according to the following scheme. At each iteration, we look in $O(n)$ time for the site j with maximum $\delta_j + \text{FLIP}(j)$, where function $FLIP(j)$ takes cardinality constraints into account, namely

$$\text{FLIP}(j) = \left\{ \begin{array}{lll} -\text{HUGE} & \text{if } x_j = 0 \text{ and } \gamma \geq N_{\text{MAX}} \\ -\text{HUGE} & \text{if } x_j = 1 \text{ and } \gamma \leq N_{\text{MIN}} \\ +\text{HUGE} & \text{if } x_j = 0 \text{ and } \gamma < N_{\text{MIN}} \\ +\text{HUGE} & \text{if } x_j = 1 \text{ and } \gamma > N_{\text{MAX}} \\ 0 & \text{otherwise} \end{array} \right\}$$

Once the best j has been found, say j^*, if $\delta_{j^*} + FLIP(j^*) > 0$, we just flip x_{j^*}; update x, z, and γ in $O(1)$ time; update all δ_j's in $O(n)$ time (through the parametric technique described in [11]); and repeat. In this way, a sequence of improving solutions is obtained, until a local optimal solution that cannot be improved by just one flip is found. To escape local minima, a simple perturbation scheme can be implemented; see again [11] for details.

A 2-opt heuristic can similarly be implemented to allow a single turbine to move to a better site—a move that requires flipping two variables. Each 2-opt exchange requires $O(n^2)$ time as it amounts to trying n 1-opt exchanges and to apply the best one.

The Overall Matheuristic

Our final approach is a mixture of ad hoc (1- and 2-opt) and general MIP (proximity search with incumbent) heuristics and works as shown in Algorithm 1.

Algorithm 1: The Overall Matheuristic Framework
1: read input data and compute the overall interference matrix (I_{ij});
2: apply ad hoc heuristics (1- and 2-opt) to get a first incumbent $\tilde{x}$;
3: **while** time limit permits **do**
4: apply quick ad hoc refinement heuristics (few iterations of 1- and 2-opt) to possibly improve $\tilde{x}$;
5: if $n > 2000$, randomly remove points $i \in V$ with $\tilde{x}_i = 0$ so as to reduce the number of candidate sites to 2000;
6: build a MIP model for the resulting subproblem and apply proximity search to refine $\tilde{x}$ until the very first improved solution is found (or time limit is reached);
7: **end while**
8: **return** $\tilde{x}$

At Step 2, the heuristics of the section "Choice of Ad Hoc Heuristics" are applied in their "initial-solution" mode, where one starts with $\tilde{x} = x = 0$ and aborts execution when 1-opt is invoked 10,000 consecutive times without improving $\tilde{x}$. At Step 4, instead, a faster "cleanup" mode is applied. As we already have a hopefully good incumbent $\tilde{x}$ to refine, we initialize $x = \tilde{x}$ and repeat the procedure until we count 100 consecutive 1-opt calls with no improvement of $\tilde{x}$. As to time-consuming 2-opt exchanges, they are applied with a certain frequency and in any case just before the final $\tilde{x}$ is returned.

Two different MIP models are used to feed the proximity-search heuristic at Step 6. During the first part of the computation, we use a simplified MIP model obtained from (19), (20), (21), (22), (23), and (24) by removing all interference constraints (22), thus obtaining a much easier problem. A short time limit is imposed for each call of proximity search when this simplified model is solved. In this way, we aggressively drive the solution $\tilde{x}$ to increase the number of built turbines, without being bothered by interference considerations and only taking pairwise incompatibility (21) into account. This approach quickly finds better and better solutions (even in terms of the true profit), until either (i) no additional turbine can be built or (ii) the addition of new turbines does in fact *reduce* the true profit associated with the new solution because of the neglected interference. In this situation, we switch to the complete model (19), (20), (21), (22), (23), and (24) with all interference constraints, which is used in all next executions of Step 6. Note that the simplified model is only used at Step 6, while all other steps of the procedure always use the true objective function that takes interference into full account.

Computational Results

The following alternative solution approaches were implemented in C language, some of which using the commercial MIP-solver IBM ILOG Cplex 12.5.1 [21]; because of the big-Ms involved in the models, all Cplex's codes use zero as integrality tolerance (`CPX_PARAM_EPINT` $= 0.0$).

(a) `proxy`: The matheuristic outlined in the previous section, built on top of Cplex with the following aggressive parameter tuning: all cuts deactivated, `CPX_PARAM_RINSHEUR` $= 1$, `CPX_PARAM_POLISHAFTERTIME` $= 0.0$, `CPX_PARAM_INTSOLLIM` $= 2$;
(b) `cpx_def`: The application of IBM ILOG Cplex 12.5.1 in its default setting, starting from the same heuristic solution $\tilde{x}$ available right after the first execution of Step 2 of Algorithm 1;
(c) `cpx_heu`: Same as `cpx_def`, with the following internal tuning intended to improve Cplex's heuristic performance: all cuts deactivated, `CPX_PARAM_RINSHEUR` $= 100$, `CPX_PARAM_POLISHAFTERTIME` $= 20\%$ of the total time limit;
(d) `loc_sea`: A simple heuristic not based on any MIP solver, that just loops on Step 4 of Algorithm 1 and randomly removes installed turbines from the current best solution after 10,000 iterations without improvement of the incumbent.

For each algorithm, we recorded the best solution found within a given time limit.

In our view, `loc_sea` is representative of a clever but not oversophisticated metaheuristic, as typically implemented in practice, while `cpx_def` and `cpx_heu` represent a standard way of exploiting a MIP model once a good feasible solution is known.

Our test bed refers to an offshore 3000×3000 (m) square with $D_{\text{MIN}} = 400$ (m) minimum turbine separation, with no limit on the number of turbines to be built (i.e., $N_{\text{MIN}} = 0$ and $N_{\text{MAX}} = +\infty$). Turbines are all of Siemens SWT-2.3-93 type (rotor diameter 93 m), which produces a power of 0.0 MW for wind speed up to 3 m/s, of 2.3 MW for wind speed greater than or equal to 16 m/s, and intermediate values for winds in range 3–16 m/s according to a nonlinear power curve [30]. Pairwise interference (in MW) was computed using Jensen's model [22], by averaging 250,000+ real-world wind samples. Those samples were grouped into about 500 macro-scenarios to reduce the computational time spent for the definition of the interference matrix. A pairwise average interference of 0.01 MW or less was treated as zero. The reader is referred to [6] for details.

We generated five classes of medium-to-large problems with n ranging from 1000 to 20,000. For each class, ten instances have been considered by generating n uniformly random points in the 3000×3000 square. (Although in the offshore case turbine positions are typically sampled on a regular grid, we decided to randomly generate them to be able to compute meaningful statistics for each value of n.)

In what follows, reported computing times are in CPU seconds of an Intel Xeon E3-1220 V2 quad-core PC with 16 GB of RAM and do not take Step 1 of Algorithm 1 into account as the interference matrix is assumed to be precomputed and reused at each run.

Computational results on our instances are given in Table 1, where each entry refers to the performance of a given algorithm at a given time limit. In particular, the left part of the table reports, for each algorithm and time limit, the *number of wins*, that is, the number of instances for which a certain algorithm produced the best-known solution at the given time limit (ties allowed).

According to the table, `proxy` outperforms all competitors by a large amount for medium-to-large instances. As expected, `cpx_heu` performs better for instances with $n = 1000$ as it is allowed to explore a large number of enumeration nodes for the original model and objective function. Note that `loc_sea` has a good performance for short time limits and/or for large instances, thus confirming its effectiveness, whereas `cpx_heu` is significantly better than `loc_sea` only for small instances and large time limits.

A different performance measure is given in the right-hand side part of Table 1, where each entry gives the *average optimality ratio*, that is, the average value of the ratio between the solution produced by an algorithm (on a given instance at a given time limit) and the best solution known for that instance—the closer to one, the better. It should be observed that an improvement of just 1% has a very significant economical impact due to the very large profits involved in the wind farm context. The results show that `proxy` is always able to produce solutions that are quite close to the best one. As before, `loc_sea` is competitive for large instances when a very small computing time is allowed, whereas `cpx_def` and `cpx_heu` exhibit a good performance only for small instances and are dominated even by `loc_sea` for larger ones.

Application 2: Prepack Optimization

Packing problems play an important role in industrial applications. In these problems, a given set of *items* has to be packed into one or more containers (*bins*) so as to satisfy a number of constraints and to optimize some objective function.

Most of the contributions from the literature are devoted to the case where all the items have to be packed into a minimum number of bins so as to minimize, for example, transportation costs; within these settings, only loading costs are taken into account. The resulting problem is known as the *bin packing problem* and has been widely studied in the literature both in its one-dimensional version [25] and in its higher-dimensional variants [23].

We will next consider a different packing problem arising in inventory allocation applications, where the operational cost for packing the bins is comparable, or even higher, than the cost of the bins themselves. This is the case, for example, for

Table 1 Number of times each algorithm finds the best-known solution within the time limit (wins) and optimality ratio with respect to the best-known solution—the larger, the better

		Number of wins				Optimality ratio			
n	Time limit (s)	proxy	cpx_def	cpx_heu	loc_sea	proxy	cpx_def	cpx_heu	loc_sea

warehouses that have to manage a large number of different customers (e.g., stores), each requiring a given set of items. Assuming that automatic systems are available for packing, the required workforce is related to the number of different ways that are used to pack the bins to be sent to the customers. To limit this cost, a hard constraint can be imposed on the total number of different box configurations that are used.

Prepacking items into box configurations has obvious benefits in terms of easier and cheaper handling, as it reduces the amount of material handled by both the warehouse and the customers. However, the approach can considerably reduce the flexibility of the supply chain, leading to situations in which the set of items that are actually shipped to each customer may slightly differ from the required one—at the expense of some cost in the objective function. In addition, an upper bound on overstocking is usually imposed for each store.

The resulting problem, known as *prepack optimization problem* (POP), was recently addressed in [20], where a real-world application in the fashion industry is presented, and heuristic approaches are derived using both constraint programming (CP) and MIP techniques.

Mathematical Model

In this section, we briefly formalize POP and review the mathematical model introduced in [20]. We are given a set I of types of products and a set S of stores. Each store $s \in S$ requires an integer number r_{is} of products of type $i \in I$. Bins with different capacities are available for packing items: we denote by $K \subset Z_+$ the set of available bin capacities.

Bins must be completely filled and are available in an unlimited number for each type. A *box configuration* describes the packing of a bin, in terms of the number of products of each type that are packed into it. We denote by NB the maximum number of box configurations that can be used for packing all products and by $B = \{1, \ldots, NB\}$ the associated set.

Products' packing into boxes is described by integer variables y_{bi}: for each product type $i \in I$ and box configuration $b \in B$, the associated variable y_{bi} indicates the number of products of type i that are packed into the b-th box configuration. In addition, integer variables x_{bs} are used to denote the number of bins loaded according to box configuration b that have to be shipped to store $s \in S$.

Understocking and overstocking of product i at store s are expressed by decisional variables u_{is} and o_{is}, respectively. Positive costs α and β penalize each unit of under- and overstocking, respectively, whereas an upper bound δ_{is} on the maximum overstocking of each product at each store is also imposed.

Finally, for each box configuration $b \in B$ and capacity value $k \in K$, a binary variable t_{bk} is introduced that takes value 1 if box configuration b corresponds to a bin of capacity k.

Additional integer variables used in the model are $q_{bis} = x_{bs}y_{bi}$ (number of items of type i sent to store s through boxes loaded with configuration b); hence, $\sum_{b \in B} q_{bis}$ gives the total number of products of type i that are shipped to store s.

A mixed-integer nonlinear programming (MINLP) model then reads:

$$\min \sum_{s \in S} \sum_{i \in I} (\alpha u_{is} + \beta o_{is}) \tag{25}$$

$$q_{bis} = x_{bs} y_{bi} \quad (b \in B; i \in I; s \in S) \tag{26}$$

$$\sum_{b \in B} q_{bis} - o_{is} + u_{is} = r_{is} \quad (i \in I; s \in S) \tag{27}$$

$$\sum_{i \in I} y_{bi} = \sum_{k \in K} k\, t_{bk} \quad (b \in B) \tag{28}$$

$$\sum_{k \in K} t_{bk} = 1 \quad (b \in B) \tag{29}$$

$$o_{is} \leq \delta_{is} \quad (i \in I; s \in S) \tag{30}$$

$$t_{bk} \in \{0, 1\} \quad (b \in B; k \in K) \tag{31}$$

$$x_{bs} \geq 0 \ \text{ integer} \quad (b \in B; s \in S) \tag{32}$$

$$y_{bi} \geq 0 \ \text{ integer} \quad (b \in B; i \in I) \tag{33}$$

The model is of course nonlinear, as the bilinear constraints (26) involve the product of decision variables. To derive a linear MIP model, the following standard technique can be used. Each x_{bs} variable is decomposed into its binary expansion using binary variables v_{bsl} ($l = 0, \ldots, L$), where L is easily computed from an upper bound on x_{bs}. When these variables are multiplied by y_{bi}, the corresponding product $w_{bisl} = v_{bsl}\, y_{bi}$ are linearized with the addition of suitable constraints.

Our final MIP is therefore obtained from (25), (26), (27), (28), (29), (30), (31), (32), and (33) by adding

$$x_{bs} = \sum_{l=0}^{L} 2^l v_{bsl} \quad (b \in B; s \in S) \tag{34}$$

$$v_{bsl} \in \{0, 1\} \quad (b \in B; s \in S; l = 0, \ldots, L) \tag{35}$$

and by replacing each nonlinear Eq. (26) with the following set of new variables and constraints:

$$q_{bis} = \sum_{l=0}^{L} 2^l w_{bisl} \quad (b \in B; i \in I; s \in S) \tag{36}$$

$$w_{bisl} \leq \overline{Y} v_{bsl} \quad (b \in B; i \in I; s \in S; l = 0, \ldots, L) \tag{37}$$

$$w_{bisl} \leq y_{bi} \quad (b \in B; i \in I; s \in S; l = 0, \ldots, L) \tag{38}$$

$$w_{bisl} \geq y_{bi} - \overline{Y}(1 - v_{bsl}) \quad (b \in B; i \in I; s \in S; l = 0, \ldots, L) \tag{39}$$

$$w_{bisl} \geq 0 \quad (b \in B; i \in I; s \in S; l = 0, \ldots, L) \tag{40}$$

where $\overline{Y}$ denotes an upper bound on the y variables.

In case all capacities are even, the following constraint—though redundant—plays a very important role in improving the LP bound of our MIP model:

$$\sum_{i \in I} (u_{is} + o_{is}) \geq 1 \quad \left(s \in S : \sum_{i \in I} r_{is} \text{ is odd} \right) \tag{41}$$

Matheuristics

The MIP model of the previous subsection is by far too difficult to be addressed by standard solvers. As a matter of fact, for real-world cases even the LP relaxation at each node turns out to be very time consuming. So we designed ad hoc heuristic approaches to exploit the special structure of our MIP, following the matheuristic paradigm.

Each heuristic is based on the idea of iteratively solving a restricted problem obtained by fixing a subset of variables, so as to obtain a subproblem which is (reasonably) easy to solve by a commercial MIP solver, but still able to produce improved solutions.

Two kinds of heuristics can be implemented: constructive and refinement heuristics. Constructive heuristics are used to find a solution H starting from scratch. In a refinement heuristic, instead, we are given a heuristic solution $H = (x^H, y^H)$ that we would like to improve. We first fix some x and/or y variables to their value in H, thus defining a solution neighborhood $\mathcal{N}(H)$ of H. We then search $\mathcal{N}(H)$ by using a general-purpose MIP solver on the model resulting from fixing. If an improved solution is found within the given time limit, we update H and repeat; otherwise, a new neighborhood is defined in the attempt to escape the local optimum.

Fixing All *x* or *y* Variables

A first obvious observation is that our basic MINLP model (25), (26), (27), (28), (29), (30), (31), (32), and (33) reduces to a linear MIP if all the x (or all the y) variables are fixed, as constraints (26) trivially become linear. According to our experience, the resulting MIP (though nontrivial) is typically solved very quickly by a state-of-the-art solver, meaning that one can effectively solve a sequence of restricted MIPs where x and y are fixed, in turn, until no further improvement can be obtained.

Let $\mathcal{N}_y(H)$ and $\mathcal{N}_x(H)$ denote the solution neighborhoods of H obtained by leaving y or x free, that is, when imposing $x = x^H$ or $y = y^H$, respectively.

A basic tool that we use in our heuristics is function REOPT (S', y^H) that considers a store subset $S' \subseteq S$ and a starting y^H and returns the best solution H obtained by iteratively optimizing over the neighborhoods $\mathcal{N}_x(H)$, $\mathcal{N}_y(H)$, $\mathcal{N}_x(H)$, etc., after having removed all stores not in S', H being updated after each optimization.

Fixing *y* Variables for All But One Configuration

Another interesting neighborhood, say $\mathcal{N}_x\left(H, y_\beta\right)$, is obtained by leaving all x variables free and by fixing $y_{bi} = y^H_{bi}$ for all $i \in I$ and $b \in B\backslash\{\beta\}$ for a given $\beta \in B$. In other words, we allow for changing just one (out of NB) configuration in the current solution, and leave the solver the possibility to change the x variables as well.

In our implementation, we first define a random permutation $\{\beta_1, \ldots, \beta_{NB}\}$ of B. We then optimize, in a circular sequence, neighborhoods $\mathcal{N}_x\left(H, y_{\beta_t}\right)$ for $t = 1, \ldots, NB, 1, \ldots$ Each time an improved solution is found, we update H and further refine it through function REOPT (S, y^H). The procedure is stopped when there is no hope of finding an improved solution, that is, after NB consecutive optimizations that do not improve the current H.

A substantial speedup can be obtained by heuristically imposing a tight upper bound on the x variables, so as to reduce the number $L + 1$ of binary variables v_{bsl} in the binary expansion (34). An aggressive policy (e.g., imposing $x_{bs} \leq 1$) is however rather risky as the optimal solution could be cut off; hence, the artificial bounds must be relaxed if an improved solution cannot be found.

Working with a Subset of Stores

Our basic constructive heuristic is based on the observation that removing stores can produce a substantially easier model. Note that a solution $H' = (x', y')$ with a subset of stores can easily be converted into a solution $H = (x, y)$ of the whole problem by just invoking function REOPT (S, y').

In our implementation, we first define a store permutation $s_1, \ldots, s_{|S|}$ according to a certain criterion (to be discussed later). We then address, in sequence, the subproblem with store set $S_t = \{s_1, \ldots, s_t\}$ for $t = 0, \ldots, |S|$.

For $t = 0$, store set S_0 is empty and our MIP model just produces a y solution with random (possibly repeated) configurations.

For each subsequent t, we start with the best solution $H_{t-1} = (xt^{-1}, yt^{-1})$ of the previous iteration and convert it into a solution $H_t = (x^t, y^t)$ of the current subproblem through the refining function `REOPT` (S_t, y^{t-1}). Then we apply the refinement heuristics described in the previous subsection to $H\,t$, reoptimizing one configuration at a time in a circular vein. To reduce computing time, this latter step can be skipped with a certain frequency—except of course in the very last step when $S_t = S$.

Each time a solution $H_t = (x^t, y^t)$ is found, we quickly compute a solution $H = (x, y)$ of the overall problem through function `REOPT` (S, y^t) and update the overall incumbent where all stores are active.

As to store sequence $s_1, \ldots, s_{|S|}$, we have implemented three different strategies to define it. For each store pair a, b, let the dissimilarity index dist(a, b) be defined as the distance between the two demand vectors $(r_{ia} : i \in I)$ and $(r_{ib} : i \in I)$.

- `random`: The sequence is just a random permutation of the integers $1, \ldots, |S|$;
- `most_dissimilar`: We first compute the two most dissimilar stores (a, b), that is, such that $a < b$ and dist(a, b) is a maximum and initialize $s_1 = a$. Then, for $t = 2, \ldots, |S|$, we define $S' = \{s_1, \ldots, s_{t-1}\}$ and let

$$s_t = \operatorname{argmax}_{a \in S \setminus S'} \left\{ \min \left\{ \operatorname{dist}(a, b) : b \in S' \right\} \right\}$$

- `most_similar`: This is just the same procedure as in the previous item, with max and min operators reverted.

The rational of the `most_dissimilar` policy is to attach first a "core problem" defined by the pairwise most dissimilar stores (those at the beginning of the sequence). The assumption here is that our method performs better in its first iterations (small values of t) as the size of the subproblem is smaller, and we have plenty of configurations to accommodate the initial requests. The "similar stores" are therefore addressed only at a later time, in the hope that the found configurations will work well for them.

A risk with the above policy is that the core problem becomes soon too difficult for our simple refining heuristic, so the current solution is not updated after the very first iterations. In this respect, policy `most_similar` is more conservative: given for granted that we proceed by subsequently refining a previous solution with one less store, it seems reasonable not to inject too much innovation in a single iteration—as `most_dissimilar` does when it adds a new store with very different demands with respect to the previous ones.

Computational Experiments

The heuristics described in the previous section have been implemented in C language. IBM ILOG CPLEX 12.6 [21] was used as MIP solver. Reported computing

times are in CPU seconds of an Intel Xeon E3-1220 V2 quad-core PC with 16 GB of RAM. For each run, a time limit of 900 s (15 m) was imposed.

Four heuristic methods have been compared: the three construction heuristics `random`, `most_dissimilar`, and `most_similar` of section "Working with a Subset of Stores," plus

- `fast_heu`: The fast refinement heuristic of section "Fixing y Variables for All but One Configuration" applied starting from a null solution $x = 0$.

All heuristics are used in a multi-start mode; for example, after completion, they are just restarted from scratch until the time limit is exceeded. At each restart, the internal random seed is not reset; hence, all methods natively using a random permutation (namely, `fast_heu` and `random`) will follow a different search path at each run as the permutations will be different. As to `most_dissimilar` and `most_similar`, after each restart the sequence $s_1, \ldots, s_{|S|}$ is slightly perturbed by five random pair swaps. In addition, after each restart the CPLEX's random seed is changed so as to inject diversification among runs even within the MIP solver.

Due to their heuristic nature, our methods—though deterministic—exhibit a large dependency on the initial conditions, including the random seeds used both within our code and in CPLEX. We therefore repeated several times each experiment, starting with different (internal/CPLEX) random seeds at each run, and also report average figures.

In case all capacities are even (as it is the case in our test bed), we compute the following trivial lower bound based on constraint (42):

$$LB := \min\{\alpha, \beta\} \cdot \left| \left\{ s \in S : \sum_{i \in I} r_{is} \ \text{ is odd} \right\} \right| \tag{42}$$

and abort the execution as soon as we find a solution whose value meets the lower bound.

Test Bed

Our test bed coincides with the benchmark proposed in [20] and contains a number of subinstances of a real-world problem (named `AllColor58`) with 58 stores that require 24 ($= 6 \times 4$) different items: T-shirts available in six different sizes and four different colors (black, blue, red, and green). The available box capacities are 4, 6, 8, and 10. Finally, each item has a given overstock limit (0 or 1) for all stores but no understock limits, and the overstock and understock penalties are $\beta = 1$ and $\alpha = 10$, respectively.

Note that our testing environment is identical to that used in [20] (assuming the PC used are substantially equivalent), so our results can fairly be benchmarked against those therein reported.

Comparison Metric

To better compare the performance of our different heuristics, we also make use of an indicator recently proposed by [1, 2] and aimed at measuring the trade-off between the computational effort required to produce a solution and the quality of the solution itself. In particular, let $\tilde{z}_{\text{opt}}$ denote the optimal solution value and let $z(t)$ be the value of the best heuristic solution found at a time t. Then, a *primal gap function* p can be computed as

$$p(t) = \begin{cases} 1 & \text{if no incumbent found until time } t \\ \gamma\left(z(t)\right) & \text{otherwise} \end{cases} \tag{43}$$

where $\gamma(\cdot) \in [0, 1]$ is the *primal gap*, defined as follows

$$\gamma(z) = \begin{cases} 0 & \text{if } \ |\,\tilde{z}_{\text{opt}}\,| \;=\; |\,z\,| \;=\; 0, \\ 1 & \text{if } \ \tilde{z}_{\text{opt}} \;\cdot\; z < 0, \\ \frac{z - \tilde{z}_{\text{opt}}}{\max\left\{|\tilde{z}_{\text{opt}}|, |z|\right\}} & \text{otherwise.} \end{cases} \tag{44}$$

Finally, the *primal integral* of a run until time $t_{\max}$ is defined as

$$P\left(t_{\max}\right) = \frac{\int_0^{t_{\max}} p(t)\,\mathrm{d}t}{t_{\max}} \tag{45}$$

and is actually used to measure the quality of primal heuristics—the smaller $P(t_{\max})$, the better the expected quality of the incumbent solution if we stopped computation at an arbitrary time before $t_{\max}$.

Computational Results

We addressed the instances provided in [20], with the aim of benchmarking our matheuristics against the methods therein proposed. Results for the easiest cases involving only NB = 4 box configurations (namely, instances Black58, Blue58, Red58, and Green58) are not reported as the corresponding MIP model can be solved to proven optimality in less than one second by our solver—thus confirming the figures given in [20].

Tables 2 and 3 report the performance of various heuristics in terms of solution value and time and refer to a single run for each heuristic and for each instance.

Table 2 Performance of CPLEX and LNSheuristics from [20]. Single run for each instance. Times in CPU seconds (time limit of 900 s)

		CPLEX		LNS	
Instance	*NB*	Value	Time (s)	Value	Time (s)

AllColor58	42	141	71	273	722	614	105	53	66

Table 2 is taken from [20], where a two-phase hybrid metaheuristic was proposed. In the first phase, the approach uses a memetic algorithm to explore the solution space and builds a pool of interesting box configurations. In the second phase, a box-to-store assignment problem is solved to choose a subset of configurations from the pool—and to decide how many boxes of each configuration should be sent to each store. The box-to-store assignment problem is modeled as a (very hard in practice) MIP and heuristically solved either by a commercial solver (CPLEX) or by a sophisticated large-neighborhood search (LNS) approach.

Table 3 reports the performance of our four matheuristics, as well as the lower bound value *LB* computed through (43)—this latter value turned out to coincide with the optimal value for all instances under consideration in the present subsection.

Comparing Tables 2 and 3 shows that matheuristics outperform the LNS heuristics analyzed in [20]. In particular, `fast_heu` is able to find very good solutions (actually, an optimal one in 3 out of 4 cases) within very short computing times. For the largest instance (AllColor58), however, `most_similar` qualifies as the best heuristic both in terms of quality and speed.

To get more reliable information about the matheuristics' performance, we ran them 100 times for each instance, with different random seeds, and took detailed statistics on each run. Table 4 reports, for each instance and for each heuristic, the average completion time (time), the average time to find its best solution (time_best), the primal integral after 900 s (pint, the lower the better), and the number of provably optimal solutions found (#opt) out of the 100 runs. Note that, for all instances, a solution matching the simple lower bound (43) was eventually found by at least one of our heuristics.

The 100-run statistics confirm that `fast_heu` is very effective in all cases, though it is outperformed by `most_similar` for the largest instance AllColor58 with respect to the #opt criterion. The results suggest that a hybrid method running `fast_heu` and `most_similar` (possibly in parallel) qualifies a robust heuristic with a very good performance for all instances.

Table 4 Average performance (out of 100 runs) of our heuristics

Instance	Heuristic	Time (s)	Time_best (s)	Pint	#opt
BlackBlue10	`fast_heu`	1.08	1.08	0.34	100
	`Random`	1.44	1.44	0.27	100
	`most_dissimilar`	1.26	1.26	0.25	100

	`most_similar`	859.86	287.50	404.29	1

Application 3: Vehicle Routing

In this section, we address the NP-hard ***distance-constrained capacitated vehicle routing problem*** (DCVRP) that can be defined as follows. We are given a central depot and a set of $n - 1$ customers, which are associated with the nodes of a complete undirected graph $G = (V, E)$ where $|V| = n$, node 1 representing the depot. Each edge $[i,j] \in E$ has an associated finite cost $c_{ij} \geq 0$. Each node $j \in V$ has a request $d_j \geq 0$ ($d_1 = 0$ for depot node 1). Customers need to be served by k cycles (*routes*) passing through the depot, where k is fixed in advance. Each route must have a total duration (computed as the sum of the edge costs in the route) not exceeding a given limit D and can visit a subset S of customers whose total request $\sum_{j \in s} dj$ does not exceed a given capacity C. The problem then consists of finding a feasible solution covering exactly once all the nodes $v \in V\backslash\{1\}$ and having a minimum overall cost; see, for example, [3, 31].

We will next outline the refinement matheuristic for DCVRP proposed in [15].

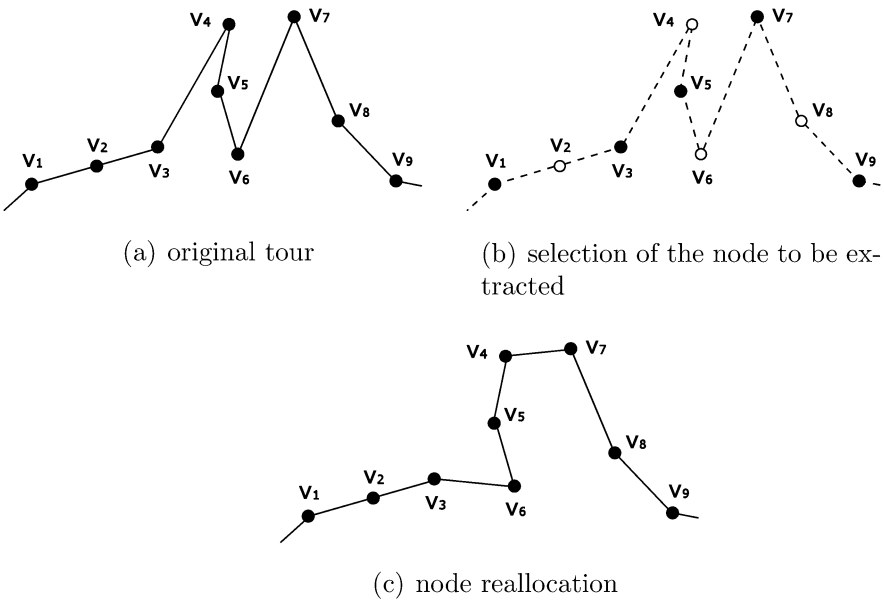
The ASSIGN Neighborhood for TSP

Sarvanov and Doroshko (SD) investigated in [28] the so-called ASSIGN neighborhood for the pure Traveling Salesman Problem (TSP), that is, for the problem of finding a min-cost Hamiltonian cycle in a graph. Given a certain TSP solution (viewed as node sequence $<v_1 = 1, v_2, \cdots, v_n>$), the neighborhood contains all the $\lfloor n/2 \rfloor !$ TSP solutions that can be obtained by permuting, in any possible

way, the nodes in even position in the original sequence. In other words, any solution $(\psi_1, \psi_2, \cdots, \psi_n)$ in the neighborhood is such that $\psi_i = v_i$ for all odd i. An interesting feature of the neighborhood is that it can be explored exactly in polynomial time, though it contains an exponential number of solutions. Indeed, for any given starting solution, the min-cost TSP solution in the corresponding ASSIGN neighborhood can be found efficiently by solving a min-cost assignment problem on a $\lfloor n/2 \rfloor \times \lfloor n/2 \rfloor !$ matrix; see, for example, [18]. Starting from a given solution, an improving heuristic then consists of exploring the ASSIGN neighborhood according to the following two phases:

- *node extraction*, during which the nodes in even position (w.r.t. the current solution) are removed from the tour, thus leaving an equal number of "free holes" in the sequence
- *node reinsertion*, during which the removed nodes are reallocated to the available holes in an optimal way by solving a min-sum assignment problem

The simple example in Fig. 1 gives an illustration of the kind of "improving moves" involved in the method. The figure draws a part of a tour, corresponding to the node sequence $\langle v_1, v_2, \cdots, v_9 \rangle$. In the node extraction phase, the nodes in even position v_2, v_4, v_6 e v_8 are removed from the sequence, whereas all the other nodes retain their position. In Fig. 1b the black nodes represent the fixed ones, while the holes left by the extracted nodes are represented as white circles. If we use symbol "–" to represent a free hole, the sequence corresponding to Fig. 1b is therefore



(a) original tour

(b) selection of the node to be extracted

(c) node reallocation

Fig. 1 A simple example of node extraction and reallocation

$\langle v_1, -, v_3, -, v_5, -, v_7, -, v_9 \rangle$. The second step of the procedure, that is, the optimal node reallocation, is illustrated in Fig. 1c, where nodes v_4 and v_6 swap their position, whereas v_2 and v_8 are reallocated as in the original sequence. This produces the improved part of tour $\langle v_1, v_2, v_3, v_6, v_5, v_4, v_7, v_8, v_9 \rangle$.

In the example, the same final tour could have been constructed by a simple 2-opt move. However, for more realistic cases, the number of possible reallocation is exponential in the number of extracted nodes; hence, the possible reallocation patterns are much more complex and allow, for example, for a controlled worsening of some parts of the solution which are compensated by large improvement in other parts.

From TSP to DCVRP

One can conjecture that the ASSIGN neighborhood would work well if applied to VRP problems. Indeed, due to the presence of several routes and of the associated route constraints, in VRP problems the node sequence is not the only issue to be considered when constructing a good solution: an equally important aspect of the optimization is to find a balanced distribution of the nodes between the routes. In this respect, heuristic refinement procedures involving complex patterns of node reallocations among the routes likely are quite effective in practice.

We can therefore extend the SD method to DCVRP so as to allow for more powerful move patterns, while generalizing its basic scheme so as to get rid of the too-simple min-sum assignment model for node reallocation in favor of a more flexible reallocation model based on the (heuristic) solution of a more complex MIP model. The resulting matheuristic will be introduced, step by step, with the help of some illustrative examples.

Let us consider Fig. 2, where a nonoptimal part of a VRP solution is depicted. It is clear that the position of node v_3 is not very clever, in that inserting v_3 between node v_1 and v_2 is likely to produce a better solution (assuming this new solution is not infeasible because of the route constraints). Even if v_3 were an even position node, however, this move would be beyond the possibility of the pure SD method, where the extracted nodes can only be assigned to a hole left free by the removal of another node—while no hole between v_1 e v_2 exists which could accommodate v_3. The example then suggests a first extension of the basic SD method, consisting of removing the 1–1 correspondence between extracted nodes and empty holes. We therefore consider the concept of *insertion point*: after having extracted the selected nodes, we construct a *restricted solution* through the remaining nodes, obtained from the original one by short-cutting the removed nodes. All the edges in the restricted solution are then viewed as potential insertion points for the extracted nodes. In the example, removing v_3 but not v_1 and v_2 would produce the restricted solution depicted in Fig. 3a, where all dashed edges are possible insertion points for the extracted nodes—this allows the method to produce the solution in Fig. 3b.

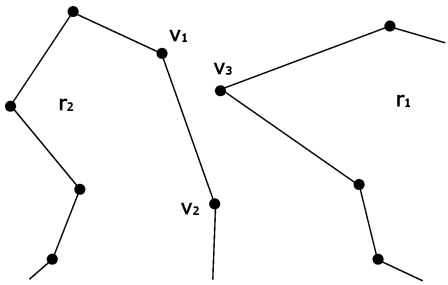


Fig. 2 The assignment of node v_3 to route r_1 is nonoptimal

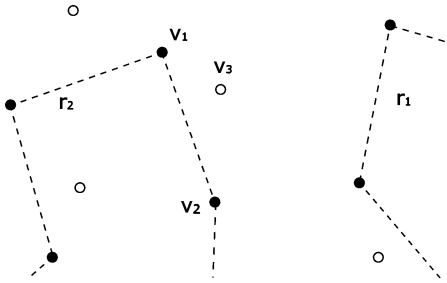
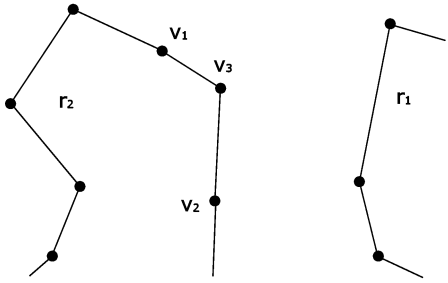


(a) Restricted solution



(b) Final solution

Fig. 3 Improving the solution depicted in Fig. 2

A second important extension comes from a more flexible node extraction scheme that allows for the removal of a *sequence* of nodes; see Fig. 4 for an illustration. Once a sequence of nodes has been extracted, one can use a heuristic procedure to generate *new* sequences through the extracted nodes, to be allocated to different insertion points. To be more specific, starting from the extracted node sequences, one can create new *derived sequences* that combine the extracted nodes in a different way and consider the possibility of assigning each derived sequence to a different insertion point. Of course, one never knows in advance which are the best sequences to be used, so all the (original and derived) sequences should be available when solving the reallocation problem.

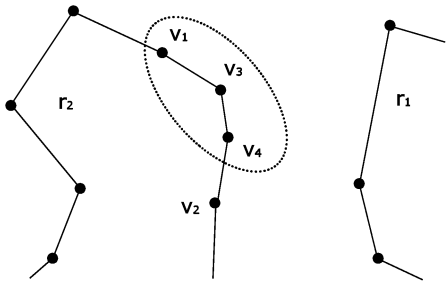


Fig. 4 Removing a sequence of nodes to better reallocate them (possibly in a different order)

The above considerations imply the use of a reallocation model which goes far beyond the scope of the original one, which is based on the solution of an easy min-cost assignment problem. Indeed, the new reallocation model becomes a MIP that receives as input the set of insertion points along with a (typically large) set of node sequences through the extracted nodes and provides an (almost) optimal allocation of at most one sequence to each insertion point, with the constraint that each extracted node has to belong to one of the allocated sequences, while fulfilling the additional constraints on the capacity and distance constraints on the routes. This model will be described in more detail in the next section.

The Overall Matheuristic

Here is a possible implementation of the ideas outlined in the previous section, leading to the so-called *selection, extraction, recombination, and reallocation* (SERR) matheuristic.

(i) (*Initialization*). Apply a fast heuristic method to find a first (possibly infeasible, see below) DCVRP solution.

(ii) (*Selection*). Apply one of the available criteria (to be described later) to determine the nodes to be extracted—the nodes need not be consecutive, and any node subset qualifies as a valid choice.

(iii) (*Extraction*). Extract the nodes selected in the previous step and construct the corresponding restricted DCVRP solution obtained by short-cutting the extracted nodes. All edges in the restricted solution are put in the list $\mathcal{I}$ of the available insertion points.

(iv) (*Recombination*). The node sequences extracted in the previous step (called *basic* in the sequel) are initially stored in a *sequence pool*. Thereafter, heuristic procedures (to be described later) are applied to derive new sequences through the extracted nodes, which are added to the sequence pool. During this phase, dual information derived from the LP relaxation of the reallocation model can be used to find new profitable sequences—the so-called *pricing* step. Each sequence s in the final pool is then associated with a (heuristically determined) subset I s of the available insertion points in $\mathcal{I}$. For all basic sequences s, we assume that $\mathcal{I}_s$ contains (among others) the *pivot* insertion point associated with s in the original tour, so as to make it feasible to retrieve the original solution by just reallocating each basic sequence to the associated pivot insertion point.

(v) (*Reallocation*). A suitable MIP (to be described later in greater details) is set up and solved heuristically through a general-purpose MIP solver. This model has a binary variable x_{si} for each pair (s, i), where s is a sequence in the pool and $i \in \mathcal{I}_s$, whose value 1 means that s has to be allocated to i. The constraints in the MIP stipulate that each extracted node has to be covered by exactly one of the selected sequences s, while each insertion point i can be associated with at most one sequence. Further constraints impose the capacity and distance constraints in each route. Once an (almost) optimal MIP solution has been found, the corresponding DCVRP solution is constructed and the current best solution is possibly updated (in which case each route in the new solution is processed by a 3-opt [26] exchange heuristic n the attempt of further improving it).

(vi) (*Termination*). If at least one improved DCVRP solution has been found in the last n iterations, we repeat from step (ii); otherwise the method terminates.

Finding a Starting Solution

Finding a DCVRP solution that is guaranteed to be feasible is an NP-hard problem; hence, we have to content ourselves with the construction of solutions that, in some hard cases, may be infeasible—typically because the total-distance-traveled constraint is violated for some routes. In this case, the overall infeasibility of the starting solution can hopefully be driven to zero by a modification of the SERR recombination model where the capacity and distance constraints are treated in a soft way through the introduction of highly penalized slack variables.

As customary in VRP problems, we assume that each node is assigned a coordinate pair (x, y) giving the geographical position of the corresponding customer/depot in a two-dimensional map.

One option for the initialization of the current solution required at step (i) of the SERR method is to apply the classical two-phase method of Fisher and Jaikumar (FJ) [14]. This method can be implemented in a very natural way in our context in that it is based on a (heuristic) solution of a MIP whose structure is close to that of the reallocation model.

According to computational experience, however, the solution provided by the FJ heuristic is sometimes "too balanced," in the sense that the routes are filled so tightly that leave not enough freedom to the subsequent steps of our SERR procedure. Better results are sometimes obtained starting from a less-optimized solution whose costs significantly exceed the optimal cost as, for example, the one obtained by using a simplified *SWEEP* method [16].

A second possibility is instead to start from an extremely good solution provided by highly effective (and time-consuming) heuristics or metaheuristics, in the attempt of improving this solution even further.

Node Selection Criteria

At each execution of step (ii), one of the following selection schemes is applied.

- Scheme RANDOM-ALTERNATE: This criterion is akin to the SD one and selects in some randomly selected routes all the nodes in even position, while in

the remaining routes the extracted nodes are those in odd position—the position parity being determined by visiting each route in a random direction.
- Scheme SCATTERED: Each node had a uniform probability of 50% of being extracted; this scheme allows for the removal of consecutive nodes, that is, of route subsequences.
- Scheme NEIGHBORHOOD: Here one concentrates on a seed node, say v^*, and removes the nodes v with a probability that is inversely proportional to the distance c_{vv^*} of v from v^*.

Schemes RANDOM-ALTERNATE and SCATTERED appear particularly suited to improve the first solutions, whereas the NEIGHBORHOOD scheme seems more appropriate to deal with the solutions available after the first iterations.

Reallocation Model

Given the sequences stored in the pool and the associated insertion points (defined through the heuristics outlined in the next subsection), our aim is to reallocate the sequences so as to find a feasible solution of improved cost (if any). To this end, we need to introduce some additional notation.

Let $\mathcal{F}$ denote the set of the extracted nodes, $\mathcal{S}$ the sequence pool, and $\mathcal{R}$ the set of routes r in the restricted solution. For any sequence $s \in \mathcal{S}$, let $c(s)$ be the sum of the costs of the edges in the sequence, and let $d(s)$ be the sum of the requests d_j associated with the *internal* nodes of s.

For each insertion point $i \in \mathcal{I}$, we define the extra-cost γ_{si} for assigning sequence s (in its best possible orientation) to the insertion point i. For each route $r \in \mathcal{R}$ in the restricted solution, let $\mathcal{I}(r)$ denote the set of the insertion points (i.e., edges) associated with r, while let $\tilde{d}(r)$ and $\tilde{c}(r)$ denote, respectively, the total request and distance computed for route r—still in the restricted tour. As already mentioned, our MIP model is based on the following decision variables:

$$x_{si} = \begin{cases} 1 \text{ if sequence s is allocated to the insertion point } i \in \mathcal{I}_s \\ 0 \text{ otherwise} \end{cases} \tag{46}$$

The model then reads:

$$\sum_{r \in \mathcal{R}} \tilde{c}(r) + \min \sum_{s \in \mathcal{S}} \sum_{i \in \mathcal{I}_s} \gamma_{si} x_{si} \tag{47}$$

subject to:

$$\sum_{s \in v} \sum_{i \in \mathcal{I}_s} x_{si} = 1 \ \forall v \in \mathcal{F} \tag{48}$$

$$\sum_{s \in \mathcal{S}: i \in \mathcal{I}_s} x_{si} \leq 1 \forall i \in \mathcal{I} \tag{49}$$

$$\tilde{d}(r) + \sum_{s \in \mathcal{S}} \sum_{i \in \mathcal{I}_s \cap \mathcal{I}(r)} d(s) x_{si} \leq C \quad \forall r \in \mathcal{R} \tag{50}$$

$$\tilde{c}(r) + \sum_{s \in \mathcal{S}} \sum_{i \in \mathcal{I}_s \cap \mathcal{I}(r)} \gamma_{si} x_{si} \leq D \quad \forall s \in \mathcal{S}, r \in \mathcal{R} \tag{51}$$

$$0 \leq x_{si} \leq 1 \text{integer} \quad \forall s \in \mathcal{S}, \quad i \in \mathcal{I}_s \tag{52}$$

The objective function, to be minimized, gives the cost of the final DCVRP solution. Indeed, each objective coefficient gives the MIP cost of an inserted sequence, including the linking cost, minus the cost of the "saved" edge in the restricted solution. Constraints (48) impose that each extracted node belongs to exactly one of the selected sequences, that is, that it is covered exactly once in the final solution. Note that, in the case of triangular costs, one could replace $=$ by $\geq$ in (48), thus obtaining a typically easier-to-solve MIP having the structure of a set-covering (instead of set-partitioning) problem with side constraints. Constraints (49) avoid a same insertion point be used to allocate two or more sequences. Finally, constraints (50) and (51) impose that each route in the final solution fulfills the capacity and distance restriction, respectively.

In order to avoid to overload the model by an excessive number of variables, a particular attention has to be paid to reduce the number of sequences and, for each sequence, the number of the associated insertion points.

Node Recombination and Construction of Derived Sequences

This is a very crucial step in the SERR method. It consists not just of generating new "good" sequences through the extracted nodes, but it also associates each sequence to a clever set of possible insertion points that can conveniently accommodate it. Therefore, one has two complementary approaches to attack this problem: (a) start from the insertion points and, for each insertion point, try to construct a reasonable number of new sequences which are likely to "fit well" or (b) start from the extracted nodes and try to construct new sequences of small cost, no matter the position of the insertion points. The following two-phase method turned out to be a good strategy in practice.

In the first phase, the sequence pool is initialized by means of the original (basic) sequences, and each of them is associated with its corresponding (pivot) insertion point. This choice guarantees that the current DCVRP solution can be reconstructed by simply selecting all the basic sequences and putting them back in their pivot insertion point. Moreover, when the NEIGHBORHOOD selection scheme is used, a further set of sequences is generated as follows. Let v^* be the extracted seed node, and let $N(v^*)$ contain v^* plus the, say, k closest extracted nodes ($k = 4$ in our implementation). A complete enumerative scheme is applied to generate all the sequences through $N(v^*)$ that are added to the pool. This choice is intended to increase the chances of locally improving the current solution, by exploiting appropriate sequences to reallocate the nodes in $N(v^*)$ in an optimal way.

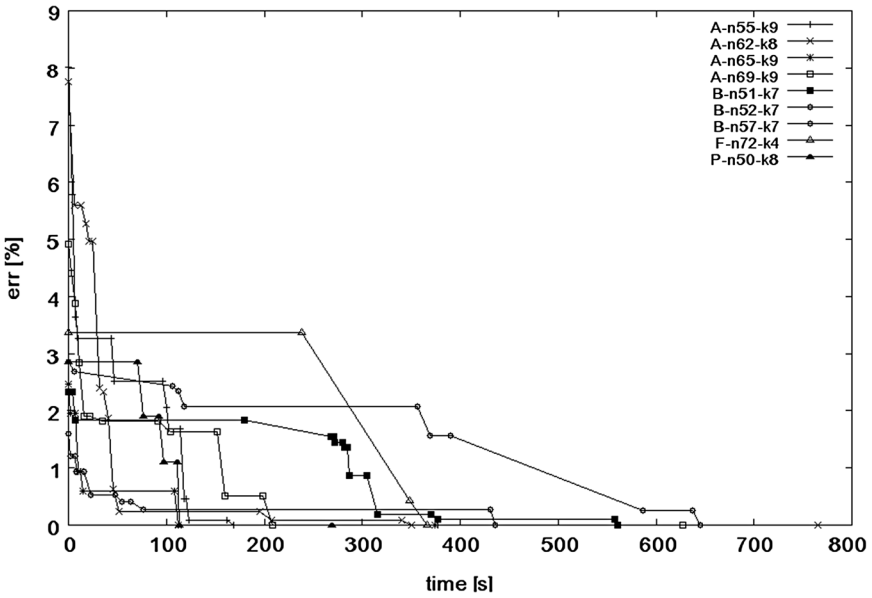

Fig. 5 Time evolution of the SERR solution for various CVRP instances, with FJ [14] initial solution

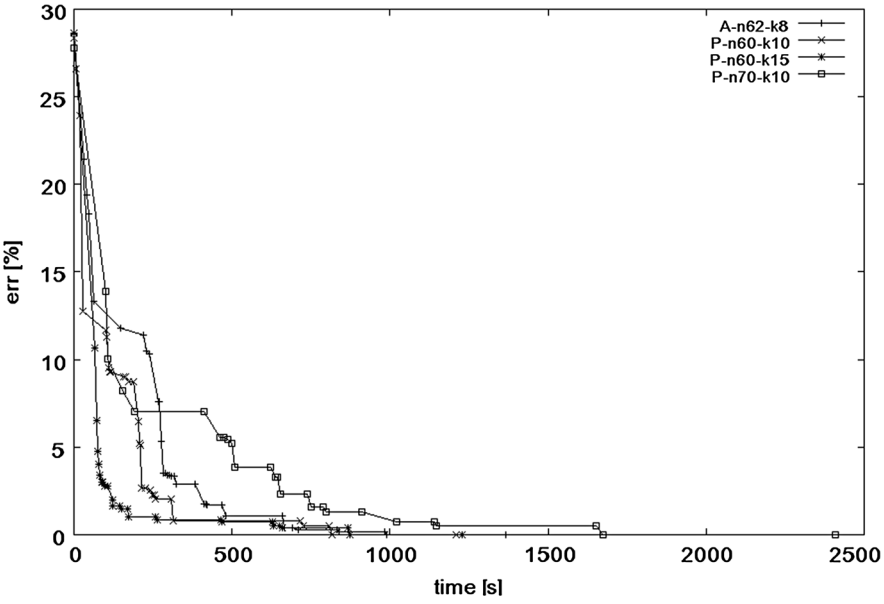

Fig. 6 Time evolution of the SERR solution for various CVRP instances, with SWEEP [16] initial solution

The second phase is only applied for the NEIGHBORHOOD and SCATTERED selection schemes and corresponds to a pricing loop based on the dual information available after having solved the LP relaxation of the current reallocation model. The reader is again referred to [15] for details.

Examples

Extensive computational results for SERR matheuristic have been reported [15] and are omitted because of space. We only report in Figs. 5 and 6 a plot of the incumbent SERR solution for some instances from the literature. Computing time is given in CPU seconds of an old AMD Athlon XP 2400+ PC with 1 GB of RAM, using ILOG Cplex 8.0 as MIP solver. The figures show that SERR is able to significantly improve the starting solution in the early part of its computation.

Conclusion

Contamination of metaheuristics with mathematical programming leads to the concept of "matheuristics." The result is a general approach to design mathematically sound heuristics. In this chapter, we presented the main ideas underlying matheuristics, and used some case studies to illustrate them. For each application, we described the specific problem at hand, the mathematical programming model that formalizes it, and the way the model—or a simplification of it—can be used to produce heuristic (as opposed to exact) solutions in an effective way.

initial solutions. Modern multi-start methods usually incorporate a powerful form of diversification in the generation of solutions to help overcome local optimality. Different metaheuristics, such as GRASP or tabu search, have been applied to this end. This survey briefly sketches historical developments that have motivated the field and then focuses on modern contributions that define the current state of the art. Two classical categories of multi-start methods are considered according to their domain of application: global optimization and combinatorial optimization. Additionally, several methods are reviewed to estimate the number of local optima in combinatorial problems. The estimation of this number can help to establish the complexity of a given instance, and also to choose the most convenient neighborhood, which is especially interesting in the context of multi-start methods. Experiments on three well-known combinatorial optimization problems are included to illustrate the local optima estimation techniques.

Introduction

Heuristic search procedures that aspire to find globally optimal solutions to hard optimization problems usually require some type of diversification to overcome local optimality. One way to achieve diversification is to restart the procedure from a new solution once a region has been explored. This chapter describes the best known multi-start methods for solving optimization problems.

The first multi-start efforts described in the literature rely on methods used in statistics and calculus as instances of utilizing repeated constructions to produce a preferred candidate, although such methods were not used to solve optimization problems. In our context, early proposals can be found in the domains of heuristic scheduling [9, 34] and the traveling salesman problem [21]. Multi-start global optimization algorithms, on the other hand, were introduced in the 1980s for bound constraint optimization problems. The well-known Monte Carlo random restart approaches simply evaluate the objective function at randomly generated points [38]. The probability of success approaches one as the sample size tends to infinity under very mild assumptions about the objective function. Many algorithms have been proposed that combine the Monte Carlo method with local search procedures [26].

The restart mechanism inherent of a multi-start design has been superimposed on many different search methods. Once a new solution has been generated, a variety of options can be used to improve it, ranging from a simple greedy routine to a complex metaheuristic such as tabu search [18] or GRASP [37]. Note that the former is based on identifying and recording specific types of information (attributes) to exploit in

future constructions, while the latter is based on order statistics of sampling and on generating unconnected solutions. Martí et al. [30] presented a detailed description of these two methodologies within the multi-start framework, in the context of combinatorial optimization.

A basic multi-start procedure simply applies a procedure that can be called `ConstructSolution` multiple times, returning the best solution found over all starts. The constructed solution is typically improved with the `LocalSearch` procedure. These two procedures, also called phases, are alternated until a stopping criterion is satisfied. Then, each global iteration produces a solution (usually a local optima) and the best overall is the algorithm's output. This is illustrated in Algorithm 1 for a minimization problem.

Algorithm 1: Pseudo-code for multi-start algorithm

```
procedure MultiStart
f* ← ∞;
while stopping criterion not satisfied do
    Construct feasible solution:
        S ← ConstructSolution;
        S ← LocalSearch(S);
    if f(S) < f* then
        S* ← S;
        f* ← f(S);
return S*;
```

As it is well known in the heuristic community, the performance of the local search-based algorithms strongly depends on the properties that the neighborhood imposes on the search space. One of the most important properties is the number of local optima. Given an instance and a neighborhood, the estimation of the number of local optima can help to both measure the instance complexity and to choose the most efficient neighborhood. This chapter reviews and tests several methods to estimate the number of local optima in combinatorial optimization problems.

This chapter is focused on studying the different strategies and methods for generating solutions to launch a succession of local searches for global optimum in the context of two domains: global optimization and combinatorial optimization. It is organized as follows. Section "Global Optimization" describes the developments and strategies applied in the context of global (nonlinear) optimization. Section "Combinatorial Optimization" introduces notation for combinatorial optimization and provides descriptions for solution construction procedures and multi-start algorithms. The difficulty of finding the global optima of a combinatorial problem is evaluated through the estimation of its number of local optima in section

"Estimating the Number of Local Optima." Specifically, methods proposed in the literature are first reviewed, and then, the associated experiments are described in section "Experiments", where statistical tests are applied to draw significant conclusions. Concluding remarks are given in section "Conclusions."

Global Optimization

As mentioned above, many algorithms have been proposed in the 1980s that combine the Monte Carlo method with local search procedures [25], being the multi-level single linkage the most relevant. In general terms, the probability of success approaches one as the sample size tends to infinity under very mild assumptions about the objective function. The convergence for random restart methods is studied in [38], where the probability distribution used to choose the next starting point can depend on how the search evolves. Some extensions of these methods seek to reduce the number of complete local searches that are performed and increase the probability that they start from points close to the global optimum [31].

From a theoretical point of view, Hu et al. [24] study the combination of the gradient algorithm with random initializations to find a global optimum. Efficacy of parallel processing, choice of the restart probability distribution, and number of restarts are studied for both discrete and continuous models. The authors show that the uniform probability is a good choice for restarting procedures.

Hickernell and Yuan Hickernell and Yuan [23] present a multi-start algorithm for unconstrained global optimization based on *quasirandom samples*. Quasirandom samples are sets of deterministic points, as opposed to random points, that are evenly distributed over a set. The algorithm applies an inexpensive local search (steepest descent) on a set of quasirandom points to concentrate the sample. The sample is reduced replacing worse points with new quasirandom points. Any point that is retained for a certain number of iterations is used to start an efficient complete local search. The algorithm terminates when no new local minimum is found after several iterations. An experimental comparison shows that the method performs favorably with respect to other global optimization procedures.

Tu and Mayne [40] describe a multi-start with a clustering strategy for constrained optimization problems. It is based on the characteristics of nonlinear constrained global optimization problems and extends a strategy previously tested on unconstrained problems. In this study, variations of multi-start with clustering are considered including a simulated annealing procedure for sampling the design domain and a quadratic programming (QP) sub-problem for cluster formation. The strategies are evaluated by solving 18 nonlinear mathematical problems and six engineering design problems. Numerical results show that the solution of a one-step QP sub-problem helps predict possible regions of attraction of local minima and can enhance robustness and effectiveness in identifying local minima without sacrificing efficiency. In comparison with other multi-start techniques, the strategies of this study are superior in terms of the number of local searches performed, the number of minima found, and the number of function evaluations required.

Ugray et al. [41] propose OptQuest/Multi-start or OQMS, a heuristic designed to find global optima for pure and mixed integer nonlinear problems with many constraints and variables, where all problem functions are differentiable with respect to the continuous variables. It uses OptQuest, a commercial implementation of scatter search developed by OptTek Systems, Inc., to provide starting points for any gradient-based local NLP solver. This solver seeks a local solution from a subset of these points, holding discrete variables fixed. Computational results include 155 smooth NLP and MINLP problems, most with both linear and nonlinear constraints, coded in the GAMS modeling language. Some are quite large for global optimization, with over 100 variables and many constraints. Global solutions to almost all problems are found in a small number of local solver calls, often one or two. An improved version of OQMS is proposed in Ugray et al. [42] in terms of the filters to apply the NLP solver.

More recently, Kaucic [27] presents a multi-start particle swarm optimization algorithm for the global optimization of a function subject to bound constraints. The procedure consists of three main steps. In the initialization phase, an opposition learning strategy is performed to improve the search efficiency. Then, a variant of the adaptive velocity based on the differential operator enhances the optimization ability of the particles. Finally, a re-initialization strategy based on two diversity measures for the swarm is act in order to avoid premature convergence and stagnation. The algorithm is evaluated on a set of 100 global optimization test problems. Comparisons with other global optimization methods show its robustness and effectiveness.

Combinatorial Optimization

Boese et al. [4] analyze relationships among local minima from the perspective of the best local minimum, finding convex structures in the cost surfaces. Based on the results of that study, they propose a multi-start method where starting points for greedy descent are adaptively derived from the best previously found local minima. In the first step, adaptive multi-start (AMS) heuristics generate r random starting solutions and run a greedy descent method from each one to determine a set of corresponding random local minima. In the second step, *adaptive starting solutions* are constructed based on the local minima obtained so far and improved with a greedy descent method. This improvement is applied several times from each adaptive starting solution to yield corresponding *adaptive local minima*. The authors test this method for the traveling salesman problem and obtain significant speedups over previous multi-start implementations. Hagen and Kahng [20] apply this method for the iterative partitioning problem.

Moreno et al. [33] propose a stopping rule for the multi-start method based on a statistical study of the number of iterations needed to find the global optimum. The authors introduce two random variables that together provide a way of estimating the number of global iterations needed to find the global optima: the number of initial solutions generated and the number of objective function evaluations performed to

find the global optima. From these measures, the probability that the incumbent solution is the global optimum is evaluated via a normal approximation. Thus, at each global iteration, this value is computed, and if it is greater than a fixed threshold, the algorithm stops; otherwise, a new solution is generated. The authors illustrate the method using the median *p*-hub problem.

One of the most well-known multi-start methods is the greedy adaptive search procedure (GRASP), which was introduced by Feo and Resende [15]. It was first used to solve set covering problems [14]. Each GRASP iteration consists of constructing a trial solution and then applying a local search procedure to find a local optimum (i.e., the final solution for that iteration). The construction step is an adaptive and iterative process guided by a greedy evaluation function. It is iterative because the initial solution is built considering one element at a time. It is greedy because the addition of each element is guided by a greedy function. It is adaptive because the element chosen at any iteration in a construction is a function of previously chosen elements (i.e., the method is adaptive in the sense of updating relevant information from one construction step to the next). At each stage, the next element to be added to the solution is randomly selected from a candidate list of high-quality elements according to the evaluation function. Once a solution has been obtained, it is typically improved by a local search procedure. The improvement phase performs a sequence of moves toward a local optimum solution, which becomes the output of a complete GRASP iteration.

Hagen and Kahng [20] implement an adaptive multi-start method for a VLSI partitioning optimization problem where the objective is to minimize the number of signals sent between components. The method consists of two phases. It first generates a set of random starting points and performs the iterative (local search), thus determining a set of local minimum solutions. Then it constructs adaptive starting points derived from the best local minimum solutions found so far. The authors add a preprocessing cluster module to reduce the size of the problem. The resulting clustering adaptive multi-start (CAMS) method is fast and stable and improves upon previous partitioning results reported in the literature.

Fleurent and Glover [16] propose some adaptive memory search principles to enhance multi-start approaches. The authors introduce a template of a constructive version of tabu search based on both, a set of elite solutions and the intensification strategies based on identifying *strongly determined and consistent variables* according to the following definitions:

- *Strongly determined variables* are those whose values cannot be changed without significantly eroding the objective function value or disrupting the values of other variables.
- A *consistent variable* is defined as one that receives a particular value in a significant portion of good solutions.

The authors propose the inclusion of memory structures within the multi-start framework as it is done with tabu search. Computational experiments for the quadratic assignment problem show that these methods improve significantly over

previous multi-start methods like GRASP and random restart that do not incorporate memory-based strategies.

Patterson et al. [35] introduce a multi-start framework called *adaptive reasoning technique* (ART), based on memory structures. The authors implement the short-term and long-term memory functions, proposed in the tabu search framework, to solve the capacitated minimum spanning tree problem. ART is an iterative, constructive solution procedure that implements learning methodologies on top of memory structures. ART derives its success from being able to learn about and modify the behavior of a primary greedy heuristic. The greedy heuristic is executed repeatedly, and for each new execution, constraints that prohibit certain solution elements from being considered by the greedy heuristic are introduced in a probabilistic fashion. The active constraints are held in a short-term memory, while a long-term memory holds information regarding the constraints that were in the active memory for the best set of solutions.

Glover [17] approaches the multi-start framework from a different perspective. The author views multi-start methods as an extreme version of the *strategic oscillation* approach. Strategic oscillation is a mechanism used in tabu search to allow the process to visit solutions around a "critical boundary," by approaching such a boundary from both sides.

Braysy et al. [5] propose a multi-start local search heuristic for the vehicle routing problem with time windows. The objective in this problem is to design least cost routes for a fleet of identical capacitated vehicles to service geographically scattered customers within pre-specified service time windows. The suggested method uses a two-phase approach. In the first phase, a fast construction heuristic is used to generate several initial solutions. Then, injection trees, an extension of the well-known ejection chain approach [18], are used to reduce the number of routes. In the second phase, two new improvement heuristics, based on CROSS-exchanges [39], are applied for distance minimization. The best solution identified by the algorithm is post-optimized using a threshold accepting post-processor with both intra-route and inter-route improvement heuristics. The resulting hybrid method is shown to be fast, cost-effective, and highly competitive.

Mezmaz et al. [32] hybridize the multi-start framework with a model in which several evolutionary algorithms run simultaneously and cooperate to compute better solutions (called *island model*). They propose a solution method in the context of multi-objective optimization on a computational grid. The authors point out that although the combination of these two models usually provides very effective parallel algorithms, experiments on large-size problem instances are often stopped before convergence is achieved. The full exploitation of the cooperation model needs a large amount of computational resources and the management of the fault tolerance issue.

Under the template of a typical multi-start metaheuristic, [28] propose Meta-RaPS (metaheuristic for randomized priority search), in which several randomization methods and memory mechanisms are present. With the set covering problem (SCP) as the application problem, it is found that these randomization and memory-based methods work well for Meta-RaPS.

Beausoleil et al. [3] consider a multi-objective combinatorial optimization problem called extended knapsack problem. By applying multi-start search and path-relinking their solving method rapidly guides the search toward the most balanced zone of the Pareto-optimal front (the zone in which all the objectives are equally important).

Essafi et al. [13] propose a multi-start ant-based heuristics for a machine line balancing problem. The proposed procedure is a constructive algorithm that assigns operations sequentially to stations. The algorithm builds a feasible solution step by step according to a greedy function that computes the contribution of each unassigned operation to the partial solution under construction based on operational time and weights. The selection of the operation to be added is performed with a roulette wheel mechanism based on the typical ant probability distribution (pheromones of previous assignments). The proposed heuristic is applied to solve a real industry problem.

Dhouib et al. [10] propose a multi-start adaptive threshold accepting algorithm (MS-TA) to find multiple Pareto-optimal solutions for continuous optimization problems. Threshold accepting methods (TAs) are deterministic and faster variants of the well-known simulated annealing algorithms, in which every new move is accepted if it is not much worse than the old one. A multi-start technique is applied in this paper to the TA algorithm to allow more diversifications.

Villegas et al. [43] propose two hybrid algorithms for the single truck and trailer routing problem. The first one is based on GRASP and variable neighborhood descent (VND), while the second one is an evolutionary local search (ELS). In the first one, large tours are constructed with a randomized nearest neighbor method with a restricted candidate list that ignores capacity constraints and trailer-point selection. VND is applied to improve these initial solutions obtained with GRASP. In the second one, a multi-start evolutionary search is applied starting from an initial solution (giant tour). The best solution found is strongly perturbed to obtain different solutions from which the search is restarted. The perturbation is managed by a mutation operator. The results of the computational experiments on a set of 32 randomly generated instances also unveil the robustness of the proposed metaheuristics, all of them achieving gaps to best known solutions of less than 1% even in the worst case. Among the proposed methods, the multi-start evolutionary local search is more accurate and faster and scales better than the GRASP/VND.

Estimating the Number of Local Optima

As previously seen, multi-start algorithms depend on a neighborhood defined in the search space. Furthermore, the same multi-start algorithm can produce different results in the same instance when it is used with two different neighborhoods. Although there are several characteristics of a neighborhood that influence the behavior of a multi-start algorithm, probably, the most relevant is the number of local optima it generates.

The knowledge about the number of local optima that a neighborhood generates in an instance of a combinatorial optimization problem (COP) can have a high impact on the choice of the multi-start algorithm used to solve the instance. On the first hand, different neighborhoods can generate a dramatically different number of local optima. Of course, as a general rule, the higher the size of the neighborhood, the lower the number of local optima. However, given two neighborhoods of the same size complexity (number of local solutions in the same order of magnitude), the one that generates a lower number of local optima will always be preferred.

Given an instance of a COP and a neighborhood, the exact calculation of the number of local optima is impractical, except for extremely low dimensions ($n \leq 14$). Furthermore, this exact calculation requires, in most of the cases, the exhaustive inspection of every solution in the search space, which makes this approach useful. Therefore, statistical estimation methods are required to have an approximation of the number of local optima of a landscape. Note, however, that the representation of such number is in itself an additional challenge. When the dimension of a problem is high (for instance, $n \geq 200$) and the size of the search space is exponential in n, the number of local optima is usually so high that cannot be accurately represented in the computer. The alternative choice to represent the proportion of solutions that are local optima deals with similar issues as this number is too small to be accurately represented. Therefore, the estimation of the number of local optima of an instance of a COP is only plausible for moderate values of the problem size.

In spite of the useful information that the knowledge of the number of local optima can provide in order to choose the best algorithm for solving a COP instance, there have not been many proposals in the literature. This can probably be due to the difficulty of the estimation problem. These proposals are mainly divided into three groups (a good review and a comparison of several proposals can be found in [22]). A first group is based on the hypothesis that the instances have been generated uniformly at random [1, 2, 19]. The second group mainly includes proposals that have been developed in the metaheuristics community. Finally, a third group includes those that were not designed with the objective of estimating the number of local optima, but were adapted to this problem.

In order to estimate the number of local optima, all the methods share some steps of the process. All of them obtain uniformly at random a sample of size M from the search space. Departing from these solutions and applying a greedy local search algorithm, they finally obtain a sample of local optima (notice that in this sample some local optima could be repeated several times). In addition to that, the concept of basin of attraction is presented in all the estimation methods. Basically, a solution belongs to the basin of attraction of a local optimum if, after applying a greedy local search to that solution, it finishes in the corresponding local optimum. Notice that, in case of injective functions, the basins of attraction represent a partition of the search space.

Methods Proposed in the Metaheuristics Arena

Most of the methods proposed in the metaheuristics field are mainly due to [11, 12, 36]. They basically developed two kinds of methods: a first group where they use confidence intervals to provide lower bounds (with high probability) for the number of local optima and a second group using bias-correcting methods.

In the first group, by assuming that the sizes of the basins of attraction of all the local optima are the same, they manage to get lower bounds by means of several methods:

- *First repetition time*: A random solution is taken from the search space, and a greedy local search algorithm is applied to reach a local optimum. This process continues until a local optimum is repeated for the first time. This number of initial solutions needed until a local optimum is seen twice is the value used to make the estimation. Note that in this method the sample size is not fixed.
- *Maximal first repetition time*: This method is similar to the previous one, except that the sample size is fixed beforehand and the maximal first repetition time (the maximum number of solutions between the first reoccurrence of a local optimum) is used to carry out the estimation.
- *Schnabel census*: In order to make the estimation, the authors take into account in this case the probability that r different local optima are discovered from a sample of size M.

The main drawback of the previous methods is that they are strongly biased by the assumption that all the local optima have the same size of basin of attraction. In order to overcome this bias, a couple of very well-known methods in the statistical literature are proposed: Jackknife and Bootstrap. These are nonparametric methods that, departing from a biased estimation, try to correct the bias:

- *Jackknife method*: It consists in calculating M new estimations by leaving each time one of the current solutions out from the original sample. These new M estimations are used to modify the original estimation decreasing its bias.
- *Bootstrap method*: This resampling technique consists in obtaining several new samples from the original sample. Each sample has the same size as the original one and is obtained by uniformly at random sampling solutions with replacement from the original sample. On the contrary to the previous method, it assumes a probabilistic model in the basins of attraction to make a new estimation for each resampling.

Methods Proposed in the Field of Statistics

The community working in metaheuristics quickly realized that the methods used by biologists and ecologists to calculate the number of species in a population could be

easily adapted to the problem of calculating the number of local optima. Particularly four nonparametric methods [6–8] were adapted to estimate the number of local optima of instances of COPs [22]. Although they are nonparametric methods, they are based on particular sampling models. An important consideration is that all these methods assume an infinite population, in our case an infinite number of local solutions. This assumption does not impose a big constraint because of the large cardinality of the search space of the COPs:

- *Chao1984 method*: It is based on multinomial sampling. The estimator is the result of adding to the number of local optima obtained from the sample a term that depends only on the number of local optima seen once and twice in the sample.
- *Chao&Lee methods*: These two methods are also based on multinomial sampling. They include the idea of sample coverage (sum of the proportions of the basins of attraction of the local optima observed in the sample). They distinguish between the local optima observed many times in the sample and those observed a few number of times in the sample. So the estimators are the sum of the number of local optima observed many times and some terms that depend on the sample coverage and the number of local optima found a few times, trying to compensate for the local optima that have small basins of attraction.
- *Chao&Bunge method*: It is based on a mixed Poisson sampling model and is closely related to the previous estimators. This method bases the estimation of unobserved local optima on a formula that depends on the expected proportion of duplicates in the sample. It also makes the distinction between the local optima observed many times in the sample and those observed a few number of times in the sample.

Experiments

The accuracy of the different estimators presented in the previous section has been tested on instances of three different common problems: permutation flow-shop scheduling problem (PFSP), linear ordering problem (LOP), and quadratic assignment problem (QAP). Using these datasets, the methods can be tested over a wide set of instances with different characteristics. The number of local optima for different neighborhoods is already known for some of these instances, which allows to evaluate the accuracy of the different estimations. A comparison of the different methods is given, together with recommendations of the methods that provide the best estimations. Based on the results found in [22], the three first methods presented in the previous section are removed for the analysis, that is, first repetition time, maximal first repetition time, and Schnabel census.

Experimental Design

The instances used in the experiments are taken from three well-known benchmarks: 5 instances of the PFSP obtained from the Taillard's benchmark, 5 instances of the LOP taken from the LOLIB benchmark [29], and 5 instances of the QAP chosen from the QAPLIB.

The flowshop scheduling problem can be stated as follows: there are b jobs to be scheduled in c machines. A job consists of c operations and the j-th operation of each job must be processed on machine j for a specific processing time without interruption. Jobs are processed in the same order on different machines. The objective of the PFSP is to find the order in which the jobs have to be scheduled on the machines, minimizing the total flow time.

In the LOP, given a matrix $B = [b_{ij}]_{nxn}$ of numerical entries, a simultaneous permutation of the rows and columns of B has to be found, such that the sum of the entries above the main diagonal is maximized (or equivalently, the sum of the entries below the main diagonal is minimized).

The QAP is the problem of allocating a set of facilities to a set of locations, with a cost function associated to the distance and the flow between the facilities. The objective is to assign each facility to a location such that the total cost is minimized, given two $n \times n$ input matrices with real values $\mathbf{H} = [h_{ij}]$ and $\mathbf{D} = [d_{kl}]$, where h_{ij} is the flow between facility i and facility j and d_{kl} is the distance between location k and location l.

For the three problems, instances of permutation size $n = 13$ are considered, so the search space is of size $|\Omega| = 13! \approx 6.23 \cdot 10^9$. In the case of the PFSP, instances have 13 jobs and 5 machines. Notice that a first step consists of evaluating all the solutions of the search space to know in advance the exact number of local optima. Therefore, working with higher permutation sizes becomes impracticable.

The local optima of the instances have been calculated according two commonly used operators: the 2-exchange and the insert neighborhoods. Denoting by $\boldsymbol{\pi} = \pi_1\pi_2 \ldots \pi_n$ a solution (permutation of size n) of the search space, the 2-exchange neighborhood considers that two solutions are neighbors if one is generated by swapping two elements of the other:

$$N_S(\pi_1\pi_2 \ldots \pi_n) = \left\{ \left(\pi'_1\pi'_2 \ldots \pi'_n\right) \mid \pi'_k = \pi_k, \forall k \neq i, j, \pi'_i = \pi_j, \pi'_j = \pi_i, i \neq j \right\}.$$

Two solutions are neighbors under the insert neighborhood (N_I) if one is the result of moving an element of the other one to a different position:

$$N_I(\pi_1\pi_2 \ldots \pi_n) =$$

$$\left\{ \left(\pi'_1\pi'_2 \ldots \pi'_n\right) \mid \pi'_k = \pi_k, \forall k < i \text{and} \forall k > j, \pi'_k = \pi_{k+1}, \forall i \leq k < j, \pi'_j = \pi_i \right\}$$

$$\cup \left\{ \left(\pi'_1\pi'_2 \ldots \pi'_n\right) \mid \pi'_k = \pi_k, \forall k < i \text{and} \forall k > j, \pi'_i = \pi_j, \pi'_k = \pi_{k-1}, \forall i < k \leq j \right\}.$$

The different methods for estimating the number of local optima are applied to the 5 instances of each of the considered problems (PFSP, LOP, and QAP) using both neighborhoods (N_S and N_I). So, a total of 30 different landscapes are considered. These two neighborhoods create different situations for the estimations. As the insert neighborhood explores at each step more solutions than the 2-exchange neighborhood, the number of local optima obtained when using the first neighborhood is probabilistically lower than when assuming the second one. However, as will be shown, due to the intrinsic nature of the QAP, given an instance of this problem, the number of local optima when using the insert neighborhood is much higher than when considering the 2-exchange neighborhood.

The estimation methods *Jackknife*, *Bootstrap*, *Chao1984*, *Chao&Lee1*, *Chao&Lee2*, and *Chao&Bunge* are applied to each of the landscapes 10 times, and the average estimation value of the 10 repetitions is reported. Methods are applied with different sample sizes: $M = 100, 500, 1000, 5000$.

Results

Our aim is to compare the accuracy of the different methods and their relation to the sample size. Results are analyzed according to the type of problem and the neighborhood used, and the effect of the sample size on the methods using different sample sizes is studied. Table 1 reports the average estimations (of the 10 repetitions) obtained with the different methods and the different sample sizes for all the instances of the three problems when using both neighborhoods. It also indicates the real number of local optima of each instance. v denotes the real number of local optima of the instances with the corresponding neighborhood.

Table 1 shows that the method that provides the best results more times is *Chao&Lee2*. In fact, in general, the estimations, given by those methods that come from the field of statistics, provide better results than *Bootstrap* and *Jackknife*, above all, when the number of local optima is considerably high.

A statistical analysis was carried out to compare the estimations obtained with the different methods and three different scenarios. In the first one, the estimations are grouped in three sets according to the type of problem: PFSP, LOP, or QAP. The second scenario considers two different sets that contain the estimations of the instances when using the neighborhoods N_S or N_I. In the last scenario, the estimations are grouped in four sets, according to the parameter $M = 100, 500, 1000, 5000$. A nonparametric Friedman's test with level of significance $\alpha = 0.05$ is used to test if there are statistical significant differences among the estimations provided by the six methods in the different scenarios. It provides a ranking of the methods while also giving an average rank value for each method. Statistical differences are found in all the cases, and then a post hoc test is applied to perform all pairwise comparisons. Particularly, the Holm's procedure is applied fixing the level of significance to $\alpha = 0.05$.

Table 2 shows the ranking obtained for the methods with the Friedman's test in the first scenario, that is, for the instances of the PFSP (first pair of columns),

Table 1 Mean of the estimations obtained for all the instances of the PFSP, LOP, and QAP, under the 2-exchange and the insert neighborhoods

		Method	M = 100	M = 500	M = 1000	M = 5000	M = 100	M = 500	M = 1000	M = 5000	M = 100	M = 500	M = 1000	M = 5000	M = 100	M = 500	M = 1000	M = 5000	M = 100	M = 500	M = 1000	M = 5000
PFSP	**2-exchange**		Instance 1. $v = 2386$				Instance 2. $v = 8194$				Instance 3. $v = 1997$				Instance 4. $v = 5119$				Instance 5. $v = 192$			
		Jackknife	158.20	517.30	744.80	1371.20	185.50	709.50	1139.10	2733.60	142.70	397.50	590.40	1098.50	167.40	575.20	886.60	1920.50	77.10	131.80	153.00	**183.10**

Table 2 Average rankings of the methods according to the type of problem

PFSP		LOP		QAP	
Method	Ranking	Method	Ranking	Method	Ranking
Chao&Lee2	4.85	*Chao&Lee2*	4.83	*Chao&Lee2*	4.77
Chao&Lee1	3.74	*Chao&Lee1*	4.08	*Chao&Lee1*	3.97
Chao1984	3.51	*Chao1984*	3.78	*Chao1984*	3.60
Bootstrap	3.37	*Chao&Bunge*	2.82	*Jackknife*	2.97
Chao&Bunge	3.05	*Jackknife*	2.78	*Bootstrap*	2.88
Jackknife	2.47	*Bootstrap*	2.69	*Chao&Bunge*	2.81

Table 3 Average rankings of the methods according to the neighborhood

N_S		N_I	
Method	Ranking	Method	Ranking
Chao&Lee2	5.22	*Chao&Lee2*	4.41
Chao&Lee1	3.94	*Chao&Lee1*	3.92
Chao1984	3.61	*Chao1984*	3.66
Bootstrap	3.12	*Jackknife*	3.26
Chao&Bunge	2.88	*Chao&Bunge*	2.91
Jackknife	2.23	*Bootstrap*	2.84

LOP (the pair of columns in the middle), and QAP (last pair of columns). The lower the rank, the worse the performance of the method is. So, the methods are ordered from best to worst. Therefore, the best methods in the three groups are *Chao&Lee2*, *Chao&Lee1*, and *Chao1984*. However, pairwise significant differences are not found between *Chao&Lee1* and *Chao1984*, *Chao1984* and *Bootstrap*, and *Bootstrap* and *Chao&Bunge*, for the PFSP instances, and between *Bootstrap* and *Chao&Bunge*, *Bootstrap* and *Jackknife*, and *Jackknife* and *Chao&Bunge*, for the LOP and the QAP instances.

In Table 3, the ranking for the methods is shown, but this time for the second scenario, that is, when grouping the estimations for the instances using the 2-exchange neighborhood N_S (the first pair of columns), and the insert neighborhood N_I (the last pair of columns). In the first case, the Holm's procedure states that significant differences exist among each pair of methods. Nevertheless, for the second neighborhood, significant differences are not found between *Chao&Lee1* and *Chao1984* and between *Chao&Bunge* and *Bootstrap*. It is observed in this table that, also in this scenario, the best estimations are provided by *Chao&Lee2*, *Chao&Lee1*, and *Chao1984*.

Finally, Table 4 shows the ranking obtained for the methods when the estimations are separated according to the sample size used by the methods $M = 100, 500, 1000, 5000$. Again, the three best methods are *Chao&Lee2*, *Chao&Lee1*, and *Chao1984*. Significant differences are not found between *Chao&Lee1* and *Chao1984* and between *Bootstrap* and *Jackknife*, when using $M = 100$. For $M = 500$ there are not significant differences among Bootstrap, *Chao&Bunge*, and *Jackknife*, while significant differences are not found between *Bootstrap* and *Chao&Bunge* when

Table 4 Average rankings of the methods according to the sample size

$M = 100$		$M = 500$		$M = 1000$		$M = 5000$	
Method	Ranking	Method	Ranking	Method	Ranking	Method	Ranking
Chao&Lee2	4.72	*Chao&Lee2*	5.01	*Chao&Lee2*	5.01	*Chao&Lee2*	4.54
Chao&Lee1	3.87	*Chao&Lee1*	4.06	*Chao&Lee1*	3.97	*Chao&Lee1*	3.83
Chao1984	3.65	*Chao1984*	3.63	*Chao1984*	3.57	*Chao1984*	3.67
Bootstrap	3.19	*Bootstrap*	2.93	*Bootstrap*	3.00	*Chao&Bunge*	3.48
Jackknife	3.12	*Chao&Bunge*	2.69	*Chao&Bunge*	2.93	*Bootstrap*	2.81
Chao&Bunge	2.46	*Jackknife*	2.67	*Jackknife*	2.52	*Jackknife*	2.67

Table 5 Average relative errors and standard deviations (in brackets) of the estimations provided by the different methods for the instances of the PFSP, according to the neighborhood and the sample size M

		$M = 100$	$M = 500$	$M = 1000$	$M = 5000$
2-exchange	*Jackknife*	0.88 (0.14)	0.74 (0.22)	0.66 (0.24)	0.44 (0.22)
	Bootstrap	0.87 (0.17)	0.69 (0.30)	0.61 (0.28)	0.38 (0.15)
	Chao1984	0.79 (0.15)	0.68 (0.21)	0.60 (0.22)	0.42 (0.20)
	Chao&Lee1	0.79 (0.14)	0.67 (0.20)	0.60 (0.20)	0.42 (0.19)
	Chao&Lee2	**0.74 (0.18)**	**0.60 (0.20)**	**0.51 (0.19)**	0.35 (0.16)
	Chao&Bunge	0.89 (0.26)	1.06 (2.23)	0.84 (1.12)	**0.28 (0.38)**
Insert	*Jackknife*	0.60 (0.28)	0.39 (0.22)	0.30 (0.18)	0.19 (0.23)
	Bootstrap	0.58 (0.26)	0.28 (0.23)	0.21 (0.16)	0.54 (0.40)
	Chao1984	0.53 (0.23)	0.34 (0.19)	0.28 (0.17)	0.19 (0.21)
	Chao&Lee1	0.54 (0.24)	0.34 (0.18)	0.29 (0.15)	**0.17 (0.19)**
	Chao&Lee2	**0.45 (0.22)**	**0.25 (0.15)**	0.24 (0.14)	0.23 (0.20)
	Chao&Bunge	0.92 (1.40)	0.50 (0.78)	**0.20 (0.18)**	0.32 (0.24)

$M = 1000$. Finally, when taking $M = 5000$, there are not significant differences among *Chao&Lee1*, *Chao1984*, and *Chao&Bunge* and between *Jackknife* and *Bootstrap*.

Although the statistical analysis gives a global picture of the performance of the methods, and *Chao&Lee2* provides the best solutions with significant differences between this method and the remaining methods, it is also relevant to consider some aspects that are not reflected in the hypothesis tests. The closeness of the estimations provided by the methods to the value to estimate is the most important factor. Obviously, there are methods that estimate better than others, but it does not mean that the estimations provided by the best methods are close enough to the real value. In order to check if the methods provide useful estimations, and so as to add more information to that deduced from Table 1, the average errors of the estimations with respect to the real number of local optima are calculated. Tables 5, 6, and 7 show the average relative errors and the standard deviations (in brackets) grouped by the neighborhood used and the sample size, for all the instances of the PFSP, LOP, and QAP, respectively.

Table 6 Average relative errors and standard deviations (in brackets) of the estimations provided by the different methods for the instances of the LOP, according to the neighborhood and the sample size M

A general conclusion drawn from Tables 5, 6, and 7 is that, in general terms, the estimations improve as the sample size grows, and they are worse as the number of local optima increases. Specifically, as shown in Table 1, the instances of the LOP with the insert neighborhood have a low number of local optima, and Table 6 shows that the average error is lower than in the rest of the cases. Moreover, the instances of the QAP with the insert neighborhood have a high number of local optima, and the errors obtained for those instances (in Table 7) are higher than for the rest. It is remarkable that, for sample size $M = 100$ and $M = 500$, the estimations are far from the real value. However, there is one method which behaves different and does not follow the general lines. This is the *Chao&Bunge* method. This estimation method

does not necessarily improve as the sample size grows, and the standard deviation presented in most of the cases is really high compared with other methods. It seems that *Chao&Bunge* is a very unstable method. The instability of this method is a consequence of the variability on the estimation of the parameter that represents the expected proportion of duplicates in the sample [22]. This estimation is unreliable when the sample has many local optima that are seen only once, but there is a small number of local optima seen a low (but higher than one) number of times. These particularities are commonly found when the sample size is small with respect to the number of local optima or even when the variance of the sizes of the attraction basins of the local optima is high.

As a conclusion from this analysis, we highly recommend the use of the *Chao&Lee2* method to estimate the number of local optima. According to the hypothesis test, this estimation method provides the best results. Although in the statistical analysis it is not reflected, the *Chao&Bunge* method gives also good estimations in a high number of occasions; however, its instability provokes that it is not trusted. Therefore, we recommend to execute both methods independently. If the results provided are close, *Chao&Bunge* is usually the choice; otherwise, select *Chao&Lee2*.

Conclusions

The objective of this study has been to extend and advance the knowledge associated to implementing multi-start procedures. Unlike other well-known methods, it has not yet become widely implemented and tested as a metaheuristic itself for solving complex optimization problems. Previous efforts have been classified according to its domain of applicability: global and combinatorial optimization.

In this chapter, different methods have been reviewed for estimating the number of local optima of instances of combinatorial optimization problems. Additionally, some methods in the optimization field have been compared with methods previously used for estimating the number of species in a population in the field of statistics. The methods have been applied to instances of three well-known problems in combinatorial optimization and two classical neighborhoods. The main conclusions are that, in general, the higher the sample used by the methods, the more precise the estimations, and the higher the number of local optima, the worse the estimations provided. Based on the results observed through the experiments, we recommend using the *Chao&Lee2* method or applying it together with the *ChaoBunge* method for a more accurate local optima estimation.

Abstract

This chapter provides a short overview of multiobjective optimization using metaheuristics. The chapter includes a description of some of the main metaheuristics that have been used for multiobjective optimization. Although special emphasis is made on evolutionary algorithms, other metaheuristics, such as particle swarm optimization, artificial immune systems, and ant colony

optimization, are also briefly discussed. Other topics such as applications and recent algorithmic trends are also included. Finally, some of the main research trends that are worth exploring in this area are briefly discussed.

Keywords

Multiobjective optimization · Metaheuristics · Optimization

Introduction

Metaheuristics have been widely used for solving different types of optimization problems (see, for example, [49, 73, 100]).

One particular class of optimization problems involves having two or more (often conflicting) objectives which we aim to optimize at the same time. In fact, such problems, which are called "multiobjective," are quite common in real-world applications, and their solution has triggered an important amount of work within Operations Research [129].

During the last 45 years, a large number of mathematical programming techniques have been developed to solve certain specific classes of multiobjective optimization problems. However, such techniques have a relatively limited applicability (e.g., some of them require the first or even the second derivative of the objective functions and the constraints, others can only deal with convex Pareto fronts, etc.). Such limitations have motivated the development of alternative optimization methods, from which metaheuristics have become a very popular alternative [26, 69].

From the many metaheuristics currently available, evolutionary algorithms have been, without doubt, the most popular choice for dealing with any sort of optimization problem [43] and multiobjective optimization is, by no means, an exception. Thus, in this chapter, we will focus our discussion mainly on the use of evolutionary algorithms for solving multiobjective optimization problems.

The use of evolutionary algorithms for solving multiobjective optimization problems was originally hinted in 1967 [150], but the first actual implementation of what is now called a "multiobjective evolutionary algorithm (MOEA)" was not produced until the mid-1980s [157, 158]. However, this area, which is now called "evolutionary multiobjective optimization," or EMO, has experienced a very important growth, mainly in the last 20 years [10, 14, 24]. The author maintains the EMOO repository, which, as of May 10th, 2024, contains over 13,650 bibliographic entries, as well as public-domain implementation of some of the most popular MOEAs. The EMOO repository is located at https://emoo.cs.cinvestav.mx/.

The remainder of this chapter is organized as follows. In section "Basic Concepts," we provide some basic concepts related to multiobjective optimization, which are required to make this chapter self-contained. The use of evolutionary algorithms in multiobjective optimization is motivated in section "Multiobjective Evolutionary Algorithms." The most popular MOEAs that have been developed

so far are briefly discussed in section "Multiobjective Evolutionary Algorithms." A short discussion on other bio-inspired metaheuristics that have also been used for multiobjective optimization is provided in section "Use of Other Metaheuristics." A set of sample applications of MOEAs is provided in section "Some Applications." Some of the main topics of research in the EMO field that currently attract a lot of attention are briefly discussed in section "Some Current Challenges." Finally, some conclusions are provided in section "Conclusions."

Basic Concepts

In this chapter, we focus on the solution of multiobjective optimization problems (MOPs) of the form:

$$\text{Minimize } \left[f_1(\vec{x}), f_2(\vec{x}), \ldots, f_k(\vec{x})\right] \tag{1}$$

subject to the m inequality constraints:

$$g_i(\vec{x}) \leq 0 \quad i = 1, 2, \ldots, m \tag{2}$$

and the p equality constraints:

$$h_i(\vec{x}) = 0 \quad i = 1, 2, \ldots, p \tag{3}$$

where k is the number of objective functions $f_i : \mathbb{R}^n \rightarrow \mathbb{R}$. We call $\vec{x} = [x_1, x_2, \ldots, x_n]^T$ the vector of decision variables. We wish to determine from among the set $\mathcal{F}$ of all vectors which satisfy (2) and (3) the particular set of values $x_1^*, x_2^*, \ldots, x_n^*$ which yield the optimum values of all the objective functions.

Pareto Optimality

It is rarely the case that there is a single point that simultaneously optimizes all the objective functions. In fact, this situation only arises when there is no conflict among the objectives, which would make unnecessary the development of special solution methods, since this single solution could be reached after the sequential optimization of all the objectives, considered separately. Therefore, we normally look for "trade-offs," rather than single solutions, when dealing with multiobjective optimization problems. The notion of "optimality" normally adopted in this case is the one originally proposed by Francis Ysidro Edgeworth [50] and later generalized by the Italian economist Vilfredo Pareto [137]. Although some authors call this notion *Edgeworth-Pareto optimality*, we will use the most commonly adopted term: *Pareto optimality*.

We say that a vector of decision variables $\vec{x}^* \in \mathcal{F}$ (i.e., a feasible solution) is *Pareto optimal* if there does not exist another $\vec{x} \in \mathcal{F}$ such that $f_i(\vec{x}) \leq f_i(\vec{x}^*)$ for all

$i = 1, \ldots, k$ and $f_j(\vec{x}) < f_j(\vec{x}^*)$ for at least one j (assuming that all the objectives are being minimized).

In words, this definition says that $\vec{x}^*$ is a Pareto optimal solution if there exists no feasible vector of decision variables $\vec{x} \in \mathcal{F}$ which would decrease some criterion without causing a simultaneous increase in at least one other criterion. Assuming the inherent conflict normally present among (at least some) objectives, the use of this concept normally produces several solutions. Such solutions constitute the so-called Pareto optimal set. The vectors $\vec{x}^*$ corresponding to the solutions included in the Pareto optimal set are called *nondominated*. The image of the Pareto optimal set under the objective functions (i.e., the objective function values corresponding to the decision variables contained in the Pareto optimal set) is called *Pareto front*.

Multiobjective Evolutionary Algorithms

The core ideas related to the development of search techniques that simulate the mechanism of natural selection (Darwin's survival of the fittest principle) can be traced back to the early 1930s [58]. However, the three main techniques based on this notion were developed during the 1960s: genetic algorithms [86], evolution strategies [162], and evolutionary programming [59]. These approaches, which are now generically denominated "evolutionary algorithms," have been found to be very effective for solving single-objective optimization problems [60, 70, 163].

The basic operation of an evolutionary algorithm (EA) is described next. First, a set of potential solutions (called "population") to the problem being solved is randomly generated. Each solution in the population (called "individual") encodes all the decision variables of the problem (i.e., each individual contains all the decision variables of the problem to be solved). The user needs to define a measure of performance for each of the solutions. Such a measure of performance is called "fitness function" and will allow us to know how good is a solution with respect to the others. Such a fitness function is normally a variation of the objective function of the problem that we wish to solve (e.g., the objective function that we aim to optimize). Then, a selection mechanism must be applied in order to decide which individuals will "mate." This selection process is generally stochastic and is normally based on the fitness contribution of each individual (i.e., the fittest individuals have a higher probability of being selected). Upon mating, a set of "offspring" (or children) are generated. Such offspring are "mutated" (this operator produces a small random change, with a low probability, on the contents of an individual) and constitute the new population to be evaluated at the next iteration (each iteration is called a "generation"). This process is repeated until reaching a stopping condition (normally, a maximum number of generations defined by the user) [51].

The main motivation for using EAs for solving multiobjective optimization problems relies on their population-based nature, which allows them to generate (if properly manipulated) several elements of the Pareto optimal set, in a single

run. In contrast, mathematical programming techniques normally generate a single element of the Pareto optimal set per run. Additionally, the so-called multiobjective evolutionary algorithms (MOEAs) are less susceptible to the shape and continuity of the Pareto front and require less specific domain information to operate [24].

MOEAs extend a traditional (single-objective) EA in two main aspects:

- **The selection mechanism**: In this case, the aim is to select nondominated solutions and to consider all the nondominated solutions in a population to be equally good (unless there is some specific preference from the user, all the elements of the Pareto optimal set are equally good).
- **A diversity maintenance mechanism**: Because of stochastic noise, EAs tend to converge to a single solution if run for a sufficiently long time [70]. In order to avoid this, it is necessary to block the selection mechanism in a MOEA, favoring the diversity of solutions, so that several elements of the Pareto optimal set can be generated in a single run.

Regarding selection, early MOEAs relied on the use of aggregating functions (mainly linear) [76] and relatively simple population-based approaches [157]. However, such approaches have evident drawbacks (i.e., the use of linear aggregating functions does not allow the generation of nonconvex portions of the Pareto front regardless of the weight combination that is adopted [34]). Towards the mid-1990s, MOEAs started to adopt variations of the so-called *Pareto ranking* selection mechanism. This approach was originally proposed by David E. Goldberg in his seminal book on genetic algorithms [70], and it consists of sorting the population of an EA based on Pareto optimality, such that all nondominated individuals are assigned the same rank (or importance). The aim is that all nondominated individuals get the same probability of being selected and that such probability is higher than the one corresponding to individuals which are dominated. Although conceptually simple, this sort of selection mechanism allows for a wide variety of possible implementations [24, 38].

Regarding diversity maintenance, a wide variety of methods have been proposed in the specialized literature to maintain diversity in a MOEA. Such approaches include fitness sharing and niching [39, 72], clustering [179, 205], geographically based schemes [103], the use of entropy [30, 102] and parallel coordinates [84], among others. In all cases, the core idea behind diversity maintenance mechanisms is to penalize solutions that are too close from each other in some space (i.e., decision variable or objective function space or even both). Most MOEAs penalize solutions that are too close from each other in objective function space, because it is normally aimed to have solutions well distributed along the Pareto front.

Additionally, some researchers have proposed the use of mating restriction schemes (which impose rules on the individuals that can be recombined) [93, 114, 202]. Furthermore, the use of relaxed forms of Pareto dominance became relatively popular some years ago, mainly as an archiving technique which encourages diversity while allowing the archive to regulate convergence (the most popular of

such mechanisms is, with no doubt, ϵ-dominance [107], which has been adopted in some approaches such as ϵ-MOEA [41]).

A third component of modern MOEAs is elitism, which normally consists of using an external archive (also called "secondary population" [88]) that may (or may not) interact in different ways with the main (or "primary") population of the MOEA during selection. The main purpose of this archive is to store *all* the nondominated solutions generated throughout the search process while removing those that become dominated later in the search (called local nondominated solutions). The approximation of the Pareto optimal set produced by a MOEA is thus the final contents of this archive. It is important to emphasize that the use of elitism is not only advisable (the lack of elitism could make us lose nondominated solutions generated during the search), but it is also required because of theoretical reasons (elitism is required in order to guarantee convergence of a MOEA to the Pareto optimal set as proved in [152]).

It is worth noticing that, in practice, external archives are normally bounded to a certain maximum number of solutions [104]. This was originally done in some MOEAs that used the external archive during the selection stage (see, for example, [205]). In such a case, allowing the size of the archive to grow too much dilutes the selection pressure, which has a negative effect on the performance of the MOEA. However, most modern MOEAs bound the size of the external archive, even if the archive is not used during the selection process, mainly because of practical reasons (this makes easier to compare results with respect to other MOEAs).

An important remark is that the use of a plus (+) selection is another possible elitist mechanism. Under this sort of selection scheme, the population of parents competes with the population of offspring (both populations are of the same size) and then we keep only the best half. This sort of selection scheme has been relatively popular in single-objective optimization and has been also adopted in some modern MOEAs (see, for example, [42]), but it is less popular than the use of external archives.

Multiobjective Evolutionary Algorithms

In spite of the very large number of publications related to MOEAs that can be found in the literature, there is only a handful of algorithms that are actually used by a significant number of researchers and/or practitioners around the world:

1. **Strength Pareto evolutionary algorithm 2** (SPEA2): This is an updated version of the strength Pareto evolutionary algorithm (SPEA) proposed in the late 1990s [205] whose main features are the following—it adopts an external archive (called the external nondominated set), which stores the nondominated solutions previously generated and participates in the selection process (together with the main population). For each individual in this archive, a *strength* value is computed. This strength value is proportional to the number of solutions that a

certain individual dominates. In SPEA, the fitness of each member of the current population is computed according to the strengths of all external nondominated solutions that dominate it. As the size of the external nondominated set grows too much, this significantly reduces the selection pressure and slows down the search. In order to avoid this, SPEA adopts a clustering technique that prunes the contents of the external nondominated set so that its size remains below a certain (predefined) threshold. SPEA standardized the use of external archives as the elitist mechanism of a MOEA, although this sort of mechanism had been used before by other researchers (see, for example, [91]). SPEA2 has three main differences with respect to the original SPEA [208]: (1) It incorporates a fine-grained fitness assignment strategy which takes into account, for each individual, both the number of individuals that dominate it and the number of individuals by which it is dominated, (2) it uses a nearest neighbor density estimation technique which guides the search more efficiently (i.e., a more efficient clustering algorithm is adopted), and (3) it uses an enhanced archive truncation method that guarantees the preservation of boundary solutions (this fixes a bug from the original SPEA).

2. **Pareto archived evolution strategy** (PAES): This is perhaps the most simple MOEA than can be possibly designed. It was proposed by Knowles and Corne [105], and it consists of a (1+1) evolution strategy (i.e., a single parent that generates a single offspring through the application of mutation to the parent) in combination with a historical archive that stores the nondominated solutions previously found. This archive is used as a reference set against which each mutated individual is being compared. Such (external) archive adopts a crowding procedure that divides objective function space in a recursive manner. Then, each solution is placed in a certain grid location based on the values of its objectives (which are used as its "coordinates" or "geographical location"). A map of such a grid is maintained, indicating the number of solutions that reside in each grid location. When a new nondominated solution is ready to be stored in the archive, but there is no room for it (the size of the external archive is bounded), a check is made on the grid location to which the solution would belong. If this grid location is less densely populated than the most densely populated grid location, then a solution (randomly chosen) from this heavily populated grid location is deleted to allow the storage of the newcomer. This aims to redistribute solutions, favoring the less densely populated regions of the Pareto front. Since the procedure is adaptive, no extra parameters are required (except for the number of divisions of the objective space).
3. **Nondominated sorting genetic algorithm II** (NSGA-II): This is a heavily revised version of the nondominated sorting genetic algorithm (NSGA), which was originally proposed in the mid-1990s [171] as a straightforward implementation of the Pareto ranking algorithm described by Goldberg in his book [70]. NSGA was, however, slow and produced poorer results than other non-elitist MOEAs available in the mid-1990s, such as MOGA [61] and NPGA [89]. NSGA-II adopts a more efficient ranking procedure than its predecessor. Additionally, it estimates the density of solutions surrounding a particular one

in the population by computing the average distance of two points on either side of this point along each of the objectives of the problem. This value is the so-called crowding distance. During selection, NSGA-II uses a crowded-comparison operator which takes into consideration both the nondomination rank of an individual in the population and its crowding distance (i.e., nondominated solutions are preferred over dominated solutions, but between two solutions with the same nondomination rank, the one that resides in the less crowded region is preferred). NSGA-II does not use an external archive as most of the modern MOEAs in current use. Instead, the elitist mechanism of NSGA-II consists of combining the best parents with the best offspring obtained (i.e., this is the $(\mu + \lambda)$-selection used in evolution strategies). Due to its clever mechanisms, NSGA-II is much more efficient (computationally speaking) than its predecessor, and its performance is so good that it became very popular, triggering a significant number of applications and becoming some sort of landmark against which new MOEAs were compared during more than 20 years, in order to merit publication. More recently, the nondominated sorting genetic algorithm III (NSGA-III) [40] was introduced. NSGA-III still adopts the same NSGA-II framework (i.e., it still performs a classification of the population in nondominated levels). However, its mechanism to maintain diversity is based on the use of a number of well-spread reference points which are adaptively updated. The NSGA-III does not require any additional parameters (other than those associated to the genetic algorithm that is used as its search engine), and it is designed to deal with many-objective optimization problems (i.e., problems having 4 or more objectives).

4. **Pareto envelope-based selection algorithm** (PESA): This algorithm was proposed by Corne et al. [28] and uses a small internal population and a larger external (or secondary) population. PESA adopts the same adaptive grid from PAES to maintain diversity. However, its selection mechanism is based on a crowding measure. This same crowding measure is used to decide what solutions to introduce into the external population (i.e., the archive of nondominated vectors found along the evolutionary process). Therefore, in PESA, the external memory plays a crucial role in the algorithm since it determines not only the diversity scheme, but also the selection performed by the method. There is also a revised version of this algorithm, called PESA-II [27], which is identical to PESA, except for the fact that region-based selection is used in this case. In region-based selection, the unit of selection is a hyperbox rather than an individual. The procedure consists of selecting (using any of the traditional selection techniques [71]) a hyperbox and then randomly selecting an individual within such hyperbox. The main motivation of this approach is to reduce the computational costs associated with traditional MOEAs (i.e., those based on Pareto ranking).
5. **Multiobjective evolutionary algorithm based on decomposition** (MOEA/D): This approach was proposed by Zhang and Li [201]—the main idea of this algorithm is to decompose a multiobjective optimization problem into several

scalar optimization sub-problems which are simultaneously optimized. The decomposition process requires the use of weights, but the authors provide a method to generate them. During the optimization of each sub-problem, only information from the neighboring sub-problems is used, which allows this algorithm to be effective and efficient. It is worth indicating that the decomposition process is based on the use of a scalarizing function [138], which plays a key role in the performance of the algorithm. MOEA/D is considered one of the most powerful MOEAs currently available, as has been evidenced by several comparative studies and many extensions of the algorithm are currently available (see, for example, [125, 180, 189]).

Recent Algorithmic Trends

Many other MOEAs have been proposed in the specialized literature based on concepts such as the use of very small population sizes [177, 178], the use of the maximin expression [124, 128], and a transformation of a multiobjective problem into a linear assignment problem [182], among many others. However, they will not be discussed here due to obvious space limitations. A more interesting issue, however, is to try to predict which sort of MOEA will become predominant in the next few years.

Efficiency is, for example, a concern nowadays, and several approaches have been developed in order to improve the efficiency of MOEAs (see, for example, [46, 95, 111]). Also, the use of fitness approximation, fitness inheritance, surrogates, and other similar techniques has become more common in recent years, which is a clear indication of the more frequent use of MOEAs for the solution of computationally expensive problems (see, for example, [20, 121, 122, 198]).

However, the most promising research line within algorithmic design seems to be the use of a performance measure in the selection mechanism of a MOEA. This research trend formally started with the indicator-based evolutionary algorithm (IBEA) [206], although this idea had been already formulated and used (in different ways) by other authors before (see, for example, [90, 103]). Nevertheless, the most representative MOEA within this family is perhaps the S metric selection evolutionary multiobjective algorithm (SMS-EMOA) [11, 52]. SMS-EMOA was originally proposed by Emmerich et al. [52] and is based on NSGA-II. SMS-EMOA creates an initial population and then it generates only one solution by iteration (i.e., it uses steady-state selection) using the operators (crossover and mutation) of the NSGA-II. After that, it applies nondominated sorting. When the last front has more than one solution, SMS-EMOA uses the hypervolume contribution to decide which solution will be removed. The **hypervolume** (also known as the S metric or the Lebesgue measure) of a set of solutions measures the size of the portion of objective space that is dominated by those solutions collectively. This is the only unary performance indicator which is known to be fully Pareto compliant [209].

Beume et al. [11] proposed not to use the contribution to the hypervolume indicator when in the nondominated sorting process we obtain more than one front. In that case, they proposed to use the number of solutions which dominate one solution (the solution that is dominated by more solutions is removed). The authors argued that the motivation for using the hypervolume indicator is to improve the distribution in the nondominated front and then it is not necessary in fronts different to the nondominated front.

The hypervolume indicator has attracted a lot of attention from researchers due to its interesting theoretical properties. For example, it has been proved that the maximization of the hypervolume is equivalent to finding the Pareto optimal set [57]. Empirical studies have shown that (for a certain number of points previously determined) the maximization of the hypervolume does indeed produce subsets of the Pareto front which are well distributed [52, 103].

However, there are also practical reasons for being interested in indicator-based selection. The main one is that MOEAs such as SMS-EMOA seem to continue working as usual as we increase the number of objectives, as opposed to Pareto-based selection mechanisms which are known to degrade quickly in problems having more than 3 objectives (this research area is known as *many-objective optimization*). Although the reasons for the poor scalability of Pareto-based MOEAs requires further study (see, for example, [161]), the need for scalable selection mechanisms has triggered an important amount of research around indicator-based MOEAs. The main drawback of adopting the hypervolume in the selection mechanism of a MOEA is its extremely high computational cost. One possible alternative for dealing with this high computational cost is to estimate the hypervolume contribution. However, MOEAs designed around this idea (e.g., HyPE [7]) seem to have a poor performance with respect to those that adopt exact hypervolume contributions. An alternative is to rely on other performance indicators. In this regard, several researchers have proposed the design of selection mechanisms based on performance measures such as Δ_p [149,160], and $R2$ [15,78,83,181]. The use of the maximin [8, 124, 127] is another intriguing alternative, as this expression seems to be equivalent to the use of the ϵ-indicator [207].

Use of Other Metaheuristics

A wide variety of other bio-inspired metaheuristics have become popular in the last few years for solving optimization problems [26]. Multiobjective extensions of many of these metaheuristics already exist [24], but few efforts have been made to actually exploit the main specific features of each of them. There are also few efforts in trying to understand the types of problems in which each of these metaheuristics can be more suitable.

Next, we briefly review three popular bio-inspired metaheuristics that are good candidates for being used as multiobjective optimizers, but many other choices also exist (see, for example, [24]).

Artificial Immune Systems (AIS)

Our natural immune system has provided a fascinating metaphor for developing a new bio-inspired metaheuristic. Indeed, from a computational point of view, our immune system can be considered as a highly parallel intelligent system that is able to learn and retrieve previously acquired knowledge (i.e., it has "memory"), when solving highly complex recognition and classification tasks. This motivated the development of the so-called artificial immune systems (AISs) during the early 1990s [35, 132].

AISs were identified in the early 1990s as a useful mechanism to maintain diversity in the context of multimodal optimization [62, 168]. Smith et al. [169] showed that fitness sharing can emerge when their emulation of the immune system is used. Furthermore, the approach that they proposed turns out to be more efficient (computationally speaking) than traditional fitness sharing [39], and it does not require additional information regarding the number of niches to be formed.

Over the years, a wide variety of multiobjective extensions of AISs have been proposed (see, for example, [23, 115, 116, 118, 140, 197]). However, most of the algorithmic trends in MOEAs have had a delayed arrival in multiobjective AISs. Also, the high potential of multiobjective AISs for pattern recognition and classification tasks has been scarcely exploited.

For more information on multiobjective AISs, the interested reader is referred to [16, 63].

Particle Swarm Optimization (PSO)

This metaheuristic is inspired on the movements of a flock of birds seeking food, and it was originally proposed in the mid-1990s [101]. In the particle swarm optimization algorithm, the behavior of each particle (i.e., individual) is affected by either the best local (within a certain neighborhood) or the best global (i.e., with respect to the entire swarm, or population) individual. PSO allows particles to benefit from their past experiences (a mechanism that does not exist in traditional evolutionary algorithms) and uses neighborhood structures that can regulate the behavior of the algorithm.

The similarity of PSO with EAs has made possible the quick development of an important number of multiobjective variants of this metaheuristic (see, for example, [106, 136, 146, 166]). Unlike AISs, most algorithmic trends adopted with MOEAs have quickly been incorporated into multiobjective particle swarm optimizers (MOPSOs). Nevertheless, few PSO models have been used for multiobjective optimization, and the study of the specific features that could make MOPSOs advantageous over other metaheuristics in some specific classes of problems is still a pending task.

For more information on MOPSOs, the interested reader is referred to [9, 22, 24, 48].

Ant Colony Optimization (ACO)

This metaheuristic was inspired on the behavior observed in colonies of real ants seeking for food. Ants deposit a chemical substance on the ground, called pheromone [45], which influences the behavior of the ants: They tend to take those paths in which there is a larger amount of pheromone. Therefore, pheromone trails can be seen as an indirect communication mechanism used by ants (which can be seen as agents that interact to solve complex tasks). This interesting behavior of ants gave rise to a metaheuristic called *ant system*, which was originally applied to the travelling salesperson problem. Nowadays, the several variations of this algorithm that have been developed over the years are collectively denominated *ant colony optimization* (ACO), and they have been applied to a wide variety of domains, including continuous optimization problems.

Several multiobjective versions of ACO are currently available (see, for example, [54, 147, 183, 203]). However, the algorithmic trends developed in MOEAs have had a slow delay in being incorporated into multiobjective ACO algorithms. Additionally, the use of alternative ACO models for multiobjective optimization has been relatively scarce.

For more information on multiobjective ACO, the interested reader is referred to [4, 24, 68].

Other Metaheuristics

Many other metaheuristics have been extended to deal with multiobjective optimization problems, including simulated annealing [77, 82, 165], differential evolution [47, 110, 191], tabu search [2, 36, 204], scatter search [85, 109, 155], and artificial bee colony [153, 193, 194], among many others. However, their discussion was omitted due to obvious space constraints.

Some Applications

Multiobjective metaheuristics have been extensively applied to a wide variety of domains. Next, we will provide a short list of sample applications classified in three large groups: (1) engineering, (2) industrial, and (3) scientific. Specific areas within each of these large groups are also identified.

By far, engineering applications are the most popular in the current literature on multiobjective metaheuristics. This is not surprising if we consider that engineering disciplines normally have problems with better understood mathematical models. A representative sample of engineering applications is the following:

- Electrical engineering [33, 96]
- Hydraulic engineering [64, 195]

- Structural engineering [94, 200]
- Aeronautical engineering [142, 173]
- Robotics [99, 196]
- Control [156, 172]
- Telecommunications [53, 170]
- Civil engineering [119, 126]
- Transport engineering [17, 174]

Industrial applications are the second most popular in the literature on multiobjective metaheuristics. A representative sample of industrial applications of multiobjective metaheuristics is the following:

- Design and manufacture [3, 74]
- Scheduling [31, 97]
- Management [6, 66]

Finally, there are several publications devoted to scientific applications. For obvious reasons, computer science applications are the most popular in the literature on multiobjective metaheuristics. A representative sample of scientific applications is the following:

- Chemistry [56, 144]
- Physics [154, 185]
- Medicine [110, 156]
- Computer science [151, 196]

This sample of applications should give at least a rough idea of the increasing interest of researchers for adopting multiobjective metaheuristics in practically all kinds of disciplines.

Some Current Challenges

The existence of challenging, but solvable problems is a key issue to preserve the interest in a research discipline. Although multiobjective optimization using metaheuristics is a discipline in which a very important amount of research has been conducted, mainly within the last fifteen years, several interesting problems still remain open. Additionally, the research conducted so far has also led to new and intriguing topics. The following is a small sample of open problems that currently attract a significant amount of research within this area:

- **Large-scale problems**: Although scalability in objective function space (the so-called many-objective problems [131, 184]) has been studied for more than 15 years, large-scale multiobjective optimization problems (i.e., problems having 100 or more decision variables) is a more recent research area (see, for example,

[87, 123, 176]). Initially, most of the proposed approaches relied on cooperative co-evolution [5] or on the analysis of the decision variables [18]. However, over the years, the use of approaches based on dimensionality reduction (this is also called problem reformulation) [81] and specialized mechanisms to generate offspring [80] became popular. Recent approaches contain mechanisms that allow solving problems with over one million decision variables, relying on clever offspring generation mechanisms (see [113]).

- **Incorporation of user's preferences**: It is normally the case that the user does not need the entire Pareto front of a problem, but only a certain portion of it. For example, solutions lying at the extreme parts of the Pareto front are normally unnecessary since they represent the best value for one objective, but the worst for the others. Thus, if the user has at least a rough idea of the sort of trade-offs that he/she aims to find, it is desirable to be able to explore in more detail only the nondominated solutions within the neighborhood of such trade-offs. This is possible, if we use, for example, biased versions of Pareto ranking [32] or some multi-criteria decision-making technique, from the many developed in Operations Research [13, 21, 134]. In spite of the importance of preference incorporation in real-world applications, the use of these schemes in multiobjective metaheuristics is still relatively scarce [112, 148].
- **Dealing with expensive problems**: There is an important number of real-world multiobjective problems for which a single evaluation of an objective function may take several minutes, hours, or even days [142]. Evidently, such problems require special techniques to be solvable using MOEAs [79]. The main approaches that have been developed in this area can be roughly divided into three main groups:

  1. **Use of parallelism**: This is the most obvious approach given the current access to low-cost parallel architectures (e.g., GPUs [92, 167]). It is worth noting, however, that in spite of the existence of interesting proposals (see, for example, [55]), the basic research in this area has remained scarce, since most publications involving parallel MOEAs focus on specific applications or on parallel extensions of specific MOEAs, but rarely involves basic research.
  2. **Surrogates**: In this case, knowledge of past evaluations of a MOEA is used to build an empirical model that approximates the fitness functions to be optimized. This approximation can then be used to predict promising new solutions at a lower evaluation cost than that of the original problem [122, 143]. Current functional approximation models include polynomials (response surface methodologies [164]), neural networks (e.g., multilayer perceptrons (MLPs) [136]), radial-basis function (RBF) networks [37], support vector machines (SVMs) [25], Gaussian processes [192], and Kriging [143] models. The use of statistical models developed in the mathematical programming literature in combination with MOEAs is also an interesting alternative (see, for example, the multiobjective P-algorithm [135, 188]).
  3. **Fitness approximation**: The idea of these approaches is to predict the fitness value of an individual without performing its actual evaluation [65, 141]. From

the several techniques available [20], fitness inheritance has been one of the most popular (in relative terms) in multiobjective optimization [145, 190] but the research in this area has been very scarce in recent years. However, other ideas, such as the use of transformation methods that allow to approximate the fitness landscape (see, for example, [19]) or incremental learning [120], are certainly worth pursuing.

- **Theoretical foundations**: Although an important effort has been made in recent years to provide a solid theoretical foundation to this field, a lot of work is still required and the work done in the Operations Research community can provide some useful hints (see, for example, [135, 187]). The most relevant theoretical work in this area includes topics such as convergence [186], archiving [1, 159], algorithm complexity [133], and runtime analysis [44, 108].
- **Constraint handling**: There has been a lot of research on constraint-handling techniques for MOEAs in recent years (see, for example, [29, 67, 98, 130]). However, there has been some criticism to state-of-the-art constraint-handling techniques developed for MOEAs, because there is evidence indicating that they cannot properly solve some real-world problems (e.g., in mechanical design [139]) in spite of the fact that such methods have a good performance in the currently available benchmarks. This has triggered an interesting discussion, since it is evident that the current benchmarks for constrained MOEAs are fairly limited. For example, these test problems are not properly characterized and, in general, the only information available about them is the number of decision variables, the number of constraints, the true Pareto front, and the feasibility rate. However, there are studies available which indicate that this information is insufficient [175].
- **Evolutionary multitasking**: Gupta et al. [75] proposed the so-called evolutionary multitasking as a new paradigm in evolutionary optimization in which the population of a sequential evolutionary algorithm is used to solve multiple optimization problems simultaneously. This idea is inspired on bio-cultural models of multifactorial inheritance. When introduced, its authors also proposed a cross-domain optimization platform that allows to solve diverse problems concurrently, and by allowing knowledge transfer, its use can speed up convergence in complex optimization problems. Multitasking has become relatively popular in multiobjective optimization in recent years (see, for example, [12, 117, 199]) and it is indeed a very promising research area.

Conclusions

In this chapter, we have provided some basic concepts related to multiobjective optimization using metaheuristics. This overview has included basic concepts related to multiobjective optimization in general, as well as some algorithmic details, with a particular emphasis on multiobjective evolutionary algorithms.

Some of the recent algorithmic trends have also been discussed, and some sample applications have been addressed. In general, breadth has been favored over depth, but a significant number of bibliographic references are provided for those interested in gaining an in-depth knowledge of any of the topics discussed herein.

The information provided in this chapter aims to serve as a general overview of the field and to motivate the interest of the reader for pursuing research in this area. As could be seen, several research opportunities are still available for newcomers.

Abstract

Physical processes can inspire the design of algorithms and (meta)heuristics. In recent years, a number of such algorithms, implemented on both quantum and classical computers, have been developed and applied. In this chapter, we provide an outline of the range of these algorithms, focusing on those inspired by quantum physics, and describe some applications, particularly to problems in the domain of operational research. The chapter begins with an overview of the most relevant concepts from physics, including digital quantum computing, annealing, and spin glasses. We give a high-level overview of the current state of quantum computing, including hardware, and discuss its potential and current limitations. The simulated annealing algorithm, as well as the related simulated quantum annealing algorithm, is introduced. The chapter concludes with evolutionary and swarm-based algorithms that derive inspiration from quantum mechanics. Because of the enormous scope of work done in quantum-inspired algorithms and quantum computing, the chapter is necessarily selective in the material covered.

Keywords

Algorithm · Metaheuristic · Heuristic · Quantum computing · Quantum annealing · Simulated annealing · Simulated quantum annealing · Quantum-inspired evolutionary algorithm · Quantum-inspired swarm algorithm

Introduction

Physical processes can inspire the design of algorithms and (meta)heuristics. (Many methods in this chapter are not strictly algorithms: they are not guaranteed to provide a true solution in a finite time and rarely have time estimates; but for many of them the term algorithm is most common in the literature they come from, so we mostly use it.) In recent years, a number of such algorithms, implemented on both quantum and classical computers, have been developed and applied. In this chapter, we provide an outline of the range of such algorithms, focussing on those inspired by quantum physics, and describe some applications, particularly to problems in the domain of operational research.

We begin with a short introduction to the major areas of physics in sections "A Brief Primer on Physics" and "Annealing and Spin Glasses," since many physical concepts are central in algorithms of interest. It is not possible to discuss in detail all of these areas in one chapter, so we focus on the aspects of each area that are most helpful in understanding the range of quantum-inspired algorithms that currently exist.

In subsequent sections, we describe a number of algorithms that are inspired by aspects of these physical phenomena (readers who are looking for a high-level overview of physically inspired algorithms may wish to initially skip to section "Simulated Annealing," and then return to earlier sections for discussion of the physical principles which underlie the algorithms). The degree of fidelity of these algorithms to the original natural process varies. Different algorithms could be devised depending on which aspect of the underlying phenomenon is chosen: an algorithm designer may choose the degree of fidelity to nature of an algorithm, to give an algorithm which is efficient on the problems to which it is applied, while not necessarily being perfectly true to nature. As described in section "Digital Quantum Computers," Feynman [36] showed that, because of entanglement, no classical computer can efficiently simulate quantum systems, as it would need exponential time or resources to do so. Thus, for algorithms run on a classical computer, the degree of inspiration that can be taken from quantum mechanics is perforce limited; all such algorithms in this chapter are at best partial approximations of nature. However, as our criterion of usefulness is not fidelity to nature but rather effectiveness in problem solving, we discuss them here: despite their lack of physical verisimilitude, they have led to a rich thread of literature and many applications.

The algorithms discussed begin with a brief overview of the simulated annealing (SA) algorithm in section "Simulated Annealing" and the simulated quantum annealing algorithm (SQA) in section "Simulated Quantum Annealing." Later sections introduce hybrid binary-valued and hybrid real-valued quantum-inspired evolutionary algorithms, as well as quantum binary particle swarm optimisation algorithms; all of whose workings draw inspiration from concepts of quantum mechanics.

To constrain the size of this chapter, which could otherwise become overweeningly large, we rule out of scope considerations such as computational experience or testing. However, the reader should be aware that many of the methods discussed here are in their infancy, particularly the pure quantum approaches on quantum hardware; while they are currently not competitive with the best classical approaches, this may change as technology advances. An example of their potential is the anecdotal evidence of harvesting of Internet financial transactions, as the encryption of these may be breakable in future with more advanced quantum computers.

A Brief Primer on Physics

This section provides a short overview of some major areas of physics and how they fit together. Sections "Classical Mechanics" and "Annealing and Spin Glasses" explore in a little more depth classical mechanics, thermodynamics, quantum mechanics, quantum computing, and models of annealing. A good further introduction to classical and modern physics, with a fair level of mathematical detail, is [84].

A High-Level Taxonomy of Modern Physics

Figure 1 provides a rough taxonomy of physics, with major areas shown as boxes with continuous outline. Continuous arrows show which areas come from others by relaxing assumptions or introducing new principles to existing areas. Dotted boxes show some of the best-known physically inspired algorithms, and dotted arrows show which area(s) of physics inspire them.

Classical Mechanics This is due to Galileo, Newton, and others. Particles and/or bodies are acted on by *forces* which instantaneously act at a distance. Lagrange, Hamilton, and others gave equivalent descriptions in terms of *energy*.

Thermodynamics This was developed by Carnot, Boltzmann, and others. It studies measurable macroscopic properties, e.g. temperature and pressure, of a system comprising microscopic components (e.g. a gas), and the ideas of thermodynamic equilibrium, thermodynamic processes, and entropy. It explains why physical systems seek the lowest state of free energy.

Statistical Mechanics This is a statistical view of thermodynamics, explaining measurable macroscopic properties in terms of statistics of distinguishable particles. The statistical mechanics Ising model of spin lattices describes spin-glass states of magnetic materials and inspires the simulated annealing and simulated quantum annealing algorithms.

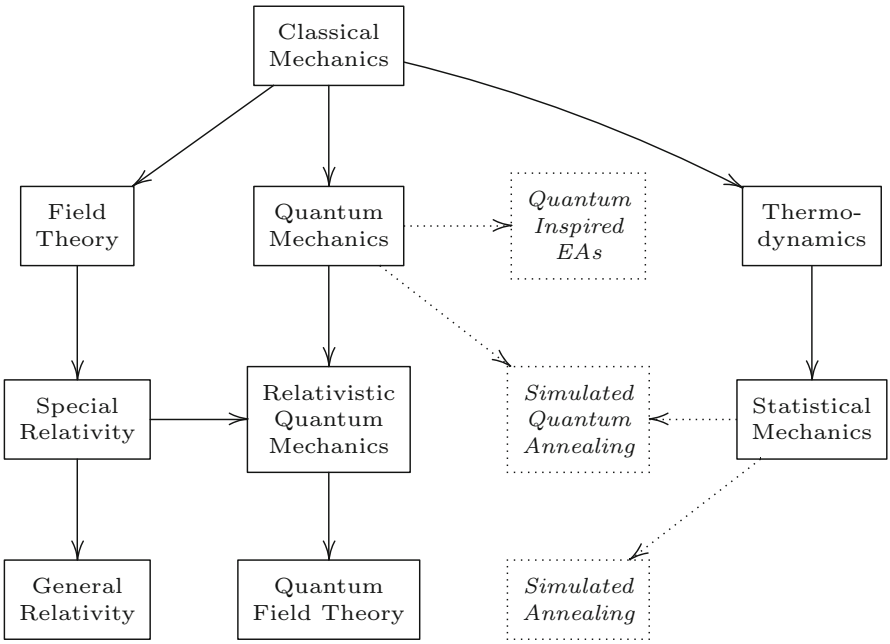

Fig. 1 Areas of physics (solid boxes) and connections among them (solid arrows); and major physically inspired algorithms (dotted boxes) and which areas of physics inspire them (dotted arrows)

Field Theory This was developed by Maxwell and others. An object may generate a scalar potential field V which gives rise to a vector field ∇V, e.g. the "classical" fields, gravitation, and electromagnetism. Other objects may be influenced by this field, e.g. a difference in electrical potential between two points can cause a flow of electrical current between them. A field can carry energy through space in the form of waves: this implies a finite signal propagation speed, dispensing with instantaneous "action at a distance." In particular, Maxwell's electromagnetism laws imply light has a constant finite speed c in a vacuum.

Special Theory of Relativity This is due to Einstein (and in part to Poincaré and Lorentz) who added the axiom of equivalence of inertial reference frames to the constant speed of light given by Maxwell's equations of electromagnetism. (Maxwell's equations are in fact relativistically invariant.)

General Theory of Relativity This was developed by Einstein from the Special Theory, by adding the *principle of equivalence* of inertial and gravitational mass: a uniform gravitational field is indistinguishable from acceleration.

Quantum Mechanics This is due to Planck, Bohr, Schrödinger, Heisenberg, Pauli, Einstein, and others. *Quantisation* means replacing physical quantities or *observables* (e.g. position, momentum, energy) by operators on a Hilbert space of *wavevectors* or *wavefunctions*.

Relativistic Quantum Mechanics Dirac reworked Schrödinger's equation for the electron to a relativistically invariant form in which the wavevectors have extra degrees of freedom, which capture the spin of the electron, and so predicted the existence of antimatter. However, to date, quantum mechanics and general relativity have not satisfactorily been combined.

Quantum Field Theory (QFT) This was developed by Feynman and others, building on Dirac's work. In QFT, the fields themselves, including the wavefunction, are quantised (called second quantisation): thus carriers of forces are particles. The first QFT, quantum electrodynamics (QED), was derived using a least action principle for path integrals and is the most precise current physical theory.

Classical Mechanics

In sections "Simulated Annealing" and "Simulated Quantum Annealing," we describe the simulated annealing and simulated quantum annealing algorithms. In these algorithms, "energy" is a core concept, so we first describe the ideas of energy and the Hamiltonian. When designing a physically inspired algorithm, constructing an artificial Hamiltonian to model the objective function of an optimisation problem is often a central step.

Energy and Momentum

Energy is the ability to perform work, e.g. move an object. (An object of negligible size is called a *particle*; otherwise – i.e. it has physical extension – it is called a *rigid body* or just *body*.) The total energy – or *Hamiltonian* – of a system may be viewed as comprised of two parts: the *kinetic* energy K, due to motion, and the *potential* energy, or *energy of interaction*, V, the energy an object has because of its position $x = (x_1, x_2, x_3)$ relative to other objects in space. Energy is a nonnegative scalar quantity. The *principle of conservation of energy* says that the total energy $K + V$ is a *conserved* or *invariant* quantity: it remains the same even if the internal configuration of the system changes (assuming no outside influences).

The time derivative of the position vector x of an object is called its *velocity* (*vector*) $v := \dot{x} := \frac{\mathrm{d}}{\mathrm{d}t}x$ (differentiation with respect to time t is commonly denoted by a dot over the variable, a notation introduced by Newton). A particle of mass m and velocity v has *momentum* $p := mv$. Momentum is a vector quantity, since velocity is a vector. The *total momentum* of a system is the vector sum of the momenta of individual objects in the system: it is a conserved quantity in that

it cannot change in the absence of influences from outside the system (Newton's first law). There are other conserved quantities in classical mechanics, e.g. angular momentum of rigid bodies.

In Newtonian dynamics, a *force* is an influence that can accelerate (change the velocity of) an object. Newton's second law, $F = ma$, relates the acceleration $a := \dot{v}$ of an object to the force vector F applied to it and the object's mass m. Because a force alters the velocity of an object, it alters its kinetic energy, and so does work. A *conservative* force is a force for which the amount of work it does (e.g. in moving a particle) is independent of the path taken: such processes are *reversible*. This is not true of nonconservative forces. Examples of conservative forces are gravity and electromagnetism.

Given a collection of particles, a conservative force can be represented by a scalar potential field $V = V(x_1, x_2, x_3)$ (i.e. a number defined at each point). Then its gradient $\nabla V := \left(\frac{\partial}{\partial x_1} V, \frac{\partial}{\partial x_2} V, \frac{\partial}{\partial x_3} V\right)$ is a vector field giving the resulting forces between particles; if there are no other forces, the particles will move in response to these forces, reducing the potential energy and converting the excess potential energy into kinetic energy, but keeping the sum $K + V$ constant. For example, if a ball is held above the surface of the earth and then released, gravitational forces will pull the earth and ball together, converting the potential energy into kinetic energy (which appears as heat energy of the atoms of the earth and ball).

The Hamiltonian

The *Hamiltonian*, or total energy of a system, is important in optimisation algorithms, both true quantum algorithms on quantum computers and physically inspired algorithms on classical computers, such as simulated annealing and simulated quantum annealing. In such physically inspired algorithms, the Hamiltonian (more precisely, an analogue of it) is constructed from a potential energy term, namely the objective function, and a kinetic energy term, representing some modification to the objective function.

Newton's laws were reformulated by Euler, Lagrange, Hamilton, and others in terms of energy, a scalar quantity, leading to unifying views of mechanics. For us, the most important of these views is the *Hamiltonian* approach; it is closely related to the *Lagrangian* view, which we discuss first.

Suppose that a system of particles and bodies is given. In both views, the *configuration space* $\mathcal{S}$ of the system is considered: each point of $\mathcal{S}$ represents an arrangement in space of all the particles and bodies, that is, all the locations of all parts of the system. $\mathcal{S}$ has a large dimension N. For example, for n particles, $\mathcal{S}$ has $N = 3n$ dimensions as it includes the three position coordinates of all n particles. As time passes, the single point q of $\mathcal{S}$ that represents the system moves around in $\mathcal{S}$ following some law that completely describes the classical behaviour of the system. This law derives from one scalar-valued function.

In the Lagrangian view, the function is known as the *Lagrangian* $\mathcal{L}$ and is defined on the $2N$-dimensional tangent bundle $T(\mathcal{S})$ of $\mathcal{S}$. The Lagrangian is the kinetic

energy minus the potential energy: $\mathcal{L} = K - V$. It is important for the following reason. As the system evolves, the point q representing it in $\mathcal{S}$ moves along some curve C; the (*Hamilton*) *principle of least action* says that the motion of q through $\mathcal{S}$ is such that the *action* (the integral of $\mathcal{L}$ along C) will be a minimum. That is, if the action is taken as a measure of curve length, C is a geodesic.

In the Hamiltonian view, the function describing the behaviour of the system is known as the *Hamiltonian* $\mathcal{H}$ and is defined on the *phase space* $\mathcal{P}$: another name for the $2N$-dimensional cotangent bundle $T^*(\mathcal{S})$ of $\mathcal{S}$. The Hamiltonian is the sum of kinetic and potential energy, that is, $\mathcal{H} = K + V$ is the total energy of the system. (Note: the cotangent bundle and tangent bundle are in general *manifolds*. Neither is a linear space, nor is there a single coordinate system for the whole space.)

Let the coordinates of a point x in $\mathcal{S}$ be $x_1, \ldots, x_N$, sometimes called *generalised position coordinates*. Let $p_1, \ldots, p_N$ be the corresponding *generalised momentum coordinates*. Here, if x_i is a position coordinate of a particle with mass m, and the particle has velocity component v_i in direction x_i, then $p_i = mv_i$. The point P in the phase space $\mathcal{P}$ corresponding to $x \in \mathcal{S}$ has coordinates $(x, p) = (x_1, \ldots, x_N, p_1, \ldots, p_N)$, and the value of the Hamiltonian at this point is $\mathcal{H}(x, p) = \mathcal{H}(x_1, \ldots, x_N, p_1, \ldots, p_N)$.

The Hamiltonian $\mathcal{H}$ leads to *Hamilton's dynamical equations*,

$$\frac{\mathrm{d}p_i}{\mathrm{d}t} = -\frac{\partial \mathcal{H}}{\partial x_i}, \qquad \frac{\mathrm{d}x_i}{\mathrm{d}t} = \frac{\partial \mathcal{H}}{\partial p_i}, \qquad i = 1, \ldots, N, \tag{1}$$

which describes the time evolution of the original system as the trajectory of the point P in the phase space.

For intuition, consider a single particle of mass m, in a field described by a potential $V = V(x_1, x_2, x_3, t)$ that depends on position and time. V defines the potential energy of the particle due to the field. The kinetic energy of a particle of mass m and velocity v is $\frac{1}{2}m\|v\|^2 = \frac{1}{2m}\|p\|^2$, which in this example gives $\frac{1}{2}m(\dot{x_1}^2 + \dot{x_2}^2 + \dot{x_3}^2) = \frac{1}{2m}(p_1^2 + p_2^2 + p_3^2)$. Therefore

$$\mathcal{H} = \frac{p_1^2 + p_2^2 + p_3^2}{2m} + V. \tag{2}$$

For example, if the particle is in the earth's gravitational field, with position coordinates x_1, x_2, x_3, where x_3 is its distance from the earth, we can take $V = mgx_3$ where $g \approx 9.8\ \mathrm{ms}^{-2}$ is the acceleration due to gravity. Equation (2) gives

$$\mathcal{H} = \frac{p_1^2 + p_2^2 + p_3^2}{2m} + mgx_3. \tag{3}$$

The phase space $\mathcal{P}$ has the important property that it is a symplectic manifold, equipped with a *Poisson bracket*, $\{\ ,\ \}$, which takes two scalar fields A and B defined on $\mathcal{P}$ and returns a third such scalar field, $\{A, B\}$. The Poisson bracket has useful properties. The time evolution of any scalar physical quantity $A = A(x, p)$ is given

by its Poisson bracket with the Hamiltonian: $\dot{A} = \{A, \mathcal{H}\}$. It can be shown that $\{\mathcal{H}, \mathcal{H}\} = 0$, the principle of conservation of energy in another form. The symplectic or *canonical* structure given by the Poisson bracket is generalised in the setup of quantum mechanics.

Thermodynamics

Annealing (see section "Simulated Annealing") may be viewed as minimising the (*Helmholtz*) *free energy* of a system, through a slow cooling; this is in the sense of the thermodynamic principle that *every system seeks to achieve a minimum of free energy*. It may also be viewed as maximising the entropy, since the system is relaxed to thermal equilibrium. We now give some intuition on these concepts.

A thermodynamic system is *macroscopic* or large scale: it is taken to consist of a large number of distinguishable particles, typically of the order of Avogadro's number, 6.022×10^{23}. In a gas or liquid, the particles are free to move; in a solid, they are largely fixed but can rotate or vibrate about their average positions. Thermal energy has two components, the kinetic energy due to random motion of particles and the potential energy of their relative positions. Each particle has several degrees of freedom that can hold energy: translational degrees (which usually dominate), namely, the velocity components in the three coordinate directions, as well as any rotation or vibration about its centre of mass that the particle may have. Measurable macroscopic properties of a system such as pressure or temperature are properly viewed as statistical averages derived from the energies in the degrees of freedom of the constituent particles (components) of the system.

We view the system at a given time as being in a state in phase space $\mathcal{P}$, often called a *microstate*. We "roughly" divide $\mathcal{P}$ into subsets called *macrostates*. If two (micro)states x and y lie in the same macrostate, this means that macroscopically we cannot tell apart x and y: the temperature, pressure, etc., of x and y may be indistinguishable to the best precision of our measuring instruments. This division into macrostates is somewhat arbitrary but suffices for our purposes.

The *entropy* S of a system microstate $x \in \mathcal{P}$ is $k_B \ln \Omega$, where Ω is the volume in $\mathcal{P}$ of the macrostate containing x and k_B is Boltzmann's constant. This definition of entropy is reasonably robust because of the slow growth of the log function, and the fact that the macrostates' volumes are generally very different. *Thermal equilibrium* (or *thermodynamic equilibrium*) is by far the most likely macrostate (its volume is almost equal to the volume of $\mathcal{P}$ itself) and so the state of maximum entropy. At thermal equilibrium, the principle of *equipartition of energy* holds, i.e. statistically, the system's energy is distributed equally among all of the system's degrees of freedom. (The Statistical Mechanics *Theorem of Equipartition of Energy*, which comes from Newton's Laws, says that *the total energy of a system of a large number of particles, exchanging energy among themselves through collisions, is, on average, shared equally among all the particles' degrees of freedom*.)

The *temperature* T of the system is a measure of the average energy per degree of freedom. If the system is not in thermal equilibrium, then the temperature differs

according to the location in the system (there is more energy at some locations), meaning there is a temperature potential and a resulting temperature gradient vector field. This leads to a flow of heat energy in the system and so it has the ability to provide useful work. Since only temperature gradients (differences) can perform useful work, a system in thermal equilibrium cannot perform any useful work, regardless of the actual quantity of (heat) energy in the system. Any disturbance to a system not already in thermal equilibrium is more likely than not to disperse energy more uniformly among degrees of freedom: this increases entropy and brings the system closer to thermal equilibrium.

Combinatorially, if units of energy are randomly allocated to degrees of freedom, this is much more likely to result in an *even* distribution of energy among degrees of freedom. Because of this, large-volume macrostates correspond to more uniformly spread energy, while smaller-volume macrostates correspond to nonuniformly distributed (peaked) distributions of energy among degrees of freedom. Thus, a low entropy means high energy (temperature) differences in the system, high temperature gradient, and high useful work, while high entropy means low energy differences in the system and low useful work. Thus, entropy may be viewed as a measure of the *unavailability* of a system's energy to do work. This allows us to interpret high entropy as low availability of "high-quality" energy and vice versa.

The *Helmholtz free energy* A is a thermodynamic measure of the useful work that can be obtained from a closed system at a constant temperature: $A = U - TS$, where U is the *internal* or total energy of the system (i.e. the Hamiltonian). It has a minimum at thermal equilibrium, that is, when entropy S is maximised. Hence, at nonzero temperatures, free energy is the quantity minimised in natural processes such as annealing.

The *first law of thermodynamics* is a restatement of the principle of conservation of energy, applied to heat energy.

The *second law of thermodynamics* says that, statistically, entropy increases over time; that is, the system's energy, which may originally have been distributed among relatively few degrees of freedom, tends to distribute itself among all possible degrees of freedom. (Thus, the second law is sometimes phrased as "Heat flows from a hotter to a colder place.") Hence, a system tends towards thermal equilibrium: differences in pressure, temperature, and density tend to even out; entropy measures how far this evening-out process has progressed. (An information-theoretic interpretation of entropy is that it is a measure of our uncertainty about a system. Thermal equilibrium maximises entropy because we lose all information about the initial conditions except for the summary statistics: temperature, etc. Maximising entropy maximises our ignorance about the details of the system: this is the sense in which entropy measures "disorder.") From the viewpoint of statistical mechanics, the second law arises because even distributions of energy across degrees of freedom are combinatorially much more likely (have bigger phase space volumes) than distributions with energy concentrated in relatively few degrees of freedom. The second law explains the effectively irreversible nature of physical processes involving large numbers of components.

Statistical Mechanics

Because of the large numbers of particles and degrees of freedom in any macroscopic physical system, measurable macroscopic quantities are described in terms of statistics of distinguishable particles.

For each microstate x of a classical thermodynamical system, we denote its total energy (Hamiltonian) by $\mathcal{H}_x$. Let $\beta = \frac{1}{k_B T}$, where $k_B \approx 1.38 \times 10^{-23}\,\mathrm{JK}^{-1}$ is Boltzmann's constant. (β is often called the *inverse temperature*, though its dimension is inverse energy.) The probability $P(x)$ that the system is in microstate x is proportional to the *Boltzmann factor* $\mathrm{e}^{-\beta\mathcal{H}_x}$. The proportionality constant is $Z := \sum_x \mathrm{e}^{-\beta\mathcal{H}_x}$ (the sum taken over all microstates), called the *partition function* of the system. In other words, the probability $P(x) = \frac{1}{Z}\mathrm{e}^{-\beta\mathcal{H}_x}$, so the energy of state x is proportional to the natural logarithm of its probability. The partition function is at the heart of statistical mechanics because all other thermodynamic properties of the system can be written in terms of Z or its derivatives. For example, the entropy is $S = \frac{\partial}{\partial T}(\frac{1}{\beta}\ln Z) = \frac{\partial}{\partial T}(k_B T \ln Z)$, and the Helmholtz free energy is $A = -\frac{1}{\beta}\ln Z$.

Ergodicity

We call a system's evolution or a thermodynamic process *ergodic* if, over a long time interval, the time spent by the system in a particular region of the phase space is proportional to the volume of the region.

To be more precise: a *weakly ergodic* evolution (*weak ergodicity*) means that the system forgets its initial state during the process of evolution; a *strongly ergodic* evolution (*strong ergodicity*) means that the system converges to a stationary distribution regardless of what its initial state was. For the design of algorithms, we prefer a search algorithm to be as ergodic as possible, and that (for a strongly ergodic evolution) the state to which the system converges is the state being sought (e.g. an optimum).

We remark later that certain physical systems such as magnets or spin glasses are not very ergodic, but that the kind of fluctuations caused by annealing or quantum annealing can make them more ergodic, so that they reach the ground (lowest) energy state more easily. Simulated annealing and simulated quantum annealing try to mimic this enhancement of ergodicity for objective functions.

Quantum Mechanics

Quantum mechanics is an extension of classical mechanics. It models behaviours of natural systems that are observed at very short time or distance scales. One example of such a natural system is a subatomic particle, e.g. a free electron or photon (a particle of light), but a quantum system may be composed of many particles.

Quantum mechanics comes about from classical mechanics by applying a formal *quantisation* procedure: variables representing observable physical quantities such as energy, position, momentum, spin, etc., are replaced by linear operators on a suitable vector space. The operators are called *observables*; examples include the position, momentum, and Hamiltonian of a particle. The vector space is actually a complete inner product space, that is, a *Hilbert space* over the complex numbers $\mathbb{C}$; the elements of this space are complex-valued (deterministic) functions of space and time coordinates.

This Hilbert "phase" space is analogous to a classical phase space. (In a classical phase space for n particles, we deal with real-valued functions of $6n$ dimensions, each particle having three spatial and three momentum coordinates. In quantum Hilbert phase space, we deal with complex-valued functions on a $3n$-dimensional space. However, much of the mathematical structure carries over.) An element ψ of the Hilbert space is associated with the system: ψ is called the system's *state vector* or *wavefunction* or *wavevector*, and it describes the *quantum state* the system is in. The only values that can be observed for a physical quantity are eigenvalues of the corresponding observable (a linear operator on the Hilbert space). When an eigenvalue is observed, the system's state vector ψ must be a corresponding eigenvector (also called an *eigenfunction* or *eigenstate*: it is viewed as a "classical state") of the operator. The operator's eigenvectors form a basis for the Hilbert space, so any wavefunction can be written as a linear combination of these eigenstates.

Observation and Wavefunction Collapse

The traditional "Copenhagen" interpretation of quantum mechanics is that to speak of the internal state of a quantum system before observation has no meaning, but that the wavefunction allows us to calculate probabilities of outcomes of experiments. The squared modulus $|\psi|^2$ of the wavefunction ψ is a probability density function (PDF). It describes the probability that an observation of, e.g. a particle will find the particle at a given time in a given region of space. The wavefunction ψ satisfies the linear *Schrödinger equation* (a differential equation):

$$\mathrm{i}\hbar \frac{\partial}{\partial t}\psi = \mathcal{H}\psi, \tag{4}$$

where $\mathrm{i} := \sqrt{-1}$, $\hbar := \frac{h}{2\pi}$ and $h \approx 6.62 \times 10^{-34}$ Js is Planck's constant. The Schrödinger equation is the basic (dynamical) equation of motion: it says that the quantum Hamiltonian of the wavefunction is equal to an imaginary constant $\mathrm{i}\hbar$ multiplied by the time derivative of the wavefunction. (The Hamiltonian contains all dynamical information: the wavefunction at time $t + \delta t$ (for δt small) is got by operating on the wavefunction at time t with $\frac{1}{\mathrm{i}\hbar}\mathcal{H}$.) This equation, a diffusion equation, describes the time evolution of the wavefunction, and thus the PDF $|\psi|^2$, at each point in space: as time proceeds, the PDF becomes more "spread

out" over space, and our knowledge of, e.g. the position of the particle becomes less precise. The spreading continues until an observation is carried out; then, the wavefunction *collapses* nonlinearly to a particular classical state (eigenstate), in this case a particular position, and the spreading out of the PDF starts all over again. (Wavefunction collapse upon observation is also called *state vector reduction*.)

We regard the system before observation as being in a linear combination of all possible classical states (called *superposition of states*); then the act of observing the system causes one classical state to be chosen, with probability as given by the PDF. This randomness in any measurement means that we cannot infer the initial state of the system from the measurement result.

Normalised Wavefunctions

The essentially complex nature of the wavefunction means that even if its amplitude is constant, it has a varying phase. (The *phase* of a wave is the argument or angle of a complex number: it is unrelated to phase space.) Thus, the wavefunction may interfere with itself, e.g. if a barrier with slits is placed in a particle's "path." The interference may be either constructive or destructive: the probability of detecting a particle in a given position may increase or decrease. Counterintuitive as it may seem, experimental evidence consistently agrees with this quantum-mechanical view of nature.

The probability of finding a particle is largest at locations where the modulus $|\psi|$ of the complex wavefunction ψ is largest; it is 0 if $|\psi| = 0$. Since the probability of finding a particle somewhere in space has to be 1, we generally restrict ourselves to *normalised* wavefunctions ψ, that is, those whose integral over all of space, $\int_{\mathbb{R}^3} |\psi(x)|^2 \mathrm{d}x = 1$. Thus, we restrict our attention to the *unit ball* in the Hilbert space: the set of all wavevectors of norm 1. Then the allowable operators on the Hilbert space are the *unitary* operators, that is the operators that preserve norms. (A linear operator A on a normed vector space V is called *unitary* if for all $v \in V$, it is the case that $\|Av\| = \|v\|$.)

Observables may be either continuous (e.g. position of a free particle) or discrete (e.g. energy of an electron in a bound state in an atom). Some discrete observables have only finitely many values, e.g. there are only two possible values for a given particle's spin in a given direction ("up" or "down"). (In Dirac's relativistic wave equation – an extension of the Schrödinger equation which is consistent with special relativity – spin is one of the arguments of the wavefunction.)

Entanglement and Decoherence

A key difference between classical and quantum physics is the phenomenon of quantum *entanglement*: the wavefunction of a system composed of many particles cannot be separated into independent wavefunctions, one for each particle. There is *one* wavefunction for the whole system, and this system wavefunction evolves

according to the Schrödinger equation until an observation is made. An observation made on one particle causes the collapse of the total system wavefunction and so produces an instantaneous nonlocal effect on other particles with which it is entangled, no matter how far apart they are: all components of the system are forced to immediately adopt a particular eigenstate. Entanglement causes an explosion in the dimension of the relevant Hilbert space. The correct Hilbert space for a quantum system of m particles, each of which can be in n distinct locations, is the m-fold tensor product, rather than the m-fold direct sum: its dimension is m^n, rather than mn as would happen classically. This is a crucial difference between quantum and classical physics and is one reason for quantum computers performing better than classical computers on certain problems [100]. Since the 1980s, physicists have come to view the nonlocal correlations of entangled quantum states as a new kind of nonclassical resource to be exploited, e.g. in quantum computers.

The issue of what exactly is an "observation" or "measurement" is a thorny one. A modern view is that the "quantumness" of a system is in the nonlocal entanglement effects among particles. Then, when a quantum system interacts with a macroscopic system (e.g. its environment, or a measuring device), the quantum nature of the system "leaks" into the environment in a thermodynamically irreversible way: the phase relations are spread so "thinly" among the many possible degrees of freedom that different elements of the combined wavefunction of system and environment can no longer effectively interfere with each other; we say they have *decohered*. This *decoherence* shows up as an apparent collapse of the wavefunction: decoherence causes superpositions of states to decay; and the larger the scale of the superposition, the faster the decay. In this view, quantum collapse is not an effect of a human observer but instead a consequence of the huge number of degrees of freedom (that is, the huge Hilbert space dimension) in any macroscopic system.

Noncommuting Operators

The symplectic or *canonical* structure given by the Poisson bracket in classical phase space is generalised in the construction of quantum mechanics: a *commutator* $[\,,\,]$ with similar properties is defined by $[A, B] := AB - BA$ for any two operators A and B. Then A and B commute (that is, the order in which they are applied does not matter) if and only if $[A, B] = 0$. The momentum operator associated with the kth coordinate direction x_k is defined as the differential operator:

$$p_k := \mathrm{i}\hbar \frac{\partial}{\partial x_k}. \tag{5}$$

(This is the *correspondence principle*: the key point of (canonical) quantisation.) The commutator $[x, p]$ of the momentum operator p and the position operator x can be shown to be nonzero (in fact $[x, p] = \mathrm{i}\hbar\mathbf{1}$, where $\mathbf{1}$ is the identity operator), telling us that the p and x operators do not commute: they are *complementary*, and each has eigenvalues which are not eigenvalues of the other. From this, via Fourier

analysis, we get Heisenberg's *uncertainty principle*, $\mathrm{d}p\,\mathrm{d}x \geq \hbar/2$: noncommuting observables cannot simultaneously be measured to arbitrary precision. (Classical mechanics is the limiting case of quantum mechanics as $h \to 0$. In this case, all commutators are 0 so all operators commute, and there is no uncertainty. Classical mechanics is also the limiting case of special relativity as $c \to \infty$, where c is the speed of light in vacuo.)

Using (5), and recalling (2) for the energy of a single particle, we can rewrite the (quantum) Hamiltonian of a particle as

$$\begin{aligned}\mathcal{H} &= \frac{p_1^2 + p_2^2 + p_3^2}{2m} + V \\ &= -\frac{\hbar^2}{2m}\Big[\Big(\frac{\partial}{\partial x_1}\Big)^2 + \Big(\frac{\partial}{\partial x_2}\Big)^2 + \Big(\frac{\partial}{\partial x_3}\Big)^2\Big] + V \\ &= -\frac{\hbar^2}{2m}\Big(\frac{\partial^2}{\partial {x_1}^2} + \frac{\partial^2}{\partial {x_2}^2} + \frac{\partial^2}{\partial {x_3}^2}\Big) + V \\ &= -\frac{\hbar^2}{2m}\nabla^2 + V. \end{aligned} \tag{6}$$

Here, multiplication of operators is just composition, so $(\frac{\partial}{\partial x_k})^2 = \frac{\partial}{\partial x_k}(\frac{\partial}{\partial x_k}) = \frac{\partial^2}{\partial {x_k}^2}$; and we have used the standard notation ∇^2 for the div operator $\frac{\partial^2}{\partial {x_1}^2} + \frac{\partial^2}{\partial {x_2}^2} + \frac{\partial^2}{\partial {x_3}^2}$. Then the particle's Schrödinger equation $\mathrm{i}\hbar\frac{\partial}{\partial t}\psi = \mathcal{H}\psi$ becomes

$$\mathrm{i}\hbar\frac{\partial}{\partial t}\psi = -\frac{\hbar^2}{2m}\nabla^2\psi + V\psi. \tag{7}$$

Apart from the imaginary factor i, this is similar to other equations in classical physics: the time rate of change of a quantity ψ is described by a diffusion term (the second spatial derivative) and a drift term (the potential V). If there was only a diffusion term, we would get the classical heat equation $\frac{\partial u}{\partial t} = k\frac{\partial^2 u}{\partial x^2}$.

Tunnelling

In *quantum tunnelling*, a particle can jump from one side of a physical or energy barrier to another, without having to occupy all intermediate positions, even if its energy is not enough to surmount the barrier. This can be explained by the wave nature of the particle. (The tunnelling effect is a property of any wave. It can be observed, e.g. when light waves hit, at a glancing angle, a boundary where the refractive index changes.) The particle's wavefunction is spread through space and, in particular, is nonzero on the opposite side of the barrier, giving a nonzero probability of observing the particle there. The narrower the barrier the greater the probability of tunnelling. From this, it follows that the expected time to tunnel

through a barrier depends not only on the height of the barrier, but also on its width. For a fixed height, the mean tunnelling time is shorter for a narrower barrier. This is seen when a particle is trapped in a potential well of finite height, for example, an electron in an atom. Another physical example of tunnelling is where a neutron may be spontaneously emitted from a Uranium ^{238}U nucleus in radioactive decay: here, the potential well is caused by the *strong nuclear* force among nucleons, which is repulsive at very short distance scales but becomes strongly attractive as nucleon separation increases. (*Nucleon* is a generic term for nuclear particles, namely, protons and neutrons.)

Quantum Statistical Mechanics

The idea of a partition function carries over to quantum physics, where $\mathcal{H}$ is now an operator: in this case, the partition function $Z = \sum_x \mathrm{e}^{-\beta \mathcal{H}_x}$ is often written as the basis-independent *trace*, $Z = \mathrm{Trace}(\mathrm{e}^{-\beta\mathcal{H}})$. The exponential of an operator is defined using the Taylor series $\mathrm{e}^t = 1 + t + \frac{1}{2}t^2 + \frac{1}{3!}t^3 + \cdots$ for the exponential function. Here, the product of operators means composition, i.e. AB is defined by $(AB)(\psi) := A(B(\psi))$. Thus, in a quantum setting,

$$Z = \mathrm{Trace}(\mathrm{e}^{-\beta\mathcal{H}}) = \mathrm{Trace}\left(\mathbf{1} - \beta\mathcal{H} + \frac{1}{2}\beta^2\mathcal{H}^2 - \frac{1}{3!}\beta^3\mathcal{H}^3 + \cdots\right). \tag{8}$$

When using quantum-inspired algorithms, a cost function to be minimised is typically mapped to a quantum Hamiltonian $\mathcal{H} = \mathcal{H}_{\mathrm{pot}} + \mathcal{H}_{\mathrm{kin}}$ made up of two parts, the "potential" objective function $\mathcal{H}_{\mathrm{pot}}$ and a "kinetic" perturbation term $\mathcal{H}_{\mathrm{kin}}$. Hence, the *Suzuki-Trotter formula* for the exponential of the sum of two operators $A + B$ is important for estimating the partition function:

$$\mathrm{e}^{A+B} = \lim_{M\to\infty} \left(\mathrm{e}^{A/M}\mathrm{e}^{B/M}\right)^M. \tag{9}$$

The Suzuki-Trotter formula can be used even if the commutator $[A, B] \neq 0$.

Quantum Computing

Quantum computers have been built based on ideas of quantum mechanics. These quantum computers are provably able to solve certain problems more efficiently than classical computers are. *Digital* quantum computers work with qubits, a quantum version of bits, while *adiabatic* quantum computers slowly evolve a quantum system to optimise some quantity such as energy, which models some real objective function.

We discuss quantum computers here for two reasons: firstly, because their workings are the inspiration for simulated quantum annealing (SQA: section "Simulated

Quantum Annealing"), quantum-inspired evolutionary algorithms (section "Quantum-Inspired Evolutionary Algorithms (QIEAs)"), and quantum-inspired particle swarm algorithms (section "Quantum Binary PSO"); and secondly, it is plausible that in the near- to medium-term future, true quantum computers of sufficient size, efficiency and error control may be available for use on complex problems [12].

Two-State Systems and Qubits

The spin of a quantum particle has precisely two possible values relative to a direction of measurement: "up" or "down." This is one example of a *two-state system*. In a two-state system, the quantum state ψ is a linear superposition of exactly two eigenstates, say $|0\rangle$ and $|1\rangle$, in the standard Dirac "bra-ket" notation; that is,

$$\psi = \alpha|0\rangle + \beta|1\rangle. \tag{10}$$

Here $|0\rangle$ and $|1\rangle$ (called "kets") are orthonormal basis vectors for a two-dimensional complex Hilbert space, and $\alpha, \beta \in \mathbb{C}$, with $|\alpha|^2 + |\beta|^2 = 1$ for ψ normalised (i.e. ψ is a unit vector). A two-state system where the states are orthogonal and normalised, as in this case, may be regarded as a *quantum bit* or *qubit*. (Geometrically, a qubit is a projective two-dimensional complex Hilbert space $P\mathbb{C}^2$: a compact two-dimensional complex manifold, the Riemann or Bloch sphere.) It is regarded as being in eigenstates $|0\rangle$ and $|1\rangle$ simultaneously, until a measurement projects ψ onto the basis $\{|0\rangle, |1\rangle\}$: then the state vector ψ collapses to $|0\rangle$ (with probability $|\alpha|^2$) or $|1\rangle$ (with probability $|\beta|^2$). The normalisation relation $\|\psi\|^2 = |\alpha|^2 + |\beta|^2 = 1$ captures the physical requirement that precisely one of $|0\rangle, |1\rangle$ must be observed, so their probabilities of observation must sum to 1.

Digital Quantum Computers

A *digital* (or *standard* or *circuit theory*) quantum computer is one which uses qubits instead of the bits used by classical computers. Paul Benioff [11] first considered a Turing machine which used a tape containing the equivalent of qubits. Richard Feynman [36], while studying the simulation of quantum systems on classical computers, developed examples of physical (quantum) computing systems that are not equivalent to the (deterministic) Turing machine. He showed that, because of entanglement, no classical computer (not even a probabilistic one) can efficiently simulate quantum systems, as it would need exponential time or resources to do so. An n-bit classical system is characterised by n times the amount of information needed to characterise a one-bit system. However, the amount of information needed to characterise a general entangled state of n qubits is $O(2^n)$: the Hilbert space has 2^n dimensions, so an entangled state is a superposition of 2^n n-qubit basis (eigen)states, and a complex coefficient is needed for each basis vector.

In a digital quantum computer, computations are carried out by applying a sequence of unitary operators, called quantum *gates* or quantum *evolutions*, to a system of qubits. A quantum gate transforms an input into an output, e.g. by a rotation, Hadamard or CNOT (controlled NOT) gate [100], and operates without measuring the value of the qubit(s); that is, no observation is performed until the end of the computation, when all gate transformations have been applied. (These ideas are described further in section "Binary-Valued QIGA," where they are used in new types of evolutionary algorithms.) A quantum gate effectively does a parallel computation on all qubits simultaneously and gives a new superposition. Because the Hilbert space of a system of n qubits has dimension 2^n, we can represent an operator on the space (e.g. a gate) by a $2^n \times 2^n$ matrix. The matrix must be unitary (and self-adjoint), so that the new coefficients for the ith qubit will still give valid probabilities.

The nature of qubits and entanglement means special algorithms must be developed for digital quantum computers. The details are beyond the scope of this chapter, but a good overview can be found in [12].

Quantum Advantage

The term *quantum advantage* (or *quantum supremacy*) is used to describe a problem that can be solved efficiently on a quantum system but cannot be solved on a classical machine in a reasonable time and at a reasonable energy cost. The term *quantum speedup* refers to the fact that for certain problems, the solving time on a quantum computer grows more slowly with the problem size than does the time on a classical computer.

Feynman [36] noted that quantum systems could efficently do computations that a classical computer could not (e.g. simulate themselves!). Deutsch [31] described the first universal quantum computer that could efficiently simulate any other quantum computer and gave the Deutsch algorithm, the first quantum algorithm that is provably faster than a classical algorithm.

In the 1990s, interest in qubit-based quantum computers was stimulated by the publication of algorithms that were provably faster than classical algorithms could be for the same problem: shor's algorithm [97, 99] for factorising a large integer of n bits into prime factors in $O(n^2)$ time – compared to $O(\exp(n^{1/3}))$ time classically – for which he received the Nevanlinna Prize in 1998; and Grover's unstructured database search algorithm [44, 45] which reduced the complexity from $O(n)$ on a classical computer to $O(\sqrt{n})$.

The problem of factorising a large integer has generated particular interest since important cryptography schemes such as RSA (used in everyday communications and commerce) depend on their security on such factorising being very difficult in practice. However, factorising an integer of practical significance on a current noisy quantum computer requires far more qubits (millions) than will be available in the near future. Note that other cryptography approaches can also be broken

efficiently by quantum computers [77, Table 2]. Quantum algorithms are successful in cryptography in part because there is "hidden problem structure that quantum computers can exploit in ways that classical computers cannot. Finding such hidden structure in other problems of practical interest remains an important open problem" [77].

In general, quantum computers need fewer operations, but each operation is slower. Whether quantum advantage exists then depends on multiple performance and cost measures [62]. However, Bova et al. [16] show that quantum computers – even if they have no quantum advantage – can still provide economic value compared to classical computers through lower cost and power consumption.

Other Applications of Quantum Computing

Other applications have been found for which quantum computers can provably outperform classical computers, such as computation of discrete logarithms [97], simulation of quantum systems [2, 56], solving certain systems of linear equations [49], the triangle finding problem in a graph [65], search and optimisation [77], sampling the output of a pseudo-random quantum circuit (using a 53-qubit quantum computer) [6], neural networks, and machine learning [71, 72] and finding one or more secret keys from a set of secret keys using a quantum oracle [101]. Some recent work [74] shows that the quantum singular value transformation (QSVT) encapsulates the three major quantum algorithms of factorisation, search, and simulation of quantum systems. Gomes et al. [43] give a wide-ranging overview of uses of quantum algorithms in operational research, with many references. Analogies of these, implemented on classical machines, form the basis of quantum-inspired evolutionary algorithms (QIEAs), described in section "Quantum-Inspired Evolutionary Algorithms (QIEAs)."

Complexity Classes for Quantum Computing

It is an active area of research to identify precisely which problems admit of a quantum advantage, and to try to define the complexity class of such problems. Because of the nature of wavefunction evolution and collapse, digital quantum computers are fundamentally probabilistic. Typically, an error probability of $\leq \frac{1}{3}$ is considered acceptable [97].

There are several complexity classes relevant to quantum computing [12, 62]. BPP (bounded-error probabilistic polynomial time) is the class of decision problems that can be solved in time polynomial in the input size by a probabilistic Turing machine with an error probability $\leq \frac{1}{3}$ for each instance. A fortiori, BPP contains the class P of all decision problems that can be solved in time polynomial in the input size by a deterministic Turing machine.

BQP (bounded-error quantum polynomial time) is the class of decision problems for which there exists a quantum algorithm that solves the decision problem with error probability of $\leq \frac{1}{3}$ and is guaranteed to run in time polynomial in the input size [100]. BQP is usually taken as the class of feasible problems for quantum computers. It contains the integer factorisation and discrete logarithm problems and some other

pure mathematics problems, e.g. the principal ideal problem. BQP is the quantum analogue to BPP and contains P and BPP. The integer factoring problem is in BQP but not in P.

NP is the class of decision problems for which the problem of verifying the correctness of a proposed solution is in P (equivalently, for which there exists an algorithm which solves the problem on a nondeterministic Turing machine in polynomial time). Although the problem of factorising integers is in both NP and BQP, quantum computers are not known to be able to solve all NP problems in polynomial time; in fact, it is widely believed that they are not able to. That is, BQP is not known to contain NP; in fact, it is conjectured that BQP does not contain NP. Thus, it is expected that quantum computers will not be able to solve NP problems quickly, in general. Proofs of inequality between BQP and these and other classical complexity classes are not yet available and are assumed to be difficult.

QMA (quantum Merlin Arthur) is the quantum equivalent of NP: a problem is in QMA if, given "yes" as the answer, the solution can be verified in a time polynomial in the problem input size.

Bharti et al. [12, Fig. 1] provide a diagram of inclusions (some proven, some conjectured) among these and other complexity classes.

Quantum Information

A key distinction between a qubit and a (classical) bit is that multiple qubits can be entangled. This means that a set of qubits can be highly correlated. Entanglement also allows many states to be acted on simultaneously, unlike bits that can only have one value at a time; thus, a quantum computer can extract global (nonlocal) information. This is sometimes called *quantum parallelism* [31] and partly explains the power of quantum computing: because the state of the quantum computer (i.e. the state of the whole system) can be a quantum superposition of many different classical computational states, these classical computations can all be carried out at the same time. For further information on quantum algorithms and entanglement, including possible use in cryptography, see [20].

Much of the art of designing quantum algorithms is in finding ways to make efficient use of nonlocal correlations. A quantum computer is usually taken to be *globally phase coherent*, that is having every qubit entangled with every other qubit (global phase coherence is, for example, assumed in Grover's proof of unstructured database search speedup [44, 45]).

However, quantum information has properties that make it more difficult to deal with, in some ways, than classical information:

- The uncertainty principle says that if A and B are complementary (noncommuting) observables, then measuring A will affect the result of any subsequent measurement of B. The act of acquiring information about a quantum system unavoidably disturbs the system: this is called the *disturbance principle*. This can lead to higher-than-desired error rates.

- Quantum information cannot be copied with perfect fidelity (this is the *no-cloning principle* [32, 114]); for, if it could be, then we could measure the copy without disturbing the original, so breaking the disturbance principle.
- John Bell [9] showed that quantum information is, because of entanglement, typically encoded in nonlocal correlations among different parts of the system: something that has no analogy in classical systems, and the main reason that we cannot efficiently simulate a quantum system with a classical computer.
- These nonlocal correlations are extremely unstable in practice, because of *decoherence*: the system interacts with its environment and its information becomes entangled with the information in the environment; since most of the information is in the nonlocal interactions, we lose the ability to recover the original system's information. Hence, long coherence times are crucial for practical quantum computers. There is a difficult balance to be struck between allowing qubit states to be controlled from outside the system and protecting them from decoherence. Shor [98] discovered quantum error correction (QEC) techniques to counteract the leakage from decoherence, essentially reducing the decoherence rate to acceptable levels. However, control of errors and noise remains a major issue [19, 53].

Digital Quantum Computer Hardware

Quantum computers are generally used together with classical computers in a hybrid approach. The classical computer controls the program flow and carries out preprocessing and postprocessing, only passing particular tasks to the quantum computer, namely, those for which there is quantum advantage. Such algorithms "variationally" update the variables of a parameterised quantum circuit and so are called *variational quantum algorithms* (VQAs) [12]. The objective function is the cost function to be variationally minimised, often a Hamiltonian or an expected value of a Hamiltonian, written as a linear combination of Pauli strings (tensor products of Pauli matrices $\hat{\sigma}_x$, $\hat{\sigma}_y$, $\hat{\sigma}_z$). For further details, see [12, Sect. II]. Converting a real-world objective into a VQA form is generally a nontrivial task, and approximations may be needed: see section "SQA Application to TSP-Type Problems" for an analogous case when applying simulated quantum annealing to the TSP (travelling salesperson problem).

Over the last two decades or so, standard quantum computers have been built. One of seven qubits, implemented using nuclear magnetic resonance (NMR) applied to seven chosen nuclei of 10^{18} identical molecules, used Shor's algorithm to factorise 15 as 3×5 [109]. The record size of an NMR digital quantum computer is 12 qubits [81]. However, other implementations of qubits have superseded the NMR approach, including two-state systems such as superconducting circuits (persistent circulating currents), trapped ions, neutral atoms, Rydberg atoms, photons in wells, nitrogen-vacancy centres, silicon quantum dots, photon polarisation, electron spins, or internal atom states [12, 62]. (Superconducting qubits are spin $\frac{1}{2}$ systems on silicon, made up of lithographically defined circuit elements: inductors, capacitors,

connections, Josephson tunnel junctions, etc. They are scalable, are controllable by electrical signals, have the possibility of high coherence, and have a superconducting digital logic: all of these factors make them attractive for the realisation of qubits [51].)

In recent years, there have been major advancements in trapped-ion devices including high-fidelity entangling gates and all-to-all connectivity [12]. By 2017, IBM had a 50-qubit quantum computer that could avoid decoherence for 90 microseconds. By 2019, Google AI Quantum had a 53-qubit "Sycamore" device in use, using transmon qubits (a kind of superconducting charge qubit), and showed a single-qubit gate fidelity of 99.85% and two-qubit gate fidelity of 99.64% on average in experiments with it [6]. By 2023, IBM had the 1,121-qubit Quantum Condor chip and Atom Computing had a 1,125-qubit machine. IBM will use its new Quantum Heron processors, with just 133 qubits each, for its "next-generation" system two quantum computer (which uses multiple simultaneous quantum processors) because of their superior error properties. At the time of writing (early 2025), there appear to be dozens of implementations of qubits, with different levels of error control, and it is not clear which – if any – will become the standard implementation.

The Current Situation: NISQ Computers

In 2018, Preskill [88] introduced the term *noisy intermediate-scale quantum* (NISQ) to describe current quantum computers. These contain of the order of a hundred (in 2018) or a thousand (at time of writing) noisy qubits, i.e. non-error-corrected qubits; thus, they carry out imperfect operations. They also have a shorter-than-desirable coherence time, typically of the order of several tens of microseconds, though some have reported almost a minute of coherence using neutral Ytterbium atoms with nuclear spin used as the qubit 0 or 1 [113]. However, an efficient universal fault-tolerant quantum computer would require millions of qubits [59] with long coherence times and low error rates. Such quantum computers are likely decades away [12].

Preskill [88] proposed reasons to believe that quantum advantage could become a reality. It is now an engineering problem to develop globally phase-coherent error-tolerant quantum computers of thousands to millions of qubits or more (which could break current encryption standards in an acceptable time); however, decoherence makes this problem very difficult. The most important quantum algorithms, e.g. Shor's factorisation algorithm [97, 99], Grover's search algorithm [44, 45], and the HHL algorithm for solving a system of linear equations [49], need error-corrected qubits to run. Currently, even the best current quantum error correction schemes on n qubits, which allow connectivity among all qubits and simultaneous execution of gates, suffer a slowdown of at least $O(\sqrt{n})$ [53].

However, some recent results [63] suggest that it may be possible to construct qubits with a much lower error rate, which could reduce the number of qubits needed for quantum advantage from millions to thousands or even hundreds.

Nevertheless, it is important to emphasise that at time of writing, quantum technology, although promising, does not have the same strength of optimisation capabilities as classical computing does, by a number of measures such as size

of problem that can be tackled, reliability of the solution procedure, and cost of the computing equipment. While it has obvious potential, it currently has strong limitations.

Adiabatic Quantum Computation

More generally, we can build quantum computation systems which are not made up of qubits. Such quantum computers are not necessarily "digital": they evolve with time and are closer in spirit to the original analogue computers, in that a physical system modelling the computation to be performed is set up, and then allowed to evolve with time. This approach, adiabatic quantum computing (AQC), began in solving optimisation problems and has become an alternative to the standard qubit quantum computing. It is universal in that it can efficiently simulate any quantum computer. It can be applied to any constraint satisfaction problem (CSP) where, given a set of constraints applied to the input bits, the problem is to output an assignment of values to the input bits that maximises the number of satisfied constraints. Many CSPs are NP-complete and of practical importance.

The *quantum adiabatic theorem* [15] describes the behaviour of a quantum system when its Hamiltonian (total energy) varies slowly in time:

Theorem 1 (Born, Fock) *A perturbed system remains in its instantaneous eigenstate if the perturbation is applied sufficiently slowly, and there is a gap between that state's eigenvalue and the Hamiltonian's other eigenvalues.*

This says that a quantum system subjected to sufficiently slowly varying external conditions can modify its functional form so as to remain in the same relative pure eigenstate of the system Hamiltonian at all times; however, if the conditions change rapidly, the functional form of the state does not have enough time to adapt, so it stays unchanged, ending in a linear superposition of states, i.e. *not* an eigenstate, of the final Hamiltonian. A *quantum adiabatic evolution* is one where the system is varied slowly enough that Theorem 1 applies, and the system stays in the same eigenstate of $\mathcal{H}$; often this is the ground state (the lowest energy state). These evolutions are the main idea of *adiabatic quantum computing* (AQC):

- The Hamiltonian is viewed as a multivariate cost function $\mathcal{H}_{\text{pot}}$ to be optimised: problem variables map to Ising spins (in, say, the z direction).
- If energy landscape barriers are high but very narrow, quantum-mechanical fluctuations in an observable because of its noncommuting with the Hamiltonian can help in tunnelling through the barriers: so a high strength transverse "tunnelling" field (in, say, the x direction) is applied which adds a noncommuting quantum kinetic term $\mathcal{H}_{\text{kin}}$.
- Begin with a quantum state that is the uniform superposition over all possible solutions to the optimisation problem; roughly speaking, this gives a very flat energy landscape for which the Hamiltonian easily reaches its ground state.

- Then slowly reduce the field strength to 0, allowing the Hamiltonian to find the ground state of the desired system (provided there is no crossing of energy levels with the ground state during the evolution).

We consider this in more detail in section "Quantum Spin Glasses" once we define Ising spins.

Because of its similarity to heat annealing of metals (section "Annealing and Spin Glasses"), AQC is also known as quantum annealing (QA). The adiabatic theorem guarantees that the result of the computation will be correct, so long as the computation (perturbation) is carried out sufficiently slowly. However, QA lacks general, rigorous worst-case upper bounds on its runtime: for certain instances of the constraint satisfaction problem on n bits, the time required for the adiabatic evolution can be exponential in n [77].

It has been shown [4] that an adiabatic quantum computer can perform any computation achievable by a "standard" qubit-based quantum computer: they are polynomially equivalent in power. As with classical analogue computers, devices based on AQC generally need to be tailored to the specific problem they are being applied to. For more details, see [5].

Applications of Adiabatic Quantum Computation

There have been a range of applications of AQC. Santoro and Tosatti [94] describe how QA/AQC may be used, by a transformation of the time variable, to address optimisation problems in classical physics. See also [102, 103]. The most important programmable quantum annealing platform is D-Wave annealers which have been used on a number of practical problems [14, 110]. However, this has some issues, e.g. requiring first solving the NP-hard minor embedding problem [110]; and there does not exist definitive evidence thus far that this form of AQC involves quantum effects or that it provides discernible speedup over classical computers [110]. This said, Choi [25] uses adiabatic quantum computers to successfully solve NP-hard quadratic unconstrained binary optimisation (QUBO) problems – involving minor embedding – on a graph G. QA has been applied to machine learning, including deep learning [10] and machine learning applied to computational biology [69]. Another application is that of [67], who use free-energy-based AQC applied to reinforcement learning.

Hardware Realisations

Experimental results [3, 18] on a TISG (a sample of $LiHo_{0.44}Y_{0.56}F_4$) show that the relaxation behaviour depends on the path taken. The sample was brought from a high-temperature paramagnetic phase to a low-temperature glassy phase along two paths from $(0.8, 0)$ to $(0.02, 7)$ in the T-Γ plane. Along the classical annealing path, the transverse field Γ was kept at 0, while T was slowly reduced; then Γ was switched on. Along the quantum annealing path, Γ was kept high, and then T was reduced, with Γ being reduced (slowly, i.e. adiabatically) only on reaching the final temperature. It was found that the quantum approach gave states with relaxation up to 30 times faster than thermal annealing. This indicates that quantum annealing is

much more effective at exploring the configuration space in the glassy "disordered" phase than thermal annealing. Crucially, it has been found [95] that even in the presence of all three ingredients of a spin glass – frustration, randomness, and long-range dipolar interactions – the spin-glass phase of $LiHo_xY_{1-x}F_4$ is destroyed by any nonzero transverse field, which demonstrates that quantum tunnelling can explore a rugged potential energy landscape with high barriers.

The current leading quantum annealers (e.g. D-Wave) use superconducting qubits and superconducting digital logic in part for control [51].

Current limitations of quantum annealing include: short coherence times (compared to digital quantum computers); limited connectivity (usually to four neighbouring Ising spins/qubits); only two-body interactions (thus only QUBO problems can be modelled, not higher degree polynomial unconstrained binary optimisation problems or PUBOs); limited ability to use different annealing schedules for different Ising spins/qubits. It is still unclear whether quantum annealers will provide quantum advantage for a general class of problems, and even whether overcoming the limitations listed will provide quantum advantage [51].

Annealing and Spin Glasses

In *annealing*, to achieve desirable physical characteristics, a material (e.g. a metal) is first heated and then slowly cooled. By adding energy to the material during heating, its atoms can take on random or *disordered* states. If the material is cooled slowly enough (by an adiabatic process), it remains approximately in thermodynamic equilibrium. (When thermodynamic equilibrium is maintained, the process is called *adiabatic*; hence the use by analogy of the word "adiabatic" in adiabatic quantum computation, where the system is slowly perturbed.) It will settle or *freeze* into a minimum energy crystalline structure with the individual atoms arranging themselves into a regular array.

If the cooling is performed too quickly (*quenching*), the metal will freeze into a local, rather than global, minimum energy state, and the atoms will not form a regular array. This can lead to a state with faults and defects in the metal, meaning the metal fractures if put under enough stress. This state or *phase* of the metal is analogous to the disordered but solid structure of glass. The annealed phase is analogous to a regular, ordered crystal. (This use of "phase" is not related to either phase space or the phase of a wave.)

A particular case of annealing, used as inspiration in simulated annealing (see section "Simulated Annealing"), is where a ferromagnetic alloy is slowly cooled to give a magnet. Physically, magnetism is caused by rotating particle charges (spins). Each such spin gives rise to a microscopic dipole which may be aligned either up or down along a given axis. Above a critical *Curie* temperature, T_c, the minimum of free energy $A = \mathcal{H} - TS$ occurs at states with no magnetisation: the spins are completely disordered. As the temperature is reduced below T_c, a phase change occurs. Ordered clusters start to appear and the material begins to show magnetism;

the minimum of A shifts towards states with higher order of magnetisation. Finally, at $T = 0$, the global minimum of free energy (and hence the global minimum of energy $\mathcal{H} = A + TS$) occurs at the highest order of magnetisation; the microscopic spins have all become aligned.

Spin glasses are a phase of magnetic alloys, so named because they bear the same relation to magnets as glasses do to crystals. In rapidly cooled or *quenched* spin glasses, different spin-spin interactions are randomly ferromagnetic or antiferromagnetic and frozen in time, called *frozen disorder*. This disorder causes competing interactions among the spins, called *frustration*; no spin state is able to satisfy all of the interactions. Because of this, the potential energy landscape becomes very rugged, with local and global minima separated by potential energy barriers. This disorder and frustration is reminiscent of the search landscapes occurring in applications, such as combinatorial optimisation problems; this motivates adapting features of the physics of spin glasses to search algorithms for these applications. In particular, the frustration effect is analogous to the conflicting constraints often encountered in optimisation applications. There is a large body of work on the physics of spin glasses, giving a good understanding of the structure of the spin-glass energy landscape, and of the slow (glassy) dynamics of many-body systems in the presence of frustration and disorder: thus, it can aid our understanding of certain computationally challenging problems. Research has found annealing approaches particularly useful for combinatorial optimisation problems: this is described in more detail in sections "Simulated Annealing" and "Simulated Quantum Annealing" and elsewhere in this book.

Kirkpatrick et al. [61] note that slow annealing of a material may avoid the frustrated spin interactions of a quenched spin glass, by allowing the material to take on a regular noncompeting pattern of spins, settling into a ferromagnet phase rather than a spin-glass phase. However, Hamiltonians encountered in applications may have a very stable spin-glass phase, even at low temperatures, with many degenerate near-to-ground states of nearly equal energy. Thus, even in the case of frustration, there will be many near-optimal solutions and a good search algorithm should find one or some of them.

Ising Spin Glasses

In statistical mechanics, a common model used for (among other things) spin glasses is the *Ising model*. It models a discrete collection of spins, each of which can take the value 1 or -1. Usually, the spins are the lattice points in a regular grid of dimensions 1, 2, or 3. The spins S_i are considered to interact in pairs, with an interaction (i.e. potential) energy J_{ij} which has one value when the two spins are the same (*aligned*), and another value when the spins are different (anti-aligned). The product of two aligned spins is 1, and the product of two anti-aligned spins is -1. The energy of a configuration of N such spins is modelled as

$$\mathcal{H} : \{-1, 1\}^N \longrightarrow \mathbb{R} \quad \text{with} \quad \mathcal{H} = -\sum_{i>j}^{N} J_{ij} S_i S_j. \tag{11}$$

The configuration space (of order 2^N) is a Cartesian product of N copies of $\{-1, 1\}$ and is in one-to-one correspondence to the search space of an evolutionary algorithm using a bit representation, with $\mathcal{H}$ playing the same rôle as a fitness or objective function.

Since the spins interact pairwise, they may be modelled as vertices of a weighted graph, with an edge (of weight J_{ij}) between vertices i and j if and only if $J_{ij} \neq 0$. This weighted graph completely characterises the Ising model.

In two or more dimensions, the Ising model undergoes a phase transition between an ordered and a disordered phase. This transition occurs at a critical temperature, T_c, above which the spins are disordered and below which is the ordered ("spin glass") phase. Below T_c, *freezing* occurs.

Quantum Spin Glasses

A quantum spin glass is a classical spin glass with an extra kinetic (quantum tunnelling) term added to the Hamiltonian. Since each Ising spin has two possible states, it can be viewed as a qubit. In quantum spin glasses, both thermal and quantum fluctuations can cause the order-disorder phase change. There are two kinds of quantum spin glasses: vector spin glasses, where the fluctuations cannot be affected by adjusting a laboratory field, and classical spin glasses perturbed by a quantum tunnelling term (the useful kind), where a transverse laboratory field Γ can affect the fluctuations. This transverse Ising spin-glass (TISG) model is the most studied [23]. The term *quantum annealing* is used for this "annealing" by reduction of the transverse field (by analogy with thermal annealing). As well as being able to tunnel through very high but narrow barriers (which makes the energy landscape more accessible to local moves), quantum annealing has the ability to "sense" the whole configuration space simultaneously via a delocalised wavefunction.

The Quantum Annealing Hamiltonian

The physical idea behind QA is to move the system from some initial Hamiltonian ground state (the "kinetic energy") to the ground state of the problem Hamiltonian (the objective: "potential energy"). In both SA and (S)QA, the kinetic term is gradually reduced to zero, according to an annealing schedule, as the algorithm progresses (respectively, by reducing temperature or the strength of a quantum field), so that by the end of the algorithm's run, the total energy that the algorithm has minimised is equal to the potential term, that is, the objective function.

In QA, to construct the kinetic term, we use noncommutative operators – a transverse magnetic field – to generate artificial quantum degrees of freedom. These induce quantum fluctuations, whose strength we control using the annealing schedule. This annealing is similar in spirit to SA, but rather than decreasing the temperature as in SA, we decrease the magnetic field strength.

Given a real-world problem, it must first be converted into a form appropriate for application of QA. A problem already in the quadratic unconstrained binary optimisation (QUBO) form is well suited, since its objective function can straightforwardly give a suitable Hamiltonian in terms of an Ising model. Many operational research combinatorial problems, including network flow problems, scheduling, sequencing and allocation problems, partitioning and clustering problems, and other graph problems can be described in QUBO terms [40]. A stream of work has been developed on applying quantum and quantum-inspired metaheuristic solvers to QUBO and the more general class of problems already in the polynomial unconstrained binary optimisation (PUBO) form; see, for example, [33, 34, 41, 42]. In particular, [33] explore the use of a special solver, Q-Card, belonging to the QUBO-Plus class, and [34] consider other quantum-inspired metaheuristic solvers that address QUBO and PUBO problems, including solvers such as the next-generation quantum (NGQ) solver for QUBO models and the NGQ-PUBO solver for PUBO models; these attain the performance of CPLEX and the D-wave quantum advantage solver.

For an n-vector of binary variables $x = (x_1, \ldots, x_n)^t$, a constant n-vector $c = (c_1, \ldots, c_n)^t$, and an $n \times n$ real matrix $A = (a_{ij})$ (the entries of c and A are derived from, and represent the constraints of, the particular problem), QUBO is defined as

$$\text{Find } x \text{ which minimises } x^t A x + c^t x. \tag{12}$$

QUBO problems can be represented by an interaction graph, where node i has node weight c_i (a bias) and edge ij has weight a_{ij} (a coupling coefficient). The goal is to find $x^* \in \{0, 1\}^n$ that encodes the optimal solution.

Suppose that we have a quantum Ising spin glass with spins aligned in the z direction. The binary variables $x_1, \ldots, x_n$ are associated to qubits $q_1, \ldots, q_n$: these qubits are the Ising spins, often represented by $\hat{\sigma}_z^i$, the Pauli matrix for Ising spin i (standing for the earlier S_i). Then the bias c_i captures the tendency for qubit q_i to end up in state 0 or 1, and two qubits q_i and q_j are pairwise coupled with an adjustable strength a_{ij}.

By mapping x_i to $\frac{1}{2}(1-\hat{\sigma}_z^i)$, we can convert this QUBO problem into the problem of finding a ground state of the diagonal n-qubit Ising Hamiltonian:

$$\mathcal{H}_{\text{QUBO}} = -\sum_{i,j} J_{i,j} \hat{\sigma}_z^i \hat{\sigma}_z^j - \sum_i h_i \hat{\sigma}_z^i, \tag{13}$$

where $J_{i,j} = -\frac{1}{4} a_{ij}$ and $h_i = \frac{1}{2}(-c_i + \sum_j a_{ij})$ [12]. This will be the basis of a potential energy term.

Now consider applying a strong transverse magnetic field in (say) the x direction: call this the base Hamiltonian $\mathcal{H}_0 = -\sum_i \hat{\sigma}_x^i$ (this will be the basis of a kinetic energy term). Assume $\mathcal{H}_0$ varies smoothly with time. Let time t run from 0 to T, where T is the time needed for an adiabatic evolution to complete.

We weight $\mathcal{H}_0$ by a real-valued function $A(t)$ where $A(0) = 1$ and $A(T) = 0$; $A(t)$ is the strength of the kinetic term $A(t)\mathcal{H}_0$ and is called the tunnelling strength or quantum field strength (sometimes denoted by $\Gamma(t)$). We weight $\mathcal{H}_{\text{QUBO}}$ by another real-valued function $B(t)$ where $B(0) = 0$ and $B(T) = 1$. Beginning with the ground state of $\mathcal{H}_0$ (at time $t = 0$, $A(t) = 1$, $B(t) = 0$), solving the QUBO problem on a quantum annealer means carrying out the annealing schedule as t goes from 0 to T for the combined Hamiltonian based on (11):

$$\mathcal{H}(t) = A(t)\mathcal{H}_0 + B(t)\mathcal{H}_{\text{QUBO}} = \mathcal{H}_{\text{kin}} + \mathcal{H}_{\text{pot}}. \tag{14}$$

Figure 2 (based on [62, Fig. 4]) illustrates the process of quantum annealing (of transverse field strength). For more details, see [12, 62], and D-wave's own documentation at https://docs.dwavesys.com/docs/latest/c_gs_2.html.

King et al. [60] "suggest that spin glasses can be brought into low-energy states faster by annealing quantum fluctuations than by conventional thermal annealing ... reproducing this phenomenon in a programmable system has remained a central challenge ... we achieve this goal by realising quantum critical spin-glass dynamics on thousands of qubits with a superconducting quantum annealer."

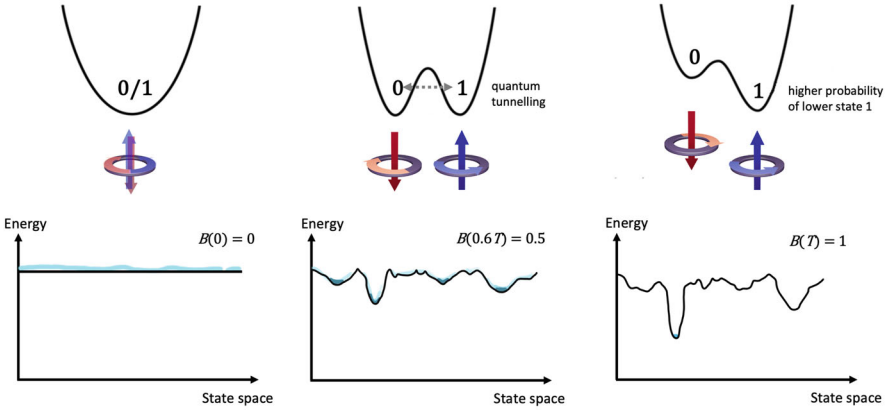

Fig. 2 The process of quantum annealing. Initially, a strong transverse magnetic field is applied to a superposition of binary quantum states (left); as the problem space is explored, the bias weight c_i gradually raises the energy barrier between the two possible states 0 and 1 of each qubit, but tunnelling means quantum fluctuations can penetrate through potential barriers (centre); during annealing, the transverse magnetic field – and so the quantum fluctuations – is reduced until when $B(t) = 0$ at time $t = T$ the system state is the optimum for this objective function (right)

The Metropolis(–Hastings) Algorithm

Simulated annealing and simulated quantum annealing (see sections "Simulated Annealing" and "Simulated Quantum Annealing," respectively) both use a Monte Carlo sampling approach due to Metropolis et al. and extended by Hastings [50,76], which incorporates controlled uphill steps, as well as downhill steps, in the search for a minimum. This Metropolis(-Hastings) algorithm (Algorithm 1) can draw samples from any probability distribution $P(x)$, and generates a Markov chain in which each state x_{t+1} depends only on the previous state x_t. It uses a *proposal density* $Q(x'|x_t)$, which depends on the current state x_t, to generate a new proposed sample x'. (The proposal density could be, e.g. a Gaussian centred on the current state x_t.) The new proposal x' is "accepted" as the next value x_{t+1} if a number a drawn (this is the "Monte Carlo" aspect of the algorithm) from the uniform distribution on [0, 1] satisfies (see [50])

$$a < \frac{P(x')Q(x_t|x')}{P(x_t)Q(x'|x_t)}. \tag{15}$$

Otherwise (the proposal is not accepted), the current value is kept: $x_{t+1} \leftarrow x_t$. In this and subsequent algorithms, the terminating condition can be based on some or all of a maximum number of iterations; a convergence tolerance test; or limits on time, memory, or other resources.

Algorithm 1: Metropolis(–Hastings) algorithm

```
1  begin MetropolisHastings(P, Q)
2      Choose starting x_0;
3      repeat
4          Generate proposed x' based on x_t;
5          Let α ← P(x')Q(x_t|x') / P(x_t)Q(x'|x_t);
6          if α > 1 then
7              x_{t+1} ← x';
8          else
9              x_{t+1} ← x' with probability α, otherwise x_{t+1} ← x_t;
10         end if
11         Increment t;
12     until terminating condition;
13     return x_t;
14 end MetropolisHastings.
```

Because P only occurs in the ratio $\frac{P(x')}{P(x_t)}$, we only require that a function proportional to the density can be calculated. In our case, the function is usually (though not necessarily) taken as the Boltzmann factor $e^{-\beta \mathcal{H}_x}$. (The proportionality constant is then the partition function Z, though the Metropolis algorithm does not need to compute it.) If Q is symmetric, that is $Q(x_t|x') = Q(x'|x_t)$, as in

Metropolis et al.'s original algorithm [76], then it suffices to compute $\frac{P(x')}{P(x_t)}$. If Q is not symmetric, then the more complicated formula $\frac{P(x')Q(x_t|x')}{P(x_t)Q(x'|x_t)}$ (as in [50]) must be used.

To apply this to Ising spin glasses, we note that the Ising model is statistical in nature, and, as in section "Statistical Mechanics," the probability of a given configuration x of spins is the normalised Boltzmann factor with inverse temperature β:

$$P(x) = \frac{1}{Z}\mathrm{e}^{-\beta\mathcal{H}}. \tag{16}$$

To generate configurations for simulation using this probability distribution, a variant of the Metropolis algorithm (Algorithm 2) may be used.

Algorithm 2: Metropolis algorithm for Ising spin models

```
1  begin MetropolisHastingsIsing(initial spin configuration)
2      repeat
3          Randomly pick a spin;
4          Calculate the contribution to the energy due to this spin;
5          Flip the value of the spin and calculate the new contribution;
6          Let Δℋ = new energy − previous energy;
7          if Δℋ < 0 then
8              Keep the flipped value;
9          else
10             Keep the flipped value with a probability e^{−βΔℋ}, otherwise keep the
                original value;
11         end if
12     until terminating condition;
13     return final configuration;
14 end MetropolisHastingsIsing.
```

The change in energy depends only on the value of the spin and its nearest neighbours in the Ising model graph. Thus, if the graph is sparse, the algorithm is fast. This process will eventually produce a choice from the distribution.

Simulated Annealing

Simulated annealing (SA) [21,22,61,85] is a global optimisation algorithm inspired by the physical process of thermal annealing of metals or glass (section "Annealing and Spin Glasses"). In the context of designing a search algorithm, the physical process of thermal annealing can be viewed as the search for a global minimum of an energy landscape. By analogy, the SA algorithm tries to find a global minimum of an objective function. This objective function could be defined on $\mathbb{R}^n$ or, more generally, on a space of "states" (or candidate solutions), e.g. valid tours of the network in a TSP. Simulated annealing is treated in detail elsewhere in

this book; in this chapter, we discuss it mainly in the context of similarities to and differences from simulated quantum annealing (SQA, section "Simulated Quantum Annealing").

A simulated annealing algorithm can be run using a single trial solution which is modified randomly during each iteration of the algorithm. Assuming the goal is to minimise the objective function, the search process usually proceeds "downhill," from a *higher* to a *lower* energy state. Modifications that improve the current trial solution are always accepted. However, occasional "wrong-way," or uphill, moves are accepted with a nonzero probability. This can allow the search process to escape a local minimum, which would entrap a standard hill climbing or other greedy approach.

The SA algorithm is based on the Metropolis algorithm 1 of statistical mechanics with the addition of a temperature schedule which controls the probability p of acceptance of uphill moves. This permits a gradual tuning of the exploration-exploitation balance away from exploration towards more intensive exploitation as the search progresses. A basic SA algorithm is given as Algorithm 3.

Algorithm 3: Simulated annealing algorithm

```
1  begin SimulatedAnnealing
2      Set initial temperature and determine the annealing schedule;
3      Generate an initial feasible solution and assess its cost;
4      repeat
5          Randomly generate new solution within a neighbourhood of the current solution;
6          Assess cost of new solution;
7          if cost of new solution < cost of previous solution then
8              Accept the new solution;
9          else
10             Accept the new solution with a probability p, otherwise keep the old
               solution;
11         end if
12         Adjust temperature according to the annealing schedule;
13     until terminating condition;
14     return current solution;
15 end SimulatedAnnealing.
```

This approach, with suitable parameter modification, allows for discrimination between the objective function's large-scale behaviour (at higher temperatures, near the start of the algorithm's run) and its finer-scale behaviour (at lower temperatures, later in the run). Earlier in the run, larger features of the system appear. The algorithm finds a broad area in the search space where a global optimum should exist, following the large-scale behaviour without regard to small-scale local optima found on the way. At lower temperatures, the finer details of this area emerge, and, with high probability, the algorithm will find a near-global optimum, or even the global optimum.

As noted earlier (section "Thermodynamics"), thermodynamic equilibrium corresponds to minimising (Helmholtz) free energy, $A = \mathcal{H} - ST$, with S being entropy and T being temperature. When $T = 0$, this reduces to the Hamiltonian. Since SA reduces a temperature parameter to 0, it may be thought of as minimising either (or both) the free energy or the Hamiltonian. Of course, in search algorithms such as SA or SQA, we may modify the Hamiltonian, e.g. by adding extra terms.

Search and Neighbourhoods

As with any search algorithm, the way in which moves are made from one state (or "point" in the search space) to another is crucial. In SA, as in SQA, a *neighbourhood structure* is defined. Let X denote the set of all possible states (assumed finite). For each state $x \in X$, there is a set N_x of states to which transitions from x may happen. N_x is called the *set of neighbours* or *neighbourhood* of x. We require that the neighbour relation be symmetric, i.e. $x \in N_y$ if and only if $y \in N_x$. In general, the neighbours of x (the possible moves) are specified by the user of the algorithm, in a way that depends on the particular problem. This neighbourhood structure defines a graph on the search space: the vertex set is the set of states X; and there exists an edge xy if and only if $x \in N_y$ (or, equivalently, $y \in N_x$); thus, the graph is undirected. The performance of the SA algorithm depends crucially on the choice of neighbourhood structure. Usually in SA (and in SQA), the neighbour of x is generated by making a small change (perturbation) to x: thus these algorithms are generally *perturbative* in nature.

Acceptance of "Bad" Moves

A key component of SA is the rule for accepting "wrong way" moves: moves which disimprove the solution. Traditionally (by analogy with the Boltzmann factor described in section "Quantum Statistical Mechanics," with Boltzmann's constant k_B scaled to 1) in SA, the acceptance probability for these cases is taken as

$$p_i = \mathrm{e}^{-\Delta f / T_i}, \tag{17}$$

where T_i is the *temperature* at iteration i and Δf is the difference in the values of the objective function at the current and previous trial solutions: $\Delta f > 0$ if the current solution is worse than the previous one.

The higher the value of T_i, the more likely that a poorer solution will be accepted. Thus, T is a tuning parameter. The value of T is varied during the algorithm's run according to an annealing or *cooling schedule*.

Simulated Quantum Annealing

The *simulated quantum annealing* (SQA) optimisation algorithm is inspired by the physical process of adiabatic quantum computing or quantum annealing (section "Quantum Spin Glasses"). (We call this algorithm the *simulated* quantum annealing algorithm, to avoid confusion with the physical quantum annealing process; however, particularly in the physics literature, the name "Quantum Annealing" seems to be used for both meanings.) It uses quantum fluctuations rather than the thermal fluctuations of SA to explore the search landscape. As in SA, a candidate solution is regarded as a system "state" and the objective function value is regarded as "energy," i.e. the Hamiltonian. Simulated quantum annealing was proposed by [37].

SQA is based on quantum tunnelling (section "Tunnelling"). In optimisation terms, this corresponds to making a jump on a landscape. This capability can permit a solution to "tunnel" through a (narrow) barrier on the landscape in one jump, rather than having to climb over the barrier by a succession of wrong-way moves as in SA. In some landscapes (Fig. 3), e.g. landscapes that often arise in combinatorial optimisation, thermal-annealing-inspired algorithms such as SA can have difficulties in escaping from poor-quality local minima, as they may be surrounded by high – though possibly narrow – barriers. The ability of a thermal fluctuation to escape a barrier depends only on the height of the barrier. Entropy is also a problem: the number of configurations grows exponentially with the number of variables; there are 2^n configurations for n Ising spins. A classical algorithm can only examine one configuration at a time; if there is no "guiding" gradient to roughly steer the algorithm from the start point towards the global optimum (which can happen, e.g., in deceptive landscapes), the algorithm must visit a significant proportion of the 2^n possible configurations. In this case, SA is little more effective than random search.

Let us use the term neighbourhood radius for the average distance between the current state x and the next x'. In SQA, as in SA, the current state x is replaced by a randomly selected neighbour state x' if x' has lower energy. The tunnelling field strength is a parameter that controls the radius of the neighbourhood explored by the

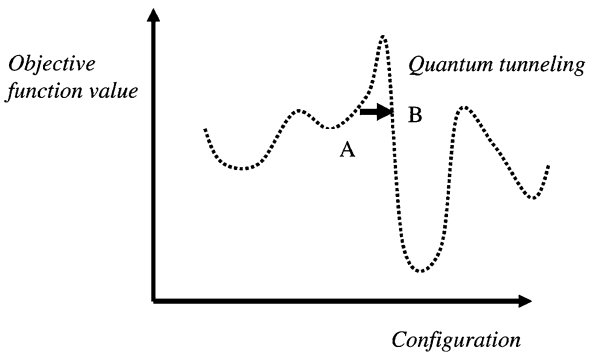

Fig. 3 Quantum tunnelling on a landscape. SA would require several "wrong way" moves to jump over the barrier between the basins of the local optimum (A) and the global optimum (B). With quantum tunnelling, this movement can potentially occur in one step

algorithm. The field strength starts at a high value: here, the neighbourhood covers the whole search space, which allows long jumps across the landscape, helping exploration. The field strength is slowly reduced during the algorithm's run, which facilitates local exploitation. Eventually the neighbourhood shrinks to include only a few states near to the current state.

Both SA and SQA are based on the physics of adiabatic processes, i.e., on systems that stay at or near thermodynamic equilibrium all through their evolution. Oliveira [35] gives more detail on this connection. Additionally, SA and SQA are both based on the Metropolis algorithm, with the SA temperature parameter playing a similar rôle to that of the SQA tunnelling strength. This means they are both stochastic local search algorithms and both generally use a perturbative approach to neighbour selection. However, in standard SA (as opposed to adaptive SA), the neighbourhood radius stays the same during the search, and the temperature controls the probability of moving to a higher energy state, whereas in SQA, it is the tunnelling field strength that controls the neighbourhood radius. The ability to tunnel through barriers can be shown to improve the "ergodicity" (section "Ergodicity") of SQA (compared to SA, which relies on thermal fluctuations) and so enhance landscape exploration [30]. The appropriate definition of the tunnelling field depends on the problem under consideration.

Implementation of SQA

To implement a quantum-inspired version (SQA) of quantum annealing (QA) on a classical machine, we must somehow simulate the quantum tunnelling effect classically. Feynman first pointed out (see [94]) that a quantum-mechanical system may be viewed as a classical system embedded in a world with one extra dimension, called imaginary time. The Suzuki-Trotter formalism maps a d-dimensional quantum Hamiltonian to an effective $(d+1)$-dimensional classical Hamiltonian, with the extra time-like dimension (called the *Trotter dimension*) discretised into M steps. At each index $k = 1, \ldots, M$ along this new dimension, there is a d-dimensional *Trotter slice*, and the Hamiltonian now represents a system of spins in a $(d+1)$-dimensional lattice. Now the Suzuki-Trotter formula (9) can be used to compute the partition function

$$Z = \mathrm{Trace}(\mathrm{e}^{-\mathcal{H}/T}) = \mathrm{Trace}(\mathrm{e}^{-(\mathcal{H}_{\mathrm{pot}}+\mathcal{H}_{\mathrm{kin}})/T}), \tag{18}$$

and this eventually gives the effective classical Hamiltonian in the Mth Trotter approximation as

$$\mathcal{H} = \sum_{i>j}^{N} \sum_{k=1}^{M} K_{ij} S_{ik} S_{jk} - K \sum_{i=1}^{N} \sum_{k=1}^{M} S_{ik} S_{ik+1}, \tag{19}$$

where $K_{ij} = J_{ik}/(MT)$, $K = \frac{1}{2} \ln \coth(\Gamma/(MT))$, k is the index in the extra Trotter dimension, i is the position in the original Ising model, and S_{ik} is the Ising spin on the lattice site (i, k). In theory, this equivalence of quantum Hamiltonian with a one-dimensional higher classical Hamiltonian only holds exactly as $M \to \infty$, but in practice there is an optimum M. In units chosen so that $\hbar = 1$, M should be of the order of $1/T$ (of course, $M \to \infty$ as $T \to 0$).

One can then study and optimise the equivalent classical Hamiltonian using Monte Carlo techniques, as in Algorithm 2, which leads to simulated quantum annealing (SQA). Path integral Monte Carlo (PIMC) and Green's function Monte Carlo (GFMC) have been used here [93]. In general, the implementation is quite technical.

One can study the thermodynamics of a d-dimensional classical system by reducing it to the study of the ground state(s) of a d-dimensional quantum system, the reverse of the above use of an equivalent classical Hamiltonian [94, 102]. SA itself can be "simulated" using a quantum algorithm, quantum simulated annealing or QSA (QSA is a *quantum* algorithm, very different from the *classical* algorithm, SQA.); when SA requires $1/\delta$ steps to get within a certain error bound of the optimum, then QSA will only require $1/\sqrt{\delta}$ steps [103].

Implementing SQA means using adjustable quantum fluctuations in the problem rather than thermal ones. For a given optimisation problem, the main tasks in developing an SQA approach are:

i. How to describe (and, usually, simplify) the Hilbert space for the problem. Real-world optimisation problems generally involve enormously large-dimension Hilbert spaces, so an alternative quantum Monte Carlo approach, often using path integrals, is required.
ii. How to formulate a quantum Hamiltonian $\mathcal{H} = \mathcal{H}_{\text{pot}} + \mathcal{H}_{\text{kin}}$, where the potential energy term $\mathcal{H}_{\text{pot}}$ is typically the cost or other objective function to be minimised, and the kinetic energy term is a perturbation term: a noncommuting operator analogous to the physical transverse field. It is useful to write $\mathcal{H} = \mathcal{H}_{\text{pot}} + \Gamma(t)\mathcal{H}_{\text{kin}}$, thus explicitly showing the time dependence of the tunnelling field strength: $\Gamma(t) \to 0$ as $t \to \infty$.

Thus SQA is more flexible than SA since not only can the "annealing schedule" be chosen, but there may be a range of choices for the kinetic term which is then weighted by $\Gamma(t)$.

Applications of SQA

SQA Application to TSP-Type Problems

An instance of the travelling salesperson problem (TSP) is defined on a (undirected) graph $G = (V, E)$ with $|V| = n$, together with a set of weights $\{d_{ij} : i, j = 1, \ldots, n\}$ (in general, some d_{ij} may be infinite, indicating that the edge ij is not present). The problem is to find a minimum length tour that starts and ends at the

same vertex and visits each vertex exactly once. This can be viewed as minimising an Ising Hamiltonian, as follows (see [73,93] for details).

A particular tour can be represented by an $n \times n$ matrix $T = (t_{ij})$ with $t_{ij} = 1$ if edge ij is on the tour and $t_{ij} = 0$ otherwise. Hence, a valid tour has a T matrix with precisely one 1 in each row and in each column, with all other entries being 0. For an undirected graph, a tour and its reverse have the same length, and we consider the undirected tour matrix $U = (u_{ij}) = T + T^t$, where T^t is the transpose of T and – since its i, j entry is t_{ji} – represents the reverse tour to T. U is a symmetric matrix with exactly two 1s in each row and column. The length of the tour is

$$\mathcal{H}_{\text{pot}} = \frac{1}{2} \sum_{i,j=1}^{n} d_{ij} u_{ij}. \tag{20}$$

Defining Ising spins by $S_{ij} = 2u_{ij} - 1$, we can rewrite this Hamiltonian in terms of S_{ij} as

$$\mathcal{H}_{\text{pot}} = \frac{1}{2} \sum_{i,j=1}^{n} d_{ij} \frac{1 + S_{ij}}{2}, \tag{21}$$

which is analogous to the Hamiltonian of noninteracting Ising spins on an $n \times n$ lattice, with fields d_{ij} on the lattice points. The frustration arises from the global constraints on the spin configurations that force them to conform to the structure of U.

$\mathcal{H}_{\text{kin}}$ is then chosen (with a high degree of arbitrariness) to induce fluctuations that generate the important elementary moves of the problem, namely, changing a valid tour into another valid tour. Deciding which configurations are to be neighbours of which others is crucial, since it controls the problem's effective landscape. The 2-opt perturbation or move can be used as it is guaranteed to transform a valid tour into another valid tour. A 2-opt move takes two edges ab and cd not incident with a common vertex and deletes them and replaces them in the tour by the edges ac and bd. The whole 2-opt perturbation can be represented (in U-matrix terms) by four spin-flip operators:

$$S^{+}_{\langle c,a\rangle} S^{+}_{\langle d,b\rangle} S^{-}_{\langle b,a\rangle} S^{-}_{\langle d,c\rangle}, \tag{22}$$

where by definition each $S^{\pm}_{\langle i,j\rangle}$ flips an Ising spin variable (defined as $S_{\langle i,j\rangle} = 2u_{ij} - 1 = \pm 1$) at position (i, j) and at the symmetric position (j, i); that is, $S^{\pm}_{\langle i,j\rangle} = S^{\pm}_{i,j} S^{\pm}_{j,i}$. From this comes a (time-dependent) TSP quantum Hamiltonian implementing the 2-opt moves:

$$\begin{aligned} \mathcal{H}_{\text{TSP}} &= \mathcal{H}_{\text{pot}}(U) + \mathcal{H}_{\text{kin}} \\ &= \sum_{\langle ij\rangle}^{n} d_{ij} \frac{1 + S_{ij}}{2} - \frac{1}{2} \sum_{\langle ij\rangle} \sum_{\langle i',j'\rangle} \Gamma(i, j, i', j'; t) S^{+}_{\langle i,i'\rangle} S^{+}_{\langle j,j'\rangle} S^{-}_{\langle j,i\rangle} S^{-}_{\langle j',i'\rangle}. \end{aligned} \tag{23}$$

Here Γ is a real positive weighting function that depends not only on the edges but also on time.

An actual Schrödinger annealing evolution is computationally impractical, because of the large dimension of the Hilbert space, so Metropolis-type Monte Carlo methods are used. The kinetic part of the quantum Hamiltonian above requires calculation of very many matrix entries of exponential operators in the Trotter-discretised system, which is computationally very expensive. Because of this, we replace it by a standard transverse Ising form, which is trivially Trotter-discretised:

$$\tilde{\mathcal{H}}_{\mathrm{TSP}} = \sum_{\langle ij \rangle}^{n} d_{ij} \frac{1 + S_{ij}}{2} - \Gamma(t) \sum_{\langle ij \rangle} [S^{+}_{\langle j,i \rangle} + \mathrm{H.c.}] \tag{24}$$

This simpler kinetic term is not guaranteed to move from a valid tour to another valid tour in the search space, but a new valid tour can be guaranteed by exclusively using 2-opt moves to generate new states in the Monte Carlo algorithm. It can be shown that this simplification still gives a working SQA algorithm.

SQAs have been applied to a variety of combinatorial problems. Battaglia and Stella [8], Martonak et al. [73] illustrate their application to the TSP. In testing on the `pr1002` instance of the standard benchmark TSPLIB [73, 93], SQA is found to anneal more efficiently than SA. However, SQA does not appear always to be superior to SA. SA outperforms SQA on the random Boolean satisfiabilty (3-SAT) problem [93]; and research [87] investigating extensions of the approach to the multivisit TSP and bottleneck TSP seems to show sensitivity of SQA to the particular flavour of TSP addressed, and to the network structure.

The conclusion seems to be that SQA has the potential to outperform SA, but may require domain knowledge in order to build the kinetic energy term. Further research is needed to clarify this.

Other Applications of SQA

For comprehensive discussions of SQA, including comparison to SA, along with several applications, see [29, 30]. Gomes et al. [43] give a wide-ranging overview of uses of both quantum and quantum-inspired algorithms in operational research.

Quantum-Inspired Evolutionary Algorithms (QIEAs)

In this and the following section, we describe a group of algorithms or metaheuristics whose workings draw inspiration from aspects of quantum mechanics, hybridised with ideas from natural computing: evolutionary algorithms and particle swarm algorithms. It should be noted that a range of metaheuristics have been hybridised with quantum-inspired approaches, but are largely omitted here for reasons of space. The interested reader may wish to refer to (among others): [1, 24, 54] for quantum-inspired approaches involving tabu search; to [64, 119] for quantum-inspired approaches hybridised with scatter search; and to [39, 105] for

adaptive memory programming and quantum-inspired variations; along with the references cited in these.

In the 1990s, Narayanan and Moore [79] first suggested the use of a quantum-inspired genetic algorithm. Since then, quantum-inspired ideas have been applied to a number of different families of natural computing algorithms, including evolutionary algorithms [46, 47, 116, 117], grammatical evolution [75], social computing [118], neurocomputing [38, 66, 108], and immunocomputing [55, 68]. There is now an enormous range of quantum-inspired metaheuristics; [90] and [39] give comprehensive overviews. Ross [90] also investigate "which quantum-inspired metaheuristics could be translated to be used in the existing quantum computers based on the circuit model programming paradigm." Li et al. [70] survey quantum-inspired genetic algorithms, quantum-inspired particle swarm optimisation, and other approaches. Sadeghi Hesar and Houshmand [92] study a memetic quantum-inspired genetic algorithm based on tabu search.

The most common quantum-inspired evolutionary algorithm (QIEA) is the quantum-inspired genetic algorithm (QIGA). We focus on two forms of QIGA, the first working with binary encodings and the second with real-valued encodings. The binary encoding version is more faithful to the quantum metaphor, though neither is completely faithful.

Quantum-inspired ideas have been applied by a number of authors to the area of evolutionary algorithms: one motivation is that because these algorithms use a quantum-inspired representation, they can keep a good balance between exploration and exploitation. Another motivation is that they can provide efficiencies in computation, since using a quantum representation can allow smaller population sizes than standard evolutionary algorithms.

We note that because a classical computer cannot efficiently simulate entanglement (section "Quantum Information"), the degree of fidelity of the algorithms of subsequent sections of this chapter to quantum computing algorithms is partial at best: they are not true quantum algorithms and cannot carry over all of the abilities of quantum computing, such as quantum parallelism.

However, recently, QIEAs have been implemented on a hybrid of classical hardware (e.g. GPUs) and IBM quantum devices, and their runs compared to a GPU-based quantum simulator and an IBM quantum simulator [91], showing interesting results. As NISQ matures, these algorithms should become more capable.

Binary-Valued QIGA

Qubit Representation on Classical Machines

Analogously to a chromosome in a genetic algorithm in evolutionary computation, a *quantum chromosome* can be defined as a system of m qubits (section "Two-State Systems and Qubits") where each qubit q_i is characterised by two scalars, α_i^2 and β_i, namely, the probability amplitudes of observing the eigenstates $|0\rangle$ and $|1\rangle$, respectively. The quantum chromosome can be written as a *qubit register*: a matrix with two rows, comprising one column for each qubit:

$$\begin{bmatrix} \alpha_1 & \alpha_2 & \dots & \alpha_m \\ \beta_1 & \beta_2 & \dots & \beta_m \end{bmatrix}. \tag{25}$$

As with a normalised system in quantum mechanics (section "Normalised Wavefunctions"), we require that for each i, the qubit norm $|\alpha_i|^2 + |\beta_i|^2 = 1$. When an observation is carried out on this register, each qubit collapses into either $|0\rangle$ or $|1\rangle$. The state of the whole system upon wavevector collapse can be depicted as a ket, for example, $|0110 \cdots 1101\rangle$. Because there is no entanglement in our classical model, the algorithm will have to choose either $|0\rangle$ or $|1\rangle$ for each qubit individually. Note that in quantum-inspired evolutionary algorithms to date, the values of α and β for each qubit are usually taken to be two real numbers whose squares sum to 1, whereas in physical qubit systems α and β are complex.

A key point about quantum systems is that they can compactly convey information on a large number of possible system states. In classical bit strings, a string of length m can represent 2^m possible states; but a quantum space of m qubits has 2^m *dimensions* (as a complex manifold). A single-qubit register of length m as in (25) can *simultaneously* represent *all* possible bit strings of length 2^m, e.g. an eight-qubit system can simultaneously encode 256 distinct strings.

From this comes the idea of modifying standard evolutionary algorithms to work with only a few quantum individuals (or even just one), each with a qubit register as its quantum chromosome, instead of using a large population of standard individuals, each of which represents a candidate solution. Because of its ability to represent multiple system states simultaneously, a qubit representation can also aid in maintaining diversity during the evolutionary algorithm's search process. Furthermore, using a qubit representation makes it possible to design hybrid quantum evolutionary algorithms that scale well.

There are several approaches to defining a quantum system to encode a set of binary strings (candidate solutions). As an example, consider the following three-qubit quantum system. Here, the quantum chromosome comprises three pairs (columns) of probability amplitudes:

$$\begin{bmatrix} \frac{\sqrt{3}}{2} & \frac{1}{\sqrt{2}} & \frac{1}{2} \\ \frac{1}{2} & \frac{1}{\sqrt{2}} & \frac{\sqrt{3}}{2} \end{bmatrix}. \tag{26}$$

The squared moduli of these numbers are the probabilities of observing a qubit in one particular eigenstate rather than another. For example, for the second qubit, observation of either of (eigen)states $|0\rangle$ or $|1\rangle$ is equally likely as both α_1 and β_1 have the same absolute value, but for the first qubit we are more likely to observe state $|0\rangle$ since its squared probability amplitude $\frac{\sqrt{3}}{2}$ is larger than that of $|1\rangle$.

The individual qubit probability amplitudes can be used to calculate the probability amplitudes of overall system eigenstates. For example, consider the system state $|000\rangle$. The probability amplitude for this state is obtained by multiplying the probability amplitudes in (26) of the $|0\rangle$ state for each of the three qubits:

$$\frac{\sqrt{3}}{2} \cdot \frac{1}{\sqrt{2}} \cdot \frac{1}{2} = \frac{\sqrt{3}}{4\sqrt{2}}.$$

Then the probability of observing this state is the square $\left(\frac{\sqrt{3}}{4\sqrt{2}}\right)^2 = \frac{3}{32}$.

Using this method, the associated probabilities of each of the individual states $|000\rangle$, $|001\rangle$, $|010\rangle$, $|011\rangle$, $|100\rangle$, $|101\rangle$, $|110\rangle$ and $|111\rangle$ are

$$\frac{\sqrt{3}}{4\sqrt{2}}, \frac{3}{4\sqrt{2}}, \frac{\sqrt{3}}{4\sqrt{2}}, \frac{3}{4\sqrt{2}}, \frac{1}{4\sqrt{2}}, \frac{\sqrt{3}}{4\sqrt{2}}, \frac{1}{4\sqrt{2}} \text{ and } \frac{\sqrt{3}}{4\sqrt{2}} \text{ respectively,}$$

giving associated probabilities

$$\frac{3}{32}, \frac{9}{32}, \frac{3}{32}, \frac{9}{32}, \frac{1}{32}, \frac{3}{32}, \frac{1}{32} \text{ and } \frac{3}{32} \text{ respectively.}$$

Then the (quantum) state of this three-qubit system is given by

$$\frac{\sqrt{3}}{4\sqrt{2}}|000\rangle + \frac{3}{4\sqrt{2}}|001\rangle + \frac{\sqrt{3}}{4\sqrt{2}}|010\rangle + \frac{3}{4\sqrt{2}}|011\rangle$$
$$+ \frac{1}{4\sqrt{2}}|100\rangle + \frac{\sqrt{3}}{4\sqrt{2}}|101\rangle + \frac{1}{4\sqrt{2}}|110\rangle + \frac{\sqrt{3}}{4\sqrt{2}}|111\rangle.$$

In the following, to simplify notation, we will often write $|0\rangle$ as 0 and $|1\rangle$ as 1.

Binary Quantum-Inspired Genetic Algorithm

Algorithm 4 is an example of a binary QIGA [46]. Many evolutionary algorithms run for a predetermined number of iterations or "generations" (of the population). We have used this as the terminating condition $t = t_{\max}$ here, but more complex termination conditions could also be used as mentioned for previous algorithms.

At the start of the algorithm's run, the population of quantum chromosomes is created as

$$Q(t) = \{q^1(t), q^2(t), \ldots, q^n(t)\},$$

where n is the population size (n could be equal to 1), and each quantum chromosome comprises m qubits (the superscript on each qubit is a label indicating which quantum chromosome it is part of, not an exponent). The α and β values for each qubit are each set to $1/\sqrt{2}$ to begin with, to ensure that for each qubit the states $|0\rangle$ and $|1\rangle$ are equally likely initially (since the probability of each state $|0\rangle$ or $|1\rangle$ is $(1/\sqrt{2})^2 = 1/2$). Alternatively, if domain knowledge indicates that some states are likely to lead to better results, this can be used to seed the initial quantum chromosome(s). During the run of the algorithm, the current population of quantum chromosomes at timestep t can be used to create a second population

$$P(t) = \{p^1(t), p^2(t), \ldots, p^n(t)\}$$

Algorithm 4: Binary quantum-inspired genetic algorithm

```
1  begin BinaryQIGA(n, t_max)
2      Set t ← 0;
3      Initialise Q(0), the population of quantum chromosome(s);
4      for j = 1 to n do
5          Create p^j(0) by carrying out an observation of q^j(0) ∈ Q(0);
6      end for
7      Set the population P(0) ← {p^1(0), ..., p^n(0)};
8      Evaluate P(0) and select the best solution from P(0);
9      Store the best solution in B(0);
10     while t < t_max do
11         t ← t + 1;
12         Create P(t) by carrying out observations of Q(t − 1);
13         Evaluate the population of solutions P(t);
14         Compare the best solution in P(t) with that of B(t − 1) and store the better of
             these in B(t);
15         Update Q(t) using B(t);
16     end while
17     return best solution found;
18 end BinaryQIGA.
```

of binary strings (candidate solution encodings) by carrying out "observations" on the quantum chromosomes. The observation step on qubit i of the jth quantum chromosome $q^j(t)$ can be carried out by drawing a random number $r \in [0, 1]$, e.g. from a uniform distribution on $[0, 1]$. If $r > |\alpha_i(t)|^2$, the corresponding bit $p_i^j(t)$ in the observed individual $p^j(t)$ is taken to be in state $|1\rangle$; otherwise, it is taken to be in state $|0\rangle$.

Since the observation step is probabilistic, the QIGA could be implemented using just a single quantum chromosome, with this chromosome being observed multiple times to create the population $P(t)$. Another option is to maintain a small population of quantum chromosomes and observe each quantum chromosome a fixed number of times to generate $P(t)$.

In the while loop of Algorithm 4, the population $Q(t)$ of quantum chromosomes is updated. This update step could be made in different ways, e.g. by using a suitable quantum gate (section "Diversity Generation in Binary QIEA") or by using "genetic" operators. The essence of the update step is to adjust the quantum chromosome to make it more likely that the best solution found so far will be generated in the next iteration. As the QIGA algorithm approaches the optimal solution, the values of each element of the quantum chromosome tend more closely towards either 0 or 1: this means there is a high probability that, when observed, the quantum chromosome will give a particular solution vector p^j. As an extreme example, the quantum chromosome $\begin{bmatrix} 1 & 1 & 1 \\ 0 & 0 & 0 \end{bmatrix}$ will generate the observed solution chromosome [0 0 0] with probability 1, no matter what value the parameter r has in the observation step.

Diversity Generation in Binary QIEA

The binary QIGA does not generally use distinct crossover and mutation operators, unlike the standard genetic algorithm (GA). Instead, it uses a single diversity-generation step. There are two common approaches to this, the first – quantum gates – being more inspired by quantum mechanics than the second – quantum mutation.

Quantum Gates

In the quantum gate approach, the QIGA simulates the working of a digital quantum computer gate (section "Digital Quantum Computers"). The idea of quantum gate has been used successfully in QIEAs, and a range of quantum gates is possible [115]. Currently, researchers appear to use real number probability amplitudes exclusively, rather than the complex probability amplitudes arising in quantum mechanics; a possible extension of such QIEAs would be to use complex probability amplitudes and take absolute values during the observation step.

Whereas the Hilbert space of a system of n physical qubits has dimension 2^n, our classical version of this in a QIEA has dimension $2n$. Rather than an operator on the space (e.g. a gate) being represented by a $2^n \times 2^n$ matrix (which would be physically more correct – see section "Digital Quantum Computers" – but prohibitively expensive computationally), a set of n 2×2 matrices is used, one for each classical qubit. Figure 4 shows an example of a quantum rotation gate which, as the name suggests, rotates the vector (α_i, β_i) through an angle. Each gate matrix must be unitary (and self-adjoint), so that the updated coefficients α'_i, β'_i for the ith qubit will still satisfy $|\alpha'_i|^2 + |\beta'_i|^2 = 1$.

In the mutation step, the idea is to alter the probability amplitudes on the quantum chromosome so that on the algorithm's next iteration, fitter individuals are more likely to be observed. We make this adjustment using information from the best-performing individual in the nonquantum population $P(t)$ and adjust the probability amplitudes using a rotation gate as in (27).

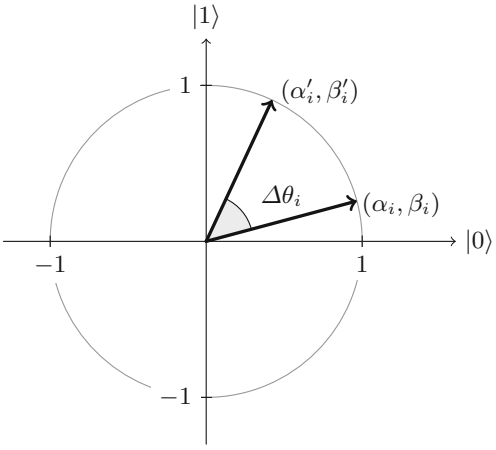

Fig. 4 Quantum rotation gate

$$\begin{bmatrix} \alpha_i' \\ \beta_i' \end{bmatrix} = \begin{bmatrix} \cos(\Delta\theta_i) & -\sin(\Delta\theta_i) \\ \sin(\Delta\theta_i) & \cos(\Delta\theta_i) \end{bmatrix} \begin{bmatrix} \alpha_i \\ \beta_i \end{bmatrix}. \tag{27}$$

A look-up table is used to find the most suitable value for $\Delta\theta$ that makes mutation tend towards the best current member $B(t)$ of the observed population $P(t)$. One straightforward way to carry this out is to generate a binary chromosome x from the current quantum chromosome q. Given

$$q = \begin{bmatrix} \alpha_1 & \alpha_2 & \dots & \alpha_m \\ \beta_1 & \beta_2 & \dots & \beta_m \end{bmatrix},$$

for each qubit q_i, if $\alpha_i^2 \leq 1/2$, then set $x_i = 0$; otherwise, set $x_i = 1$. Table 1 is the look-up table for $\Delta\theta$. The parameter a controls the mutation step size.

If a bit has the same value in both x_i and the best element b_i, then the quantum chromosome is not changed. As an example, suppose the quantum chromosome has a single qubit: $q = \begin{bmatrix} 0.7 \\ 0.3 \end{bmatrix}$. Since $\alpha_1^2 > 0.5$, we set $x_1 = 1$. Assume $b_1 = 1$. Then from the look-up table, we get $\Delta\theta = 0$. Applying the quantum rotation gate (27), the values of $\begin{bmatrix} \alpha_1 \\ \beta_1 \end{bmatrix}$ stay the same, because $\begin{bmatrix} 0.7 \\ 0.3 \end{bmatrix} = \begin{bmatrix} \cos(0) & -\sin(0) \\ \sin(0) & \cos(0) \end{bmatrix} \begin{bmatrix} 0.7 \\ 0.3 \end{bmatrix}$.

On the other hand, if $x_i > b_i$, the corresponding value of the quantum chromosome is reduced by $-a$, which reduces the probability of observing a $|1\rangle$ from the quantum chromosome in the future.

While Table 1 illustrates a simple quantum gate, it does not explicitly consider the quadrant that $\begin{bmatrix} \alpha_i \\ \beta_i \end{bmatrix}$ is in (since α_i and/or β_i could be negative). We can use a variation on the method for updating the ith qubit value $\begin{bmatrix} \alpha_i \\ \beta_i \end{bmatrix}$:

$$\begin{bmatrix} \alpha_i' \\ \beta_i' \end{bmatrix} = \begin{bmatrix} \cos(\xi(\Delta\theta_i)) & -\sin(\xi(\Delta\theta_i)) \\ \sin(\xi(\Delta\theta_i)) & \cos(\xi(\Delta\theta_i)) \end{bmatrix} \begin{bmatrix} \alpha_i \\ \beta_i \end{bmatrix}, \tag{28}$$

where $\xi(\Delta\theta_i) = s(\alpha_i, \beta_i) \times \Delta\theta_i$. The terms $s(\alpha_i, \beta_i)$ and $\Delta\theta_i$ are the direction of rotation and the angle, respectively. A number of variations of rotation schemes

Table 1 A look-up table for $\Delta\theta$

x_i	b_i	$\Delta\theta$
1	1	0
0	1	a
0	0	0
1	0	$-a$

exist, some quite complex: for further details, see [115, Sect. 3]. The step size for $\Delta\theta_i$ controls the speed of convergence of the algorithm and depends on the problem. We usually set the step size to a small value; e.g. [46,111] suggest $\Delta = 0.01\pi$. Trial and error or a more systematic grid search may be needed to find a good value.

Quantum Mutation

A simpler approach to diversity generation is quantum mutation [116, 117], which derives more inspiration from the standard GA mutation operator than from quantum physics. It is defined by

$$Q_{\text{pointer}}(t) = a \times B_{\text{best}}(t) + (1 - a) \times (1 - B_{\text{best}}(t)) \tag{29}$$

$$Q(t + 1) = Q_{\text{pointer}}(t) + b \times r, \tag{30}$$

where $B_{\text{best}}(t)$ is the best solution found in iteration t, $Q_{\text{pointer}}(t)$ is a temporary quantum chromosome that is used to guide the tailoring of $Q(t + 1)$ towards the form of B_{best}, and r is a random number drawn from a $N(0, 1)$ normal distribution. The parameters a and b determine the balance between exploration and exploitation: a controls the importance attached to $B_{\text{best}}(t)$, while b controls the degree of variance generation, centred on $Q_{\text{pointer}}(t)$. [116, 117] suggest choosing values of $a \in [0.1, 0.5]$ and $b \in [0.05, 0.15]$.

Another simple method for adapting the quantum chromosome [117] is

$$\alpha(t + 1) = [2 - B_{\text{best}}(t)] \times 0.5. \tag{31}$$

Using this approach, the bits in the current best individual will be more likely to be chosen during quantum chromosome observation in the next iteration.

Real-Valued QIEA

da Cruz et al. [27] proposed an alternative real-valued QIEA approach. As with the binary QIGA, the real-valued QIGA maintains two distinct populations: a quantum population and an observed population. In this approach, the observed population consists of real-valued m-dimensional solution vectors; the quantum population $Q(t)$ consists of n quantum chromosomes q_i with $i = 1, 2, \ldots, n$, where each individual q_i is composed of m genes q_{ij} with $j = 1, 2, \ldots, m$: q_{ij} is the jth gene of the ith quantum individual. Each gene is a pair of real values, $q_{ij} = (p_{ij}, \sigma_{ij})$, where p_{ij} and σ_{ij} are the mean and the width of a rectangular pulse, respectively. Representing a gene in this way corresponds loosely to quantum superposition of states, since a gene is a range of possible values, rather than a unique value; also, the act of observation (in this case, periodically sampling from an associated distribution) can be viewed as causing a wavefunction to collapse to an eigenstate. On observation, a chromosome gives a particular solution vector $\in \mathbb{R}^m$.

Algorithm 5 gives a version of the real-valued QIEA, which uses a single quantum chromosome. Here, $E(t)$ is a temporary population and $C(t)$ is a population of "best-so-far." The population $C(t)$ is maintained between iterations of the algorithm.

Algorithm 5: Real-valued quantum-inspired genetic algorithm

```
1  begin RealValuedQIGA(K, n, t_max)
2      Set t ← 0;
3      Initialise the quantum chromosome Q(t);
4      while t < t_max do
5          Create the PDFs and corresponding CDFs for each gene locus using the quantum
             individual;
6          Create a temporary population E(t) of K real-valued solution vectors through a
             series of observations of Q(t) via the CDFs;
7          if t = 0 then
8              C(t) ← E(t);
9          else
10             Let E(t) ← outcome of crossover between E(t − 1) and C(t − 1);
11             Evaluate E(t);
12             Let C(t) ← K best individuals from E(t) ∪ C(t − 1);
13             Evaluate C(t);
14         end if
15         With the n best individuals from C(t);
16         Q(t + 1) ← output of translate operation on Q(t);
17         Q(t + 1) ← output of resize operation on Q(t + 1);
18         t ← t + 1;
19     end while
20     return best solution found;
21 end RealValuedQIGA.
```

Initialising the Quantum Population

At the beginning of the algorithm's run, each quantum gene q_{ij} is initialised by randomly drawing a value for p_{ij} from the range of allowable values for that component j of the m-dimensional solution space $\mathbb{R}^m$. A gene's width value is set to the range of allowable values for the corresponding component of the solution vector. For example, if the allowable values for component j are $[-75, 75]$, then q_{ij} is initially found by randomly selecting a value from this range, (say) -50. The corresponding width value will be the width of the range, $75 + 75 = 150$. Hence, $q_{ij} = (-50, 150)$, a rectangular pulse of width 150 centred on -50.

The rectangular pulse need not be completely inside the allowable range for a component when initially created, since the algorithm will automatically adjust for this during its run. The height of the pulse of gene j in chromosome i is calculated using

$$h_{ij} = \frac{1/\sigma_{ij}}{n}, \tag{32}$$

where n is the number of chromosomes in the quantum population (n could be 1). The height assigned by (32) ensures that the rectangular pulse has area 1, so it is a valid probability density function (PDF) for generating the observed solution vectors (see below). Figure 5 illustrates the quantum gene $q_{ij} = (-50, 150)$ above.

Observing Quantum Chromosomes

To generate a population of real-valued solution vectors, we must make a series of observations of the population of quantum chromosomes (individuals). A pseudointerference process between the quantum individuals is simulated by summing up the rectangular pulse for each individual gene across all members of the quantum population. This generates a separate PDF for each gene, and applying (32) ensures that the area under this PDF is 1. Hence, the PDF for gene j on iteration t is

$$\mathrm{PDF}_j(t) = \sum_{i=1}^{n} q_{ij}. \tag{33}$$

To use this PDF to make an observation, its corresponding cumulative distribution function (CDF) is first obtained:

$$\mathrm{CDF}_j(x) = \int_{L_j}^{U_j} \mathrm{PDF}_j(x)dx, \tag{34}$$

where U_j and L_j are the upper and lower limits of the probability distribution. A separate PDF and CDF is calculated for each of the m gene positions.

By drawing a random number r uniformly from the interval (0,1), the CDF can be used to give an observation of a real number $x = \mathrm{CDF}^{-1}(r)$. If the "observed" value x is outside the allowable range for that component, then x is limited to the nearer allowable boundary value. The observation process is iterated to create a temporary population $E(t)$ with K members.

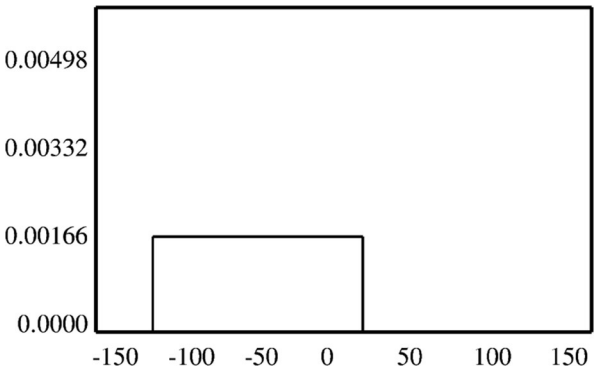

Fig. 5 A rectangular pulse, representing a quantum gene with a width of 150, centred on -50. The height of the pulse is $\frac{1}{150} = 0.001666\dot{6}$

Crossover Operation

Crossover takes place between $C(t)$ and the temporary population $E(t)$. This step can be implemented in a number of ways: da Cruz et al. [27] choose a variation of uniform crossover for real numbers. After the K crossover operations have been carried out, and the resulting offspring copied into $E(t)$, the best K individuals $\in C(t-1) \cup E(t)$ are copied into the current $C(t)$.

Updating the Quantum Chromosomes

After carrying out the crossover operation in Algorithm 5, the quantum population $Q(t)$ is updated using the "translate" and "resize" operations.

In "translate" the n quantum chromosomes are updated using the n best individuals from the current population $C(t)$. Each quantum gene's centre (mean value) is changed using

$$p_{ij} = c_{ij}. \tag{35}$$

Thus, the mean value of gene j of quantum chromosome i is set to the jth component of the ith ranked individual in population $C(t)$.

In the final "resize" step in Algorithm 5, the corresponding width value of gene j is updated. The purpose of this is to adjust the exploration-exploitation balance of the search algorithm, according to feedback from previous iterations. If the search process is still finding many new better solutions, then we should continue with exploration by keeping the pulse widths relatively broad. Conversely, if we are not finding many new better solutions, we reduce the pulse widths so as to encourage exploitation: finer-grained search around regions of the solution space already found to be good. This can be implemented in several ways: for example, da Cruz et al. [27] suggest the $\frac{1}{5}$ mutation rule from evolutionary strategies [89], where we adjust the width σ_{ij} of gene j of quantum chromosome i:

$$\sigma_{ij} = \begin{cases} \sigma_{ij} g & \text{if } \varphi < 1/5 \\ \sigma_{ij} / g & \text{if } \varphi > 1/5 \\ \sigma_{ij} & \text{if } \varphi = 1/5 \end{cases}. \tag{36}$$

Here, g is a constant in the range $[0, 1]$ and φ is the proportion of individuals in the new population that have improved their fitness.

QIEAs and EDAs

Although the real-valued QIEA has some similarity to the quantum ideas of superposition of states and wavevector collapse to a classical state when observed (in the QIEA, this is sampling from a gene's PDF), it takes less inspiration from quantum physics than does the binary QIEA, since the real-valued QIEA does not have an equivalent to the qubit representation. Also, it draws from uniform

distributions (unlike those which arise in physics) and only allows constructive interference (whereas destructive interference of wavevectors is experimentally observed in physical systems): in addition, this constructive interference is among wavevectors of *different* individuals, whereas physically interference is observed between a system's wavevector and *itself*.

An important difference between QIEAs and other nature-inspired algorithms such as the genetic algorithm (GA) and particle swarm optimisation (PSO) is that in QIEAs, a single probability vector (or a small population of probability vectors) is updated and used to guide search space exploration, rather than a population of individual solution vectors being manipulated.

The QIEA approach is similar to the approaches taken in binary and continuous estimation of distribution algorithms (EDAs). In particular, the design of real-valued QIEAs is very similar to that of univariate continuous EDAs; this suggests that a typical real-valued QIEA would struggle in situations where there are strong relationships among variables, given that EDAs have these issues. The binary-valued QIEA is also similar to binary EDAs such as population-based incremental learning (PBIL) [7] and the compact genetic algorithm (cGA) [48]; however, the binary QIEA diversity-generating mechanisms, especially the use of pseudoquantum gates, differ from the typical mechanisms used in EDAs to generate diversity. Platel et al. [86] discuss some of the similarities and differences between EDAs and QIEAs.

Applications of QIEAs

Early works on QIEAs include [46, 47, 79, 116, 117]. QIEAs have been widely applied; other applications include ordering problems [28], continuous optimisation (using a real-coded QIEA) [106], user pairing in non-orthogonal multiple access [80], neural architecture search [104], and the design of miniaturised reconfigurable Internet of Things antennas [13]. Montiel et al. [78] develop a QIEA (also partly inspired by ant colony optimisation) and find that it "outperforms existing outstanding quantum-inspired evolutionary algorithms when testing benchmark functions."

Quantum Binary PSO

The particle swarm optimisation algorithm (PSO) was introduced by Kennedy and Eberhart [57]. It can be applied in both continuous and discrete (including binary) settings. The best-known version of binary PSO, *BinPSO* [58] converts the continuous PSO algorithm into one which operates on binary representations. An alternative approach to applying PSO to binary-encoded problems, *angle-modulated PSO*, is outlined in [82]. For further discussion, see [17].

An alternative version of binary PSO, *Quantum Binary PSO*, proposed by Yang et al. [118], draws inspiration from quantum mechanics. The main quantum concepts used are the superposition of states and the collapse of the quantum state of a particle to a single eigenstate upon observation. Unlike many applications

of quantum concepts to evolutionary algorithms, two populations of the same size are maintained: one population of candidate solutions and a corresponding population of the same size of quantum particles. The population of quantum particles is updated from one algorithm iteration to the next by applying a variation of the PSO velocity update equation to the quantum population (replacing the original PSO two-step process of calculating velocity updates and then moving the population of particles). Each quantum particle is then observed in turn, to generate a corresponding binary particle whose fitness can be computed.

The Algorithm

In the algorithm, a population of N quantum particle vectors, each with m components, is created, defined as follows:

$$Q(t) = \{q^1(t), q^2(t), \ldots, q^N(t)\}, \tag{37}$$

where

$$q^j(t) = (q_1^j(t), q_2^j(t), \ldots, q_m^j(t)), \quad j = 1, 2, \ldots, N, \tag{38}$$

with $q_i^j(t)$ being the probability of the ith bit of the jth particle being 0 at time t. Thus, for each $q_i^j(t)$, the range of possible values is the closed interval $[0, 1]$. The population of binary particles has the same size and number of components (dimension) as the population of quantum particles; thus:

$$X(t) = \{x^1(t), x^2(t), \ldots, x^N(t)\}, \tag{39}$$

where

$$x^j(t) = (x_1^j(t), x_2^j(t), \ldots, x_m^j(t)), \tag{40}$$

and $x_i^j(t) \in \{0, 1\}$ is the binary value of particle j in position i derived from observing the quantum particle $q_i^j(t)$, for each $i = 1, 2, \ldots, m$ and each $j = 1, 2, \ldots, N$.

After the quantum population has been generated – or updated as the algorithm runs – a population of binary-encoded particles is generated by observing the corresponding quantum particle. That is, the first binary particle is created by observing the first quantum particle, and so on. The observation mechanism is relatively simple:

- For each $q_i^j(t)$, where $i = 1, 2, \ldots, m$, $j = 1, 2, \ldots, N$, generate a random number r uniformly in the range $[0, 1]$.
- If the random number is greater than $q_i^j(t)$, then set $x_i^j(t) = 1$; otherwise, set $x_i^j(t) = 0$.

A variation of the PSO velocity update step is applied to drive the search process of the quantum particle population from one iteration to the next. To begin, an m-dimensional quantum particle called $q_{g^{\text{best}}}(t)$ is determined using the global best binary particle $x_{g^{\text{best}}}(t)$,

$$q_{g^{\text{best}}}(t) = \alpha x_{g^{\text{best}}}(t) + \beta(1 - x_{g^{\text{best}}}(t)); \tag{41}$$

next, for each member of the quantum population, a quantum particle $q_{p^{\text{best}}}$ is calculated using the $x_{p^{\text{best}}}(t)$ of their associated binary vector:

$$q_{p^{\text{best}}}(t) = \alpha x_{p^{\text{best}}}(t) + \beta(1 - x_{p^{\text{best}}}(t)). \tag{42}$$

Here, α, β, where $\alpha + \beta = 1$, $0 < \alpha, \beta < 1$, are control parameters which control the speed of adaptation towards g^{best} and p^{best}. Finally, each quantum population member is updated using:

$$q(t+1) = wq(t) + c_1 q_{p^{\text{best}}}(t) + c_2 q_{g^{\text{best}}}(t), \tag{43}$$

where $w + c_1 + c_2 = 1$ and $0 < w, c_1, c_2 < 1$. Algorithm 6 lists the steps of quantum binary particle swarm.

Algorithm 6: Quantum binary particle swarm

```
1  begin QuantumBinaryPS(m, N)
2      Set t ← 0;
3      Initialise the populations Q(t) of quantum particles and X(t) of binary particles;
4      Evaluate the fitness of each (binary) individual in X(t);
5      Find the binary particle with highest fitness, and store as x_{g^best};
6      repeat
7          t ← t + 1;
8          Update all individuals in Q(t) using Eqs. (41)–(43);
9          Observe each individual in Q(t) in turn to get each individual in X(t);
10         for each i ∈ {1, ..., N}, each j ∈ {1, ..., m} do
11             Generate a random number r uniformly in the range [0, 1];
12             if r > q_i^j then
13                 x_i^j ← 1;
14             else
15                 x_i^j ← 0;
16             end if
17         end for
18         Evaluate fitness of each individual in X(t);
19         Update x_{g^best} for X(t) and individual x_{p^best}s if necessary;
20     until terminating condition;
21     return best solution found;
22 end QuantumBinaryPS.
```

Applications and Further Reading

Applications

The range of applications in section "Quantum Advantage" suggests that as and when sufficiently large and powerful quantum computers become available, they could productively be applied to difficult problems arising in decision-making, operational research (OR), and related areas. There are many interconnections and indeed synergies between operational research and quantum computing [83]. Recently, quantum computers have been increasingly applied to OR problems. For example, Creemers et al. [26] apply Grover's quantum database algorithm to the knapsack problem and Bochkarev et al. [14] apply a range of quantum approaches to a range of OR problems. However, it is generally necessary to reformulate the problem, especially the objective function, into qubit terms [14]. Klug [62, Fig. 1] provides a quantum landscape of optimisation algorithms in operational research, and Gomes et al. [43] provide an overarching view of the literature on applications of quantum and quantum-inspired algorithms to operational research, including a systematic classification of quantum and quantum-inspired algorithms in the context of possible operational research applications, with detailed analyses of 149 studies drawn from more than 2000 found. Klug [62] discusses operational research application areas of quantum algorithms in the contexts of routing, sequencing, scheduling, batching and loading, inventory management, and max-cut problems, as well as applications in finance. He emphasises that "From the point of view of practical OR applications, it is quite often more important to find a good instead of a perfect solution." Weinberg et al. [112] discuss applications of quantum computing approaches to supply chain management.

It should be noted that as of writing, there does not yet exist an exponential quantum advantage for optimisation problems [53]. Also, quantum algorithms can only sometimes achieve an exponential speed-up over classical algorithms but can in general attain a significant polynomial speed-up, e.g. quadratic; bigger improvements in speeding up solving require special structures in the problem [74]. These limited quantum speed-ups for particular tailored problems do not suggest a general quantum advantage for real decision problems in OR [62]. Also, which quantum technology is best is moot: bochkarev et al. [14] solve instances of three classical discrete optimisation problems – the traveling salesperson problem, weighted maximum cut, and maximum independent set – in a series of experiments on three types of quantum computer – a neutral atom machine (QuEra), a quantum annealing computer (D-Wave), and a gate-based device (IBM) – but find it difficult to assess which of the currently available systems is superior.

Further Reading

A number of papers are useful for the reader interested in acquiring further knowledge of quantum computing approaches, both on true quantum computers

and by simulations on classical computers. Good overviews of quantum computing, including more detail on the underlying physics than is given here, can be found in [12, 52, 62].

In particular, [12] is extensive and provides a detailed review of NISQ computers and QA computational paradigms and algorithms, along with a summary of recent quantum hardware and experiments. The authors note that scientists and engineers are also developing hybrid quantum computing platforms, but that such devices – built to solve particular problems – do not necessarily have universal quantum gate sets. They discuss a range of applications of NISQ algorithms, including machine learning, combinatorial optimisation, and numerical solvers. They point out that most current NISQ algorithms use quantum computers in a hybrid quantum-classical arrangement, where the algorithms perform the classically difficult part of a computation on a quantum computer and carry out the rest on a sufficiently powerful classical machine. These algorithms *variationally* update the variables of a parameterised quantum circuit and so are called variational quantum algorithms (VQA). Bharti et al. [12] concentrate mostly on VQA but consider quantum computing paradigms using different types of algorithms which are inspired by and hybridised with analogue approaches, such as quantum annealing. In addition, the article studies the methods developed to best utilise NISQ algorithms as well as theoretical and experimental challenges; they discuss the theoretical guarantees of some of these algorithms, as well as noisy quantum device error-mitigation techniques.

Ye and Lu [121] give an overview of research and current trends in the field of quantum science. Hauke et al. [51] provide a detailed introduction to quantum annealing and discuss challenges and future perspectives. Yulianti et al. [122] discuss implementations of quantum annealing and compare it to other common metaheuristics: simulated annealing, the genetic algorithm, particle swarm optimisation, and tabu search. Yarkoni et al. [120] review the literature to provide a centralised and condensed source on applications of quantum annealing.

Conclusions

This chapter has given an overview of the current state of quantum computing and quantum-inspired algorithms and metaheuristics. We began with a summary of the physics necessary to understand quantum computers and associated concepts, then related this to existing quantum hardware, and then to existing and potential quantum and quantum-inspired algorithms.

While quantum hardware is still in its infancy, and we are still in the NISQ phase of quantum computing, quantum and quantum-inspired algorithms have shown strengths; and quantum computing – together with ideas arising from it – has the potential to be a transformative technology.

Although quantum-inspired algorithms and metaheuristics predate working quantum computers, they have been found to have interesting properties in their

own right and are able to give useful results on classical computers; the wheel has turned, and some are now being implemented in limited ways on quantum hardware.

There is a range of applications across domains including operational research, and it is very likely that, in the near to medium term, quantum computing will have a major impact on optimisation and problem-solving in general.

Abstract

This chapter is focused on restart strategies in optimization, which often provide a substantial algorithmic acceleration for randomized optimization procedures. Theoretical models that describe optimal restart strategies are presented alongside with their relations to parallel computing implementations.

Keywords

Algorithm · Algorithm portoflio · Parallel optimization · Restart · Superlinear speedup

Introduction

When evaluating performance of an optimization method, the most commonly reported statistics are running time (or execution time) and solution quality. Often these statistics are sensitive to initial conditions and algorithm parameters, especially in randomized algorithms. To capture this variability when analyzing computational performance, it is common to report a sequence of run-times and the corresponding objective function values (or their averages and some measures of dispersion) for different problem instances, initial conditions, and parameter settings. In general, it is natural to consider a probability distribution of time that an algorithm requires to obtain a solution of a given quality (e.g., an optimal solution or a solution whose value is within factor α from optimal). The variability in run-times can often be attributed to randomized algorithmic steps, such as randomized branching rules and column selection in branch-and-price methods, arbitrarily resolved ties, stochastic initial solutions, and random local search moves in metaheuristics.

In some applications, the distribution of the algorithm's run-time has a large spread, and there is a relatively high probability of having a run-time that is far from the average run-time value [6]. Such peculiar distributions can be exploited to accelerate the search via multi-start strategy: each run has a limited duration, and the algorithm is repeatedly restarted with different initial conditions or random seeds. Importantly, such acceleration opportunity is not just a mathematical curiosity, but it is commonly found in many real-life applications providing significant acceleration for the state-of-the-art optimization algorithms; see, e.g., [6, 12, 16, 18].

If a probability distribution of an algorithm's run-time admits such acceleration, it is referred to as a *restart distribution*. In [18], the authors provide the formal definition of a restart distribution. The authors also establish the theoretical explanation of the efficient restart strategies for enumeration algorithms. A search tree model is described in [2] to provide a formal proof of heavy-tailed behavior in imbalanced search trees.

Incorporating variability into deterministic methods may lead to faster algorithms. Randomizing certain decision in the deterministic algorithms may also induce restart distribution of run-times. This type of acceleration has been reported for various applications of randomized backtracking search. In [6], random steps are embedded in a complete search algorithm for the constraint satisfaction problem and the propositional satisfiability problem, and it is shown that the proposed randomization accelerates deterministic methods.

Finally, multi-start is a popular framework in many metaheuristics (see, e.g., [3, 13, 14, 16]). However, the impact of restart strategies on the computational performance is often underestimated. One of the most successful metaheuristics—tabu search—and its run-time distributions in the context of restart strategies are discussed in [19].

The following example of a restart distribution is based on a randomly generated instance of the directed *maximum cut problem* [20] with 400 vertices, where every possible edge between vertices is included in the graph with probability $\frac{1}{2}$ (both

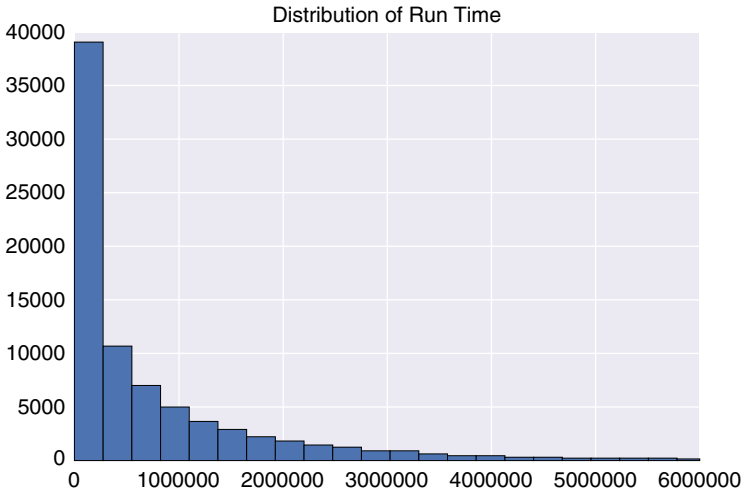

Fig. 1 The distribution of run-time of a tabu search algorithm for an instance of the maximum cut problem based on 80,000 runs

directions are considered separately). This random instance is repeatedly solved by a simple version of the *tabu search* method [4] starting from different initial solutions, terminating when the algorithm finds a solution whose objective is better than a predefined threshold value. The implementation of the tabu search in this example has a fixed tabu tenure of ten iterations, and it does not include any advanced features, except for the cycle detection [4].

The distribution of the run-times is presented in Fig. 1. Markedly, it can be observed that the probability of large computational times is rather high or, in other words, the run-time has a heavy-tailed distribution (the tails are not exponentially bounded). In order to accelerate the search, one can select a restart parameter value and repeatedly restart the algorithm after the number of iterations exceeds this predefined parameter. Figure 2 provides the average run times for the tabu algorithm as a function of the number of iterations between restarts. It is clear from the plot that certain values of the restart parameter guarantee superior algorithmic performance, when compared to the original algorithm that does not employ any restart strategy. In this context, an interesting question can be stated: What is the best restart value for algorithm acceleration? The following discussion provides an overview of the research that addresses this important question.

Basic Restart Strategies

Unlike Monte Carlo algorithms, which are guaranteed to provide approximate answers or solutions within a fixed time, the Las Vegas-type algorithms are defined as algorithms that always find "correct solutions," but the required computational

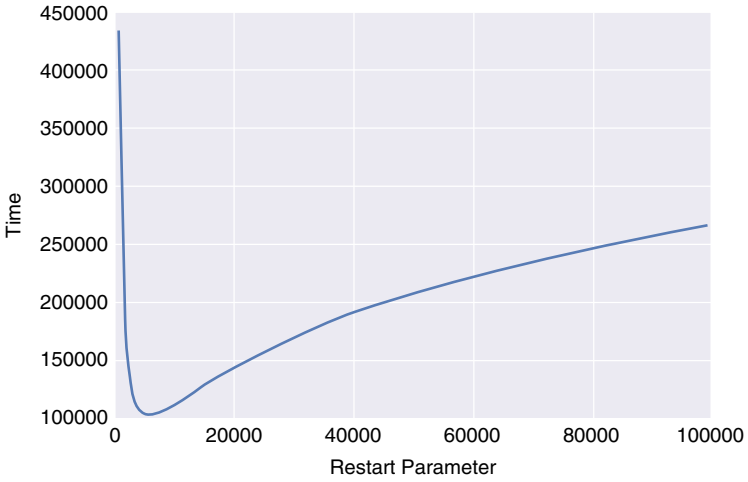

Fig. 2 The average run-time of a tabu search algorithm for an instance of the maximum cut problem as a function of the restart parameter (the same instance as in Fig. 1)

time is uncertain. To define the correctness of a solution, one can demand a proof of optimality or comparison of the solution objective function to a predefined threshold, in which case the "correct solution" is any solution with the objective function better than the threshold.

In general, the run-time of an algorithm can be measured either in iterations or in computational time. A *restart strategy* associated with a given algorithm is typically defined (see, e.g., [10, 22]) as a sequence, $S = \{t_1, t_2, \ldots\}$, that represents allocated run-times between restarts. According to the strategy S, the first run continues for t_1 time units (iterations) or until the correct answer is found. The second run lasts t_2 time units or until the correct answer is found and so on. The runs are independent from each other, as no information is passed between different computational runs. As briefly discussed in section "Introduction," different restart strategies might lead to different average run-times.

In [10], the authors consider integer run-times that represent the total number of iterations until a desired outcome is achieved. They consider a wide domain of restart strategies including strategies with random restart intervals and those that enable suspension of algorithm execution in favor of another run with an option to continue its execution later. It is shown that there always exists a *uniform restart strategy* (i.e., $t_1 = t_2 = \ldots = t^*$) that is optimal. It is easy to see that the same result holds if a run-time is determined using continuous time units instead of iterations—for example, consider rounding continuous times to the nearest integral values (number of seconds) and redefining the run-time distribution accordingly.

To find an optimal restart period t^*, a good estimate of the underlying run-time distribution is required, which might be problematic in practice. If this information is not available, the *universal restart strategy* introduced in [10] can provide a decent

performance guarantee. In this strategy, all run length are powers of 2 starting with a run of length 2^0 (this sequence may be rescaled). Considering the duration of the current run, if the number of previous runs with the same length is even, then the next run duration is double of the current run duration. Otherwise, the next run has the length equal to one. These rules define the following numerical sequence:

$$S^{\text{univ}} = \{1, 1, 2, 1, 1, 2, 4, 1, 1, 2, 1, 1, 2, 4, 8, 1, \dots\}$$

When comparing S^{univ} to the optimal restart strategy, its performance is within a logarithmic factor from optimality without any requirements on prior knowledge of the run-time distribution [10]. Formally, if T^{univ} denotes the expected run-time of the algorithm that uses universal restart strategy and T^{opt} denotes the expected run time under the optimal restart strategy, then

$$T^{\text{univ}} \leq 192 \cdot T^{\text{opt}} \left(\log_2 \left(T^{\text{opt}}\right) + 5\right).$$

Unfortunately, the difference between run-times of the universal and optimal strategies may be large in practice, which limits the applicability of this important theoretical result.

Restart strategies can be naturally extended to parallel optimization [9], where copies of the same algorithm are executed in parallel. Note that due to randomness, the search trajectories are in general different. As in the serial setting, a restart strategy defines maximum run-times for each copy of the algorithm, i.e.,

$$S = \begin{cases} t_1^1, t_2^1, t_3^1, \dots \\ t_1^2, t_2^2, t_3^2, \dots \\ \dots \\ t_1^n, t_2^n, t_3^n, \dots \end{cases} \tag{1}$$

In a uniform parallel restart strategy, each copy of the algorithm has the same restart schedule (i.e., $t_j^i = t^*$). This strategy is no longer optimal as it was in the serial case, but its performance is provably within a constant factor from optimality. An example of nonuniform optimal strategy can be found in [9].

Restart Distribution and Optimal Restart Strategies

Next, we overview some formal characterizations of run-time distribution that can be exploited to gain computational acceleration. Our discussion in this and the next sections is mostly based on the results from [22].

Consider a randomized algorithm A for solving a problem instance P. The execution time of A when solving P is a random variable, ξ. Based on the algorithm A, one can define its uniform restart version, A_R, which follows the same algorithmic steps as A, but is restarted after R iterations or time units if the correct solution is

not found. Similarly to A, algorithm A_R terminates as soon as the correct solution is obtained. The positive parameter R is referred to as a *restart period* (or a *restart parameter*) of A_R.

The number of restarts before the first successful run of A_R is a geometric random variable, and the expected run-time, $T(R)$, of A_R can be expressed as

$$T(R) = R \cdot \frac{1 - \Pr\{\xi \leq R\}}{\Pr\{\xi \leq R\}} + E[\xi | \xi \leq R] \tag{2}$$

The first part of (2) is an expected number of restarts multiplied by the duration of each run, while the second is an average duration of the run that produces the final solution.

Definition 1 A probability distribution of a random variable ξ, $Pr\{\xi \leq x\}$, is called a *restart distribution* if there exists $R > 0$, such that

$$R \cdot \frac{1 - \Pr\{\xi \leq R\}}{\Pr\{\xi \leq R\}} + E[\xi | \xi \leq R] < E[\xi] \tag{3}$$

From (3), if a run-time of an algorithm follows a restart distribution, then the algorithm has a restart version that outperforms the algorithm without restarts in terms of its average run-time. Clearly, the properties of the run-time distribution depend on the optimization problem and the algorithm itself. If, for example, an optimization algorithm uses an optimal restart policy, then its run-time will no longer follow a restart distribution.

A log-normal distribution is an example of a restart distribution. For example, consider three log-normal random variables with the same location parameter, $\mu = 1$. The scale parameters, σ, are 2, 2.5, and 1.5. The expected values of these random variables are 20.08, 61.86, and 8.37, respectively. If these variables represented run-times of some algorithms, we would be able to achieve acceleration by restarting after R units of run-time. Figure 3 illustrates this opportunity by showing the expected run-time given by (2) as a function of restart period R. It shows that restarting an algorithm allows us to achieve significant acceleration for these run-time distributions. Furthermore, we can see that the larger variability in run-times provides a better opportunity for acceleration by the restart mechanism.

The optimality conditions can be derived for continuous and differentiable (first and second derivative) cumulative distribution functions (CDF) of run-times (see [22] for more details). If this is not the case, then a continuous and differentiable approximation of original CDF can be used instead.

Proposition 1 *Let R^* be an optimal restart period for A_R. Then the expected run-time of A_{R^*} is*

$$T(R^*) = \frac{1 - \Pr\{\xi \leq R^*\}}{\left.\frac{dPr\{\xi \leq R\}}{dR}\right|_{R=R^*}} \tag{4}$$

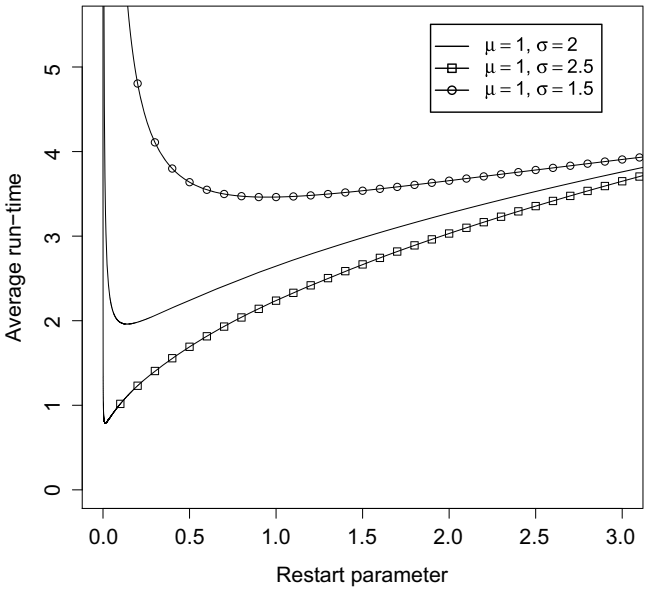

Fig. 3 The average run-time as a function of the restart parameter, R, for log-normally distributed run-times

Proof

$$\frac{dT(R)}{dR} = \frac{1 - \Pr\{\xi \leq R\}}{\Pr\{\xi \leq R\}} + R \cdot \left(\frac{-\frac{dPr\{\xi \leq R\}}{dR}}{\Pr\{\xi \leq R\}} - \frac{1 - \Pr\{\xi \leq R\}}{(\Pr\{\xi \leq R\})^2} \cdot \frac{dPr\{\xi \leq R\}}{dR} \right)$$

$$+R \cdot \frac{dPr\{\xi \leq R\}}{dR} \frac{1}{\Pr\{\xi \leq R\}} + \frac{-\frac{dPr\{\xi \leq R\}}{dR}}{(\Pr\{\xi \leq R\})^2} \int_0^R x f(x) dx$$

$$= \frac{1 - \Pr\{\xi \leq R\}}{\Pr\{\xi \leq R\}} - \frac{\frac{dPr\{\xi \leq R\}}{dR}}{\Pr\{\xi \leq R\}} \left(R \cdot \frac{1 - \Pr\{\xi \leq R\}}{\Pr\{\xi \leq R\}} + E[\xi | \xi \leq R] \right)$$

$$= \frac{1 - \Pr\{\xi \leq R\}}{\Pr\{\xi \leq R\}} - \frac{\frac{dPr\{\xi \leq R\}}{dR}}{\Pr\{\xi \leq R\}} \cdot T(R)$$

The reciprocal of the expression in the right-hand side of (4) is known as a *hazard rate function*, which is an important concept in reliability engineering [17]. The hazard rate function, or failure rate, can be used to describe general properties of restart distributions.

Proposition 2 *A hazard rate function of a restart distribution is nonincreasing on some interval containing an optimal restart period.*

This property allows us to rule out the distribution that has an increasing hazard rate functions [7]. The previous proposition shows, for example, that the following distributions are not restart distributions:

- Weibull distributions with the shape parameter $k > 1$,
- Gamma distribution with the shape parameter $k > 1$,
- Uniform distribution,
- Normal distribution.

Single Algorithm Portfolios of Restart Algorithms

Algorithmic acceleration can be achieved by combining algorithms in portfolios that are executed concurrently in a distributed manner. For example, a *single algorithm portfolio* consists of different copies of the same algorithm that are deployed on different processors. This simple parallelism can be extremely efficient in practical applications that involve randomized algorithms. There are numerous reports of superlinear speedup when using this type of parallelization (e.g., see [15]). By *superlinear speedup*, we imply that the algorithm utilizes up to n processors and on average is more than n time faster than the algorithm utilizing one processor.

The superlinear speedup can be related to the concept of restart distributions. Consider a single restart algorithm portfolio: a parallel algorithm A_R^n that consists of n independent copies of A_R running in parallel (no communication), where, as previously, A_R is the restart version A with parameter R. The algorithm A_R^n halts whenever one of n copies finds a correct solution. Let random variable $\xi_{\min}^n$ denote the run-time of A_R^n, while $T_n(R)$ denotes the expected run-time of A_R^n.

The expected run-time of the single algorithm portfolio with a uniform restart strategy is given by

$$T_n(R) = R \cdot \frac{(1 - \Pr\{\xi \leq R\})^n}{1 - (1 - \Pr\{\xi \leq R\})^n} + E\left[\xi_{\min}^n | \xi_{\min}^n \leq R\right] \tag{5}$$

An optimality condition similar to the serial case can be derived for parallel restart algorithms (see [22]).

Proposition 3 *Let R_n^* be the optimal restart period for A_R^n; then the expected running time of A_R^n is*

$$T_n\left(R_n^*\right) = \frac{\left(1 - \Pr\left\{\xi \leq R_n^*\right\}\right)}{n \cdot \left.\frac{dPr\{\xi \leq R\}}{dR}\right|_{R=R_n^*}} \tag{6}$$

As mentioned earlier, the log-normal distribution is a restart distribution. We use this distribution to illustrate some of the ideas, since we can easily calculate the exact values for the conditional expectations in (5) without resorting to statistical sampling. For example, we can use the log-normal run-time to provide an illustration of the superlinear speedup.

Let ξ be a random variable with a log-normal distribution with parameters $\sigma = 2$ and $\mu = 1$. We define a *parallel speedup* as a ratio between run-time of a serial algorithm and run-time of its parallel version. Firstly, we consider the speedup for the algorithm that does not apply any restart strategy. The data presented in Fig. 4 clearly indicates the superlinear average speedup relative to the run-time of the serial algorithm.

The following proposition from [22] states that if the superlinear parallel speedup is achieved by a single algorithm portfolio, then the underlying distribution of the run-time is a restart distribution.

Proposition 4 *If R^* and R_n^* are optimal restart periods for A_R and A_R^n, respectively, then* $\frac{T(R^*)}{T_n(R_n^*)} \leq n$.

Simply speaking, Proposition 4 indicates that the superlinear parallel speedup can be attributed to the inefficiencies of the serial algorithm, and these inefficiencies can be alleviated by adopting an appropriate restart strategy.

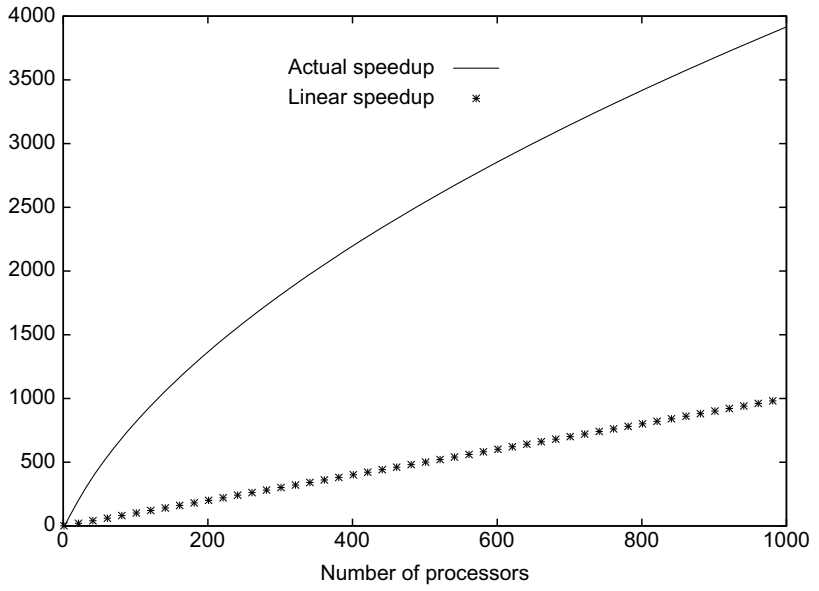

Fig. 4 Speedup is obtained by comparing the **serial no-restart** version with the **parallel no-restart** version [22]; ξ has log-normal distribution with $\mu = 1$ and $\sigma = 2$

Consider now the situation when both serial and parallel algorithms implement optimal restart strategies. It is important to note that the optimal values in parallel and serial cases are not necessarily the same. The following proposition relates the number of processors to the value of the optimal restart parameter.

Proposition 5 *If the hazard rate function of the run-time distribution is unimodal and* $\frac{T(R^*)}{T_n(R_n^*)} < n$, *then* $R^* < R_n^*$.

Intuitively, it might seem that the best serial algorithm is the best candidate for parallelizing. However, Proposition 5 shows that the optimal restart parameter for the serial algorithm is not necessarily optimal when considering the performance of the corresponding single algorithm portfolio. In other words, good average performance in serial setting can often provide suboptimal parallel performance.

Suppose that the run-time of a serial algorithm follows the same log-normal distribution as in the previous example. The optimality conditions (4) and (6) for the optimal restart parameters provide the corresponding optima. Figure 5 illustrates the computational speedup achieved by the parallel algorithms with optimal restart parameters and varying number of parallel processors compared to the serial algorithm (for the log-normal run-times). The restart parameters of the serial and parallel algorithms are different: in fact, it turns out that the optimal restart parameter is monotonically increasing as a function of the number of processors. The speedup is almost linear for the number of processors below 100. For large

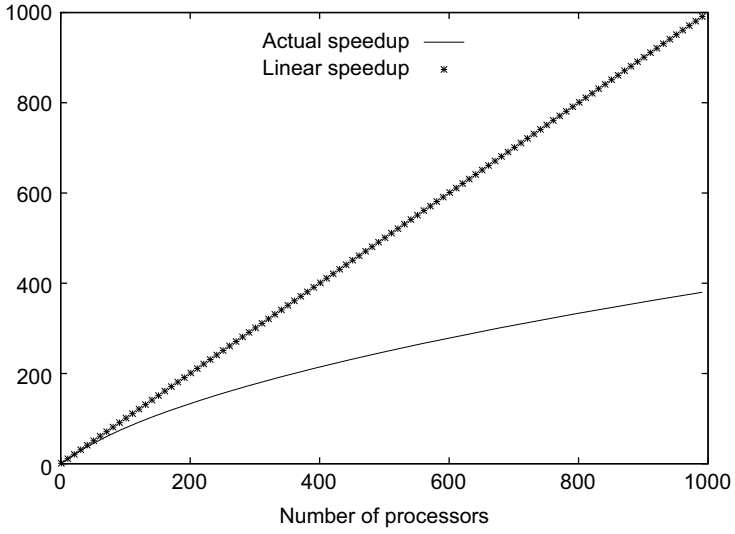

Fig. 5 Speedup is obtained by comparing the **optimal serial restart** version with the **optimal parallel restart** version [22]; ξ has log-normal distribution with $\mu = 1$ and $\sigma = 2$

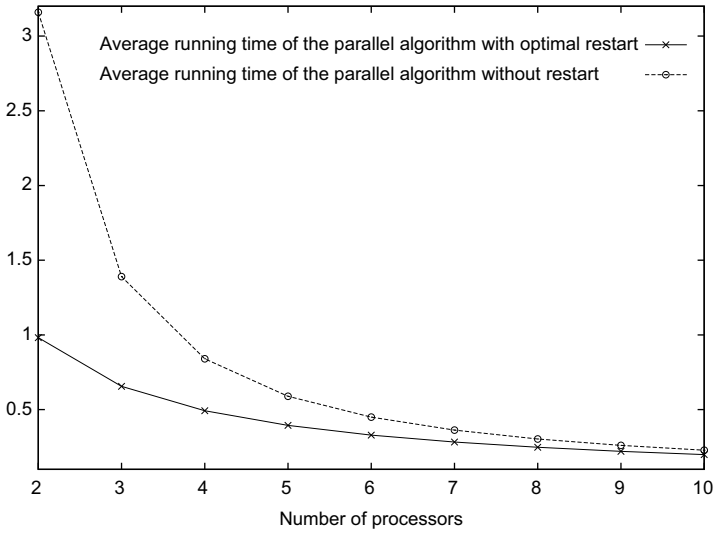

Fig. 6 Comparison of the parallel algorithms with and without implementation of the optimal restart strategy [22]; ξ has log-normal distribution with $\mu = 1$ and $\sigma = 2$

numbers of processors, the speedup quickly becomes sublinear, and the single algorithm portfolio parallelization becomes less effective.

Another interesting question that is important for practical applications is: what is the value of knowing the optimal restart parameter? Figure 6 shows the value of implementing optimal restart strategy with respect to the number of processors. As the number of processors increases, the benefit of knowing the exact value of optimal restart parameter is steadily decreasing. In some sense, the single algorithm portfolio framework takes advantage of restart-distribution properties without restarting the algorithm. The performance can be improved by applying an effective restart strategy explicitly; however, the value of such improvement quickly diminishes as the number of processes increases.

An optimal value of restart parameter is typically unknown in a realistic problem setting. Furthermore, as mentioned previously, the value of the optimal restart parameter may decrease as the number of processors grows. These observations suggest that the main effort should be concentrated on developing and identifying algorithms with run-times that follow restart distributions instead of focusing on the methods that find optimal restart values. The potential for acceleration of run-times that follow restart distributions can be automatically exploited via portfolio parallelization. Furthermore, any errors in estimating the exact value of the optimal restart sequence can degrade the performance with respect to adopting no-restart strategy.

We illustrate this idea by looking at different tenure parameters of tabu search. Again we consider a random instance of the maximum directed cut problem with 400 vertices. The computational experiment is based on a simple tabu search with

different values of tabu tenure that was mentioned in earlier examples. Table 1 shows the results for two tabu algorithms with different tenure parameters. The algorithm with tenure parameter 30 is significantly faster than the algorithm with tenure parameter 10 when deployed on a single processor. However, the situation changes when parallel implementation is considered: the parallel algorithm with tenure 10 is much faster than its serial version. This example (see [19]) shows that if one uses the average serial run-time as the main criterion for choosing an algorithm for parallel implementation, the better parameter choices (or even algorithmic approaches) can be dropped in favor of suboptimal choices.

Figure 7 highlights the value of knowing the optimal restart parameter. The tabu algorithm with tenure 10 without restarts quickly converges to the performance of the same tabu algorithm that uses an optimal restart strategy.

Table 1 Average number of iterations for different number of processors

Number of processors	Average number of iterations	
	Tabu tenure = 10	Tabu tenure = 30
1	192,216	26,073
2	19,950	13,264
4	1049	6996
8	434	3664

32	325	1124

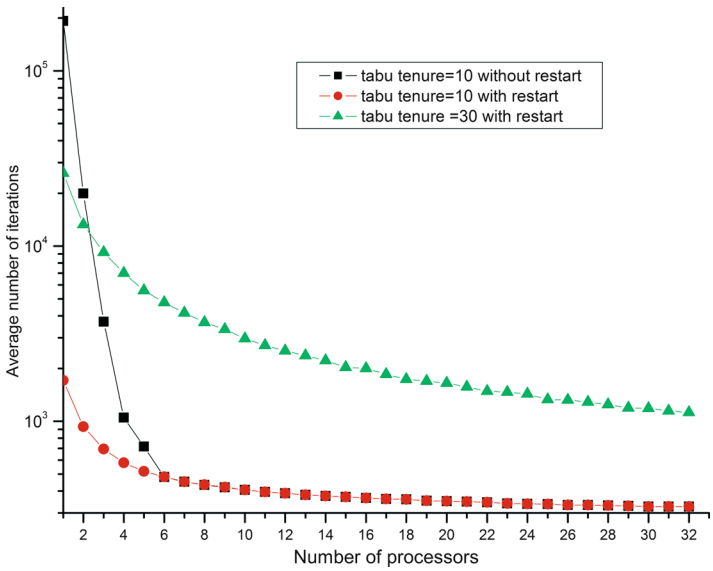

Fig. 7 Computational results for MAXDICUT problem using tabu search in a single algorithm portfolio [19]

Mixed Algorithm Portfolios of Restart Algorithms

Instead of focusing on a single algorithm portfolio, one may consider a combination of different algorithms. The diversity of mixed algorithms can improve the overall performance with respect to a single algorithm portfolio. Suppose that we have a set of available randomized algorithms and we want to select a subset of them to include into a mixed algorithm portfolio of a given size. If the available algorithms are simply different copies of the same algorithm, we call such selection a single algorithm portfolio; otherwise, we will refer to it as a *mixed algorithm portfolio*.

There are a number of examples in the literature of mixed algorithm portfolios that outperform single algorithm portfolios. In particular, the algorithm portfolio approach for constraint satisfaction and mixed integer programming is presented in [5]. The authors show that the mixed algorithm portfolio can outperform a single algorithm portfolio and discuss intuition behind such situations. An efficient algorithm portfolio approach using backtracking search for the graph-coloring problems is considered in [8]. Extensive computational experiments with restart strategies and algorithm portfolios for benchmark instances of network design problem are also investigated in [1].

The mathematical model of mixed portfolios of restart algorithms can be outlined as follows. Consider a set of m algorithms $A_1, \ldots, A_m$ with restart parameters $R_1, \ldots, R_m$ and random run-times $\xi_1, \ldots, \xi_m$, respectively. Additionally, there are N parallel processors that are available, and we need to select N algorithms to deploy on each processor. Each processor should be used by a single algorithm, and the same algorithm can be deployed on multiple processors. We assume that the run-time of each algorithm is an integer multiple of its restart parameter. In other words, even if an algorithm finds a solution in the beginning of the run, an actual run-time will be rounded up to the next restart period.

Using this setup, there are m single algorithm portfolios that can be formed. Let T_s denote the average run-time of the best single algorithm portfolio, which can be easily defined using the properties of the geometric distribution:

$$T_s\left(A_1, \ldots, A_m, N\right) = \min\left\{R_1 \frac{1}{1-p_1^N}, \ldots, R_m \frac{1}{1-p_m^N}\right\}.$$

Let $T_m(A_1, n_1, \ldots, A_m, n_m)$ denote the expected run-time of the mixed algorithm portfolio, which consists of n_1 copies of A_1, n_2 copies of A_2, and so on $\left(\sum_{i=1}^{m} n_i = N\right)$. The mixed algorithm portfolio terminates as soon as one of the algorithms finds the target solution (e.g., a solution with objective below a certain threshold).

To identify the computational benefit that can be achieved by mixing randomized algorithms with different properties, we define the *speedup ratio* S as

$$S = \frac{T_s\left(A_1, \ldots, A_m, n_1 + \cdots + n_m\right)}{T_m\left(A_1, n_1, \ldots, A_m, n_m\right)}. \tag{7}$$

Unlike the serial case, in [9] the authors demonstrate that the best uniform restart strategy repeated on every processor is not necessarily optimal; however, its performance is within a constant factor of the optimal strategy. Furthermore, in [21] and the subsequent work in [11], it is shown that the speedup ratio S of any mixed algorithm portfolio satisfies

$$S \leq \frac{1}{1 - e^{-1}} \approx 1.58. \tag{8}$$

Therefore, if one has a full knowledge of run-time distributions, the best mixed algorithm portfolio is less than two times faster than the best single algorithm portfolio. However, a mixed algorithm portfolio can be viewed as a strategy that can reduce risks associated with a nonoptimal algorithm selection for single algorithm portfolios. Recall that by the definition in (7), the value of S compares the performance of a mixed algorithm portfolio against the best possible algorithm portfolio.

Moreover, it is interesting to note that according to the theoretical approach described above (see derivation details of (8) in [11, 21]), the best performance of a mixed algorithm portfolio is achieved when it consists of N algorithms that can also be used as *candidates to form the best single algorithm portfolio*. Thus, the expected performance of these algorithms in the case of a single algorithm portfolio is the same. However, for the mixed algorithm portfolio, one should select $N - 1$ algorithms with a relatively short restart parameter and exactly one algorithm with a long restart parameter. As all of these algorithms have the same performance in the single portfolio setting, it also implies that each of the former $N - 1$ algorithms is relatively unreliable within its short restart period (thus, these algorithms have to be restarted a large number of times), while the remaining N-th algorithm, despite its large restart parameter, is very reliable (i.e., the corresponding p is close to one). Clearly, the existence of such algorithms is not necessarily guaranteed. Nevertheless, the above result provides an intuitive characterization of effective mixed algorithm portfolios. Namely, if there exists a trade-off that involves the restart parameter value and the algorithm reliability, then it can be exploited within a mixed algorithm portfolio.

Conclusions

In the discussion above, we only consider a setting with a single problem instance. However, the same framework can be easily extended to the setting with multiple problem instances. For example, optimization models of daily locomotive scheduling remain constant, i.e., one needs to find optimal routes using existing railroad network for a given demand. The particular demand patterns can vary substantially from day to day producing different problem instances. We can form a training set by selecting a set of problem instances from historical demands and use them for construction of optimal restart strategies and/or algorithm portfolios. This is also

a typical approach for computational experiments. The researchers often test their techniques on a small set of instances, tune the algorithms, and then conduct the final experiment on a larger set of problems.

Abstract

Uncertainty affects many industries and sectors, including transportation and logistics, health care, production, smart cities, and finance. Simulation models are frequently employed to analyze complex systems under stochastic uncertainty. Many real-world systems are large scale and complex, requiring metaheuristic algorithms to generate high-quality solutions in reasonable computing times. However, metaheuristics are usually designed to solve optimization problems under deterministic scenarios. This chapter describes simheuristics, which merge simulation with metaheuristics to effectively tackle stochastic and complex optimization problems. It discusses the relevance of simheuristics today, reviews related research, outlines important methodological and computational aspects, and provides practical examples from various industries. Additionally, the chapter identifies open research areas and future trends in this emerging field.

Simheuristics · Combinatorial optimization problems · Stochastic optimization problems · Metaheuristics · Simulation

Introduction

Since uncertainty is present in most real-world systems, simulation methods are often employed to analyze complex systems in sectors like manufacturing, production logistics, transportation, health care, finance, smart cities, telecommunications, etc. [14]. Typically, this uncertainty is modeled using either theoretical or empirical probability distributions. A logical model of the system is then constructed, and computer simulation is employed to understand system performance across various scenarios, each representing a possible system configuration [57]. As noted by Lucas et al. [50], advancements in computing power and simulation software have made simulation a primary method for analyzing complex systems under uncertainty.

However, simulation alone cannot optimize complex systems as it lacks mechanisms to efficiently explore the vast solution spaces found in combinatorial optimization problems. To solve stochastic optimization problems, simulation must be combined with an optimization engine [67]. Examples include finding the best distribution plan in a vehicle routing problem (VRP) with random demands, the optimal scheduling plan in a flow-shop problem with random processing times, or the best configuration of assets in a rich portfolio optimization problem with real-life constraints and random returns. These optimization problems are often NP-hard, limiting the effectiveness of exact solvers to small- and medium-sized instances.

Since real-life instances are usually large, metaheuristic algorithms are required as they can produce high-quality solutions in reasonable computing times, even for large instances, making them a preferred approach for real-world optimization problems [51].

A well-designed combination of simulation methods and metaheuristic algorithms can effectively solve many real-life optimization problems under uncertainty. Therefore, different authors have proposed integrating simulation and optimization methods to address such issues [19]. Simulation-optimization approaches incorporate various optimization methods, such as mathematical programming, metaheuristics, and reinforcement learning. Additionally, statistical and machine learning methods can be used to create surrogate models based on simulation output [4]. These models establish analytical relations among system variables and can provide quick estimates of simulation outputs. Figueira and Almada-Lobo [20] classified simulation-optimization approaches by their use of simulation, which can be: *(i)* evaluate an objective function or constraint in a stochastic optimization problem, *(ii)* generate solutions for an optimization problem, or *(iii)* enhance an analytical model. Comprehensive reviews and tutorials on simulation-optimization approaches are available in [3] and [19].

In recent years, the hybridization of simulation with metaheuristics, also known as simheuristics, has become a common approach for addressing stochastic optimization problems [41]. Early discussions on combining these methodologies can be found in [24, 25] and [6]. Simheuristic algorithms are designed to solve large-scale, NP-hard combinatorial optimization problems with stochastic elements, which can include stochastic objective functions or probabilistic constraints [13].

Figure 1 provides a visual comparison of optimization approaches and simulation, evaluating their performance (good, very good, or excellent) across four dimensions: *(i)* ability to generate optimal solutions (optimality); *(ii)* ability to model uncertainty (uncertainty); *(iii)* computing time required to deliver results (computing time); and *(iv)* capability to handle large-size instances (scalability). By combining the strengths of metaheuristics and simulation, simheuristics are able to enhance the performance of traditional metaheuristics in the "uncertainty" dimension. Additionally, they enhance the capabilities of pure simulation in the "optimization" dimension and can also outperform exact methods in several dimensions.

The term "simheuristics" first appeared in [39], although the underlying concept was already introduced in [38]. Moreover, the first description in detail of the concept "simheuristics" was depicted in [40]. Since then, the number of articles published in Scopus-indexed journals has grown significantly, from two articles in 2014 to around 21 in 2024, as displayed in Fig 2 (note that the value for 2024 is a forecasted estimate based on current data).

Figure 3 shows Scopus-indexed journals that have published at least two articles on simheuristics. Hence, "Journal of Simulation" includes eight articles on simheuristics, while "Simulation Modelling Practice and Theory" and "International Transactions in Operational Research" include seven each. Also, journals such as "Mathematics," "Algorithms," "SORT," and "Annals of Operations Research" have published five or more articles on simheuristics each. According to the Scopus database, articles on simheuristics have been published in up to 48 different journals.

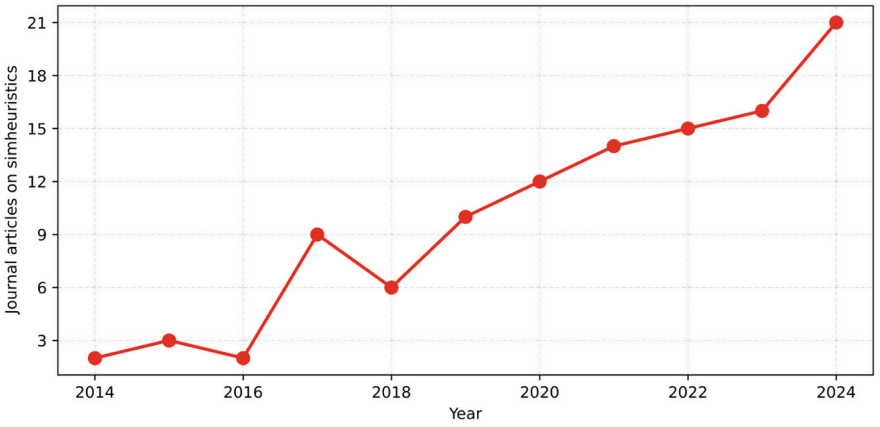

Fig. 2 Journal articles on simheuristics for the period 2014–2024

This chapter introduces the core concepts of simheuristics, along with recent applications and current research directions. The rest of the chapter is organized as follows: section "Stochastic Optimization Problems" describes the stochastic optimization problems that can be addressed with simheuristics.

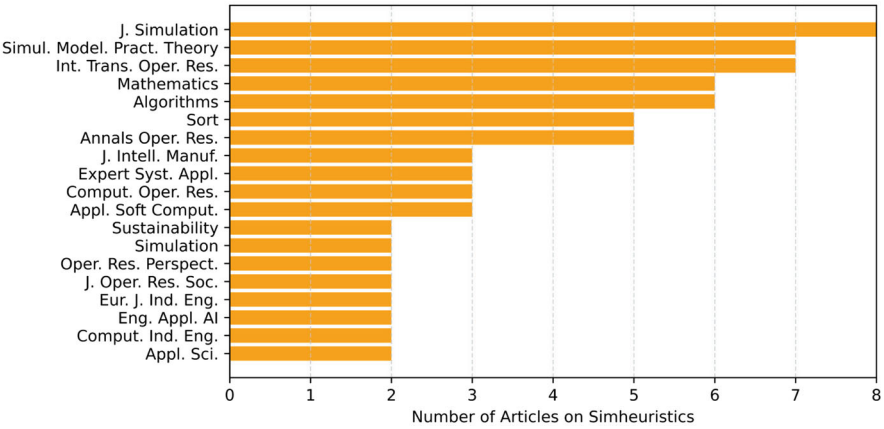

Fig. 3 Number of simheuristic articles by Scopus-indexed journal

Section "Simheuristic Methodology" explains the fundamental concepts of the methodology, while section "Simheuristic Extensions" discusses how simheuristics can be extended in order to incorporate fuzzy uncertainty as well as dynamic elements. Sections "Recent Applications in Transportation, Recent Applications in Logistics, Recent Applications in Production, Recent Applications in Health Care, Recent Applications in Finance, and Other Recent Applications" review recent simheuristic applications to fields such as transportation, logistics, production, health care, finance, and others, respectively. Section "Overview of Computational Results" provides an overview of the computational results that have made simheuristics an attractive approach methodology. Section "Some Open Challenges" highlights some trends and open challenges to be considered. Finally, section "Conclusions" summarizes the contents of the chapter.

Stochastic Optimization Problems

Reviewing the scientific literature on optimization reveals that many combinatorial optimization problems in industries such as transportation and logistics, production and manufacturing, energy, finance, etc. are still often formulated using deterministic models. However, deterministic models do not take into account the uncertainty and variability inherent in real-life systems, such as random travel and processing times, random customer demands, or random investment returns. At least in part, this oversimplification is due to the added complexity that stochastic components introduce into the problem modeling and solving processes. Many of these problems are NP-hard, making even their deterministic versions challenging and time-consuming to solve, particularly for realistic, large-scale instances. Consequently, numerous studies focus on finding an optimal solution to a deterministic version of the problem rather than a near-optimal solution to a more realistic version including stochastic elements. This approach results in an optimal solution for a model

that does not accurately represent the real-world system. When this deterministic optimal solution is applied to the actual system under uncertain conditions, it often turns out to be suboptimal. This can be easily demonstrated by running the deterministic optimal solution through a simulation model of the system.

Simheuristic algorithms aim to resolve the aforementioned discrepancy by using stochastic optimization models that more accurately reflect real-world operating conditions. These algorithms then try to find near-optimal solutions for these models. Typically, the stochastic optimization models used have the following form:

$$\text{optimize } f(s) = \Phi(s, X) \tag{1}$$

subject to:

$$Pr\Big(g_i(s, X) \leq l_i(X)\Big) \leq t_i \qquad \forall i \in I \tag{2}$$

$$Pr\Big(g_j(s, X) > l_j(X)\Big) \leq t_j \qquad \forall j \in J \tag{3}$$

$$g_k(s) \leq t_k \qquad \forall k \in K \tag{4}$$

$$s \in S \tag{5}$$

where

- As represented in Eq. (5), s denotes a potential solution (a configuration of decision variables) to the optimization problem, with S representing the space of all possible solutions.
- The term $\Phi(s, X)$ in Eq. (1) stands for a stochastic function that needs to be optimized (either minimized or maximized). Here, X is a vector of random variables, each following a specific probability distribution with a known mean. Note that $\Phi(s, X)$ does not have to be an expected value. On the contrary, it can be any statistic (standard deviation, median, percentile, etc.), or even a combination of them.
- Equations (2) and (3) describe probabilistic constraints related to the problem. For instance, the probability that the number of serviced customers in solution s, $g_i(s, X)$, falls below a certain lower bound $l_i(X)$ is less than a user-defined threshold t_i. Alternatively, the probability that the time delay in solution s, $g_j(s, X)$, exceeds a certain upper bound $l_j(X)$ is constrained by a user-defined threshold t_j.
- Lastly, Eq (4) represents the standard deterministic constraints found in combinatorial optimization problems.

There are other promising methods for addressing stochastic optimization problems, such as probabilistic programming [83], robust optimization [30], and stochastic programming [34]. However, as highlighted by Onggo et al. [60], it is important to notice that any given solution $s \in S$ exhibits probabilistic behavior when solving

stochastic optimization problems. Therefore, knowing as much as possible on the distribution of s could be valuable when making informed decisions. For example, in a stochastic VRP, while the primary objective may be to minimize the expected cost of a routing plan, other statistics such as the variance of s or its reliability (i.e., the probability of completing the route without failures) should also be evaluated. Similarly, in a stochastic portfolio optimization problem, minimizing risk may require understanding the probabilistic behavior of the random returns associated with a given solution s (portfolio configuration). In essence, optimization under uncertainty is more complex than optimization under deterministic conditions. Hence, experts should not only provide a solution s that optimizes an expected value but also offer insights into the statistical and probabilistic behavior of multiple alternative solutions. This is where simheuristic algorithms excel. They are effective in searching large solution spaces due to their metaheuristic component and can enhance the analysis of solutions with the statistical and probabilistic insights provided by their simulation component.

Simheuristic Methodology

When dealing with a deterministic optimization problem, it is reasonable to assume that its optimal and near-optimal solutions will likely perform with high quality even when moderate uncertainty is introduced into the problem. For example, in a VRP, routing plans with near-optimal performance under deterministic conditions are expected to maintain a high-quality performance even if some travel times have small variances. Similarly, in a deterministic portfolio optimization problem, low-risk asset configurations that guarantee a return of r_0 are likely to remain low risk under random returns with moderate variance, potentially achieving expected returns that exceed $r_0 - \epsilon$ with some probability, where $\epsilon > 0$.

For a given solution configuration s to a deterministic optimization problem with objective function $f(s)$, it is possible to consider its value under deterministic conditions, $determ(s) = f(s)$, as well as its expected value under stochastic conditions, $stoch(s) = E[f(s)]$. Under moderate uncertainty, it makes sense to assume a strong positive correlation between $determ(s)$ and $stoch(s)$, meaning that high-quality solutions for the deterministic version of the problem are likely to perform as high-quality solutions (on the average) for the stochastic version of the problem. However, the existence of such correlation does not necessarily imply that the best solution for the deterministic version of the problem will also be the best solution for the stochastic version. Hence, for example, solution s_1 could outperform solution s_2 in the deterministic version of the problem, while s_2 could perform better than s_1 in the stochastic version. In the VRP example, this could be the case if s_2 offers a more balanced distribution of routes than s_1, which allows it for supporting moderate variances in travel times or customer demands without suffering excessive delays or route failures.

Figure 4 illustrates the underlying logic of the simheuristic approach. It starts by considering the deterministic version of a stochastic optimization problem, which is achieved by substituting all random variables with their expected values, thus

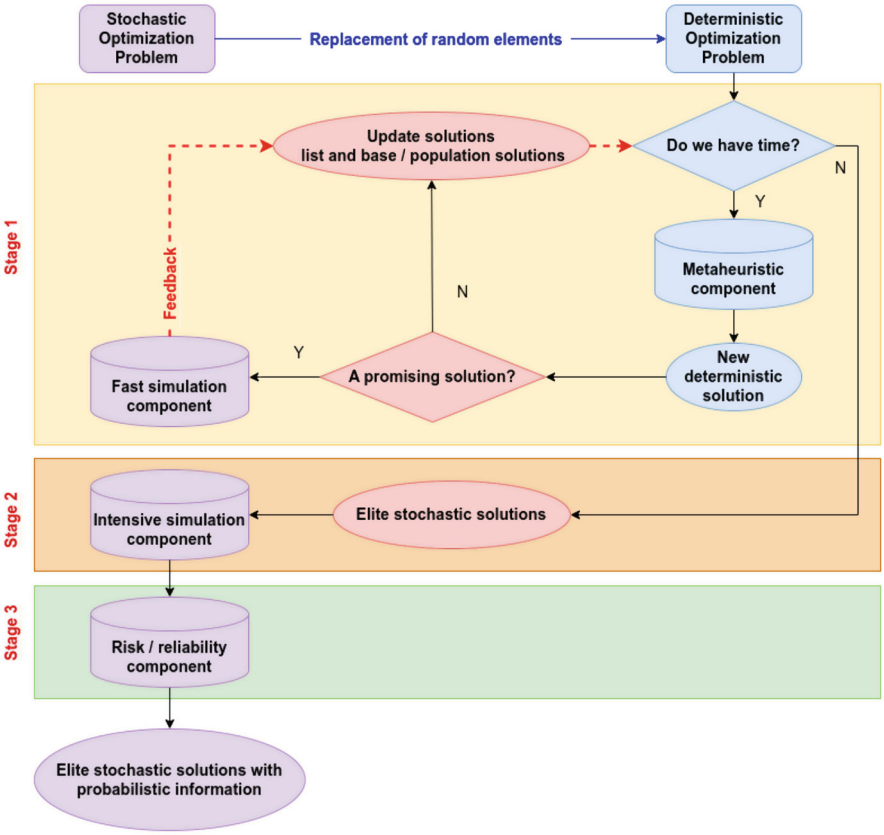

Fig. 4 The logic behind simheuristics

simplifying the problem by removing uncertainty. A metaheuristics is then applied to effectively explore the solution space, generating progressively better solutions for the deterministic problem. When the metaheuristics identifies a promising solution—one that is likely to perform well under uncertainty—it is evaluated through a simulation to determine its performance in the stochastic context. The simulation provides estimates of key statistics like the mean, variance, and percentiles, as well as probabilistic insights useful for risk or reliability analysis, along with data on various system variables. Given that simulations can be time-consuming, it is often advisable to limit the number of runs per evaluation to avoid slowing down the metaheuristics' convergence to near-optimal solutions. Suggestions for speeding up these computations are available in [70].

As explained in [13], the simulation feedback can also be employed to better guide the searching process carried out by the metaheuristics. This feedback can even be further processed by a machine learning component in order to better

identify promising solutions or to create a surrogate model of the simulation component that saves computational time. At the end of this first stage, a shortlist of elite solutions is generated. Each of these solutions is expected to perform well under uncertainty based on initial estimates. To improve the precision of these estimates, a more detailed simulation is run for each elite solution. Variance reduction techniques can be applied to speed up this process, with simulations potentially running in parallel on multiple processors. Finally, the results from these simulations can be used to conduct a risk or reliability analysis on the elite solutions, providing valuable probabilistic insights that enhance the decision-making process by detailing the stochastic behavior of each elite solution. This is one of the main strengths of simheuristics compared to other stochastic optimization techniques. Two additional key points should be noticed:

- As uncertainty increases, the correlation between deterministic and stochastic values is expected to weaken. In cases of high uncertainty (e.g., very large variances in random variables), it might be more effective to seek robust or reliable solutions rather than optimizing the expected value, as the latter could result in solutions with high variability.
- In optimization problems, the objective function's optimal value typically worsens as uncertainty increases, especially when the objective function is asymmetrical—where a favorable outcome from random variables does not offset the negative impact of an unfavorable outcome. If s^* is an optimal or near-optimal solution for the deterministic problem, and s^{**} is an optimal or near-optimal solution for the stochastic problem, the following inequalities should generally hold: *(i)* in a minimization problem, $determ(s^*) \leq stoch(s^{**}) \leq stoch(s^*)$; and *(ii)* in a maximization problem, $stoch(s^*) \leq stoch(s^{**}) \leq determ(s^*)$. In essence, the optimal or near-optimal solution of the deterministic version of a problem can be used to set lower and upper bounds for the near-optimal value of the stochastic problem.

Simheuristic Extensions

This section analyzes two emerging extensions of the simheuristic concept: fuzzy simheuristics and sim-learnheurisitics. As previously discussed, in many real-life applications, inputs may be subject to uncertainties, such as variations in travel times, customer demands, service times, or battery life for electric vehicles. When these inputs are modeled as random variables, simheuristic algorithms can be employed to tackle the resulting stochastic optimization problems. However, stochastic uncertainty is not the only type encountered in real-world problems. For non-probabilistic uncertainty, fuzzy techniques can be applied [12]. This type of uncertainty often arises from insufficient or scarce data, making it challenging to model with traditional probability distributions. It can also occur in scenarios requiring qualitative expert judgments. To tackle both types of uncertainty, [82] propose

a fuzzy simheuristic method, which integrates metaheuristics with simulation and fuzzy logic. This approach allows some inputs to be modeled as random variables while others follow fuzzy patterns. A fuzzy logic system computes outputs based on rules established by experts, accommodating scenarios where outputs have degrees of truth rather than binary values. Thus, for instance, [11] examine the permutation flow-shop problem incorporating both stochastic and fuzzy processing times. The primary objective is to minimize the expected makespan of job permutations while also considering additional solution characteristics due to uncertainty. The paper demonstrates how survival analysis can enhance the probabilistic information available to decision-makers. The study extends the simheuristic framework to accommodate fuzzy elements, integrating both stochastic and fuzzy uncertainties in the problem. Classical instances were modified to include either stochastic or fuzzy processing times for testing purposes.

Real-life applications frequently involve not just randomness but also dynamic elements that evolve over time or change according to some environmental conditions. For instance, travel times may vary with traffic conditions or weather, customer demands might shift based on environmental factors or the order in which each customer is delivered, processing times might vary according to the level of fatigue of the machine, and resource availability can fluctuate due to various real-time influences. In such cases, simheuristics alone may not suffice, because they are designed primarily to handle uncertainty rather than dynamic changes. To take into account these dynamic aspects, machine learning predictive models and in particular learnheuristics [9] can be highly beneficial. Learnheuristics combine machine learning models with metaheuristics in order to properly tackle optimization problem with dynamic inputs that need to be predicted as the environmental conditions vary. Integrating learnheuristics with simheuristics into what is called sim-learnheuristics can significantly enhance the capabilities of simheuristics to deal with dynamic elements. The machine learning component provides more accurate predictions of dynamic inputs, which are then used to inform the simheuristic algorithm. This combination allows for better anticipation of how these variables will evolve, leading to more robust and adaptive solutions. Peyman et al. [68] present a sim-learnheuristic approach tailored for the team orienteering problem, specifically applied to unmanned aerial vehicles. Unlike previous studies that focus on deterministic or stochastic versions of the problem, their method explores a more complex scenario that includes deterministic, stochastic, and dynamic elements. The approach becomes particularly intricate due to the uncertain travel times, which are influenced by dynamic factors like weather and traffic. For solving this problem, the authors propose a hybrid solution that combines a heuristic algorithm with Monte Carlo simulation and a multiple regression model. Similarly, [21] study a stochastic and dynamic variant of the capacitated dispersion problem. They propose a sim-learnheuristic algorithm that combines a biased-randomized metaheuristics for optimization, simulation to handle uncertainty, and machine learning to tackle dynamic behavior.

Recent Applications in Transportation

The following sections review journal articles on applications of simheuristics to different fields that have been published in 2020 or later. Previous articles, as well as conference articles, can be found in [13] and [10]. Transportation is one of the fields where simheuristics have been extensively employed. Panadero et al. [63] tackle the problem of routing unmanned aerial vehicles for surveillance, where the value of information varies across target locations, and not all locations need to be visited. The authors develop a simheuristic algorithm starting with a fast, original heuristic. This heuristic is then enhanced into a variable neighborhood search metaheuristics. Finally, simulation is integrated into the framework. Keenan et al. [43] tackle the stochastic time-capacitated arc routing problem, where the actual demand on each edge is a random variable, affecting service times as well. To solve this problem, the authors propose a strategic oscillation simheuristic algorithm. Latorre-Biel et al. [47] address a stochastic version of the vehicle routing problem, where customer demands are both uncertain and correlated. The authors propose a simheuristic approach combined with an adaptive demand predictor that employs Petri nets. Yazdani et al. [87] explore the challenges of managing construction and demolition waste. A hybrid genetic algorithm is used to optimize vehicle routing for transporting waste from construction sites to recycling facilities. The proposed method uses simulation to account for uncertainties in routing. Panadero et al. [61] explore both deterministic and stochastic versions of a team orienteering problem. The paper introduces a scenario where rewards depend on the order of visits, rewarding early customers and penalizing later ones, with travel times treated as random variables. Herrera et al. [36] explore a stochastic version of the team orienteering problem where random delays are considered. The goal is to find solutions that not only maximize the expected reward but also ensure high reliability, meaning there is a low probability of encountering delays beyond a specified threshold. Ramirez-Villamil et al. [74] focus on the two-echelon vehicle routing problem with stochastic travel times by proposing a simheuristic approach. Using real data from a French delivery company, their model also accounts for CO_2 and fine particle emissions. Ghorpade and Corlu [22] tackle the one-commodity pickup and delivery traveling salesman problem, which involves transporting a single type of good from supply locations to demand points while minimizing transportation costs. To address this, the paper introduces a new simheuristic algorithm, which combines a variable neighborhood descent metaheuristics with Monte Carlo simulation. Kızıloğlu and Sakallı [44] present a mathematical model that simultaneously optimizes flight planning, fleet assignment, and aircraft routing, while incorporating codesharing. While optimization software can handle smaller-scale problems effectively, it struggles with larger problems and multiple stochastic scenarios due to computational limitations. To address this, the study introduces two simheuristic algorithms. Rabet et al. [73] analyzes the integration of production, maintenance, and delivery operations within supply chains. Using a fertilizer producer case study with seasonal demand and outdated management practices,

the study proposes a mathematical model and two multi-objective simheuristics. Panadero et al. [64] discuss a team orienteering problem where travel times are uncertain and modeled as random variables, introducing reliability issues due to route-length constraints. The performance of their simheuristic is compared using the sample average approximation (SAA) method and a hybrid model that merges the simheuristic with SAA. Peyman et al. [68] present a new sim-learnheuristic method for solving the team orienteering problem. Their approach tackles a hybrid scenario incorporating deterministic, stochastic, and dynamic elements. Hence, travel times might be both uncertain and dynamically affected by factors like weather and traffic. Shone et al. [81] consider a runway scheduling problem where aircraft landings on a single runway are influenced by stochastic and dynamic factors. Due to the intractability of exact methods for this multistage optimization problem, the authors propose a simheuristic approach.

Recent Applications in Logistics

Similar to transportation, logistics is another natural application field for simheuristics. In effect, distribution of goods challenge logistics companies in urban areas, which defines problems related to last-mile delivery. Quite often, distribution problems are NP-hard and demand advanced optimization methods to be utilized. In real-life scenarios, problem parameters encounter uncertainty. Thus, various researchers have used simheuristics in solving such problems.

Gruler et al. [31] introduce a simheuristic approach for solving the multi-period inventory routing problem (IRP) with stochastic customer demands. The IRP involves both inventory management and delivery route planning, aiming to optimize refill policies for each customer over multiple periods to minimize the total expected costs, including both inventory and routing costs. Yazdani et al. [86] examine the challenge of evacuating populations in urban areas in response to extreme weather events, which are becoming more frequent and intense. The research proposes a hybrid simulation-optimization approach aimed at maximizing the number of evacuees transported from disaster zones to safe locations. Martins et al. [53] focus on the omnichannel delivery concept for the retailing industry, which addresses the replenishment of a set of retail stores and the direct shipment of the products to customers within an integrated vehicle routing formulation. Raba et al. [72] focus on optimizing a real-life supply chain for delivering animal feed to livestock farms. They consider a computer-aided system that manages orders, which can include various types of feed, from multiple depots using a fleet of diverse vehicles. The proposed method integrates biased-randomization techniques with a simheuristic framework, utilizing sensor data for optimization. Quintero-Araujo et al. [69] analyze the capacitated location routing problem with stochastic demands, where the exact demands are unknown until reaching each customer. The proposed iterated local search simheuristics aims to minimize the expected costs associated with facility operations, vehicle usage, routing, and corrective actions needed due to route failures from unexpected high demands. Martínez-Reyes et al. [54]

present a simheuristic approach to optimize the distribution of personal protective equipment (PPE) to intensive care units amid the COVID-19 pandemic. Examining the critical need for PPE, the approach uses the location-routing problem framework to consider uncertain demand, distribution costs, and solution reliability. de León et al. [16] addresses berth allocation at ports by proposing a proactive simulation-optimization approach using real-time data and a multi-objective method with a non-dominated sorting genetic algorithm. Rabe et al. [71] tackle the complexity of distribution in business-to-business materials trading, where decision-makers must balance conflicting goals like high service levels and low costs. It proposes two main strategies to enhance simheuristic processes. Firstly, it explores using reinforcement learning to reduce response times by learning from idle periods between decisions. Secondly, it incorporates domain-specific information to support metaheuristic algorithms, which helps in defining equivalent solutions and reducing the number of required simulation runs. Kabadayi and Dehghanimohammadabadi [42] explore the challenge of supplier selection in supply chain management by developing a decision support system (DSS) that integrates multi-criteria decision-making (MCDM) with simulation and optimization. The system includes an MCDM module to identify key criteria, a simulation model to assess supply chain performance with these criteria, and a multi-objective metaheuristic algorithm to optimize the criteria combinations for improved supply chain performance. Vieira et al. [84] study the challenge of sustainable supply chain network design by integrating risk management into the design process. It introduces a simulation-based decision support system applied to a Portuguese wine supply chain case study. Leon et al. [48] tackle the challenge of optimizing storage location assignments in warehouses, which is crucial for supply chain efficiency. Traditional methods often overlook the stochastic variability and interactions between warehouse activities. The study introduces a discrete-event simheuristic framework that integrates order sequence and picking routes to create robust solutions under real-life conditions. Gök et al. [23] present a novel simulation-optimization approach for scheduling aircraft turnarounds at airports, addressing the complexities and coordination challenges among various stakeholders such as airport operators, airlines, and ground service providers. The proposed method uses simheuristic techniques combined with an efficient search mechanism to enhance planning robustness. Bayliss and Panadero [7] examine the challenge of efficiently deploying temporary medical facilities during epidemic outbreaks, aiming to minimize costs, completion time, population travel time, and waiting time. It introduces a learnheuristic algorithm that integrates machine learning with a queuing model to evaluate facility location and population assignment decisions. The algorithm is trained on simulation data to rapidly assess facility performance and waiting times. Gomez et al. [27] focus on the capacitated dispersion problem with stochastic capacities, which aims to select facilities to maximize the minimum distance between any pair while meeting service levels under capacity uncertainties. The study introduces two models: one using probabilistic constraints to ensure service levels with a certain probability and the other incorporating soft constraints with penalty costs for capacity violations. A forward–backward simheuristic algorithm is proposed to solve these models

efficiently. Peidro et al. [66] introduce a simheuristic approach for solving the uncapacitated facility location problem with fluctuating service costs. The proposed method combines a tabu search metaheuristics with path-relinking and simulation techniques to consider random service costs. Ramirez-Villamil et al. [75] concentrate on a variant of the two-echelon capacitated vehicle routing problem used for urban logistics, focusing on a heterogeneous fleet with limited capacities and time windows. The study proposes a decomposition algorithm based on mixed integer linear programming for solving the deterministic version and a simheuristics for the stochastic version.

Recent Applications in Production

Similar to the applications of simheuristics in transportation and logistics, simheuristics has been utilized in solving problems related to production. Santos et al. [79] present a decision support system for optimizing the amount of active equipment in an ore crushing circuit to maximize production while accounting for variations in ore feed rate. The system uses a simheuristic approach, incorporating a simulated plant model to evaluate production rates. Lopes et al. [49] tackle the balancing optimization of mixed-model assembly lines under uncertainty, focusing on maximizing throughput in environments with stochastic product sequences and given workstation counts and buffers. The authors introduce a specialized cycle time simulator (CTS) and a novel simheuristic approach that employs CTS to evaluate cycle times and optimize line balancing. Gnanavelbabu et al. [26] investigate the flexible job shop scheduling problem with added complexities of worker flexibility and uncertain processing times. They introduce a simheuristic approach combining Monte Carlo simulation with a multi-objective modified backtracking search algorithm to minimize both the expected makespan and its standard deviation. The stochastic flexible job shop scheduling problem with uncertain operation processing times has been tackled by Caldeira and Gnanavelbabu [8]. The authors propose a simulation-optimization approach, and computational results demonstrate the algorithm's effectiveness across various levels of variability, with performance assessed using reliability-based methods. Villarinho et al. [85] discuss the permutation flow-shop problem with delivery dates and cumulative payoffs, where processing times are stochastic. The goal is to maximize the expected payoff by determining the optimal job sequence. A metaheuristic using a variable neighborhood descent framework is extended into a simheuristics by incorporating Monte Carlo simulation. Gonzalez-Neira et al. [29] present a hybrid simheuristic approach for solving a multicriteria stochastic permutation flow-shop problem with both stochastic processing times and sequence-dependent setup times. The proposed method integrates a greedy randomized adaptive search procedure, Monte Carlo simulation, Pareto archived evolution strategy, and analytic hierarchy process (AHP). The AHP is used to select the optimal sequence from the Pareto frontier that best aligns with decision-makers' objectives. Negri et al. [56] introduce a simheuristic framework designed for robust scheduling in the context of the

flow-shop scheduling problem, also utilizing digital technologies for real-time data analysis. The framework integrates genetic algorithms for schedule optimization with discrete event simulation, and it is enhanced by a digital twin that represents the production system to be scheduled, and it is equipped with an equipment prognostics and health management module that receives real-time data from the physical equipment and elaborates them to feed predictive information to the simulation model DT. Yazdani et al. [87] consider challenges in prefabricated construction, particularly focusing on on-time production of precast components under sequence-dependent due dates. They propose new scheduling methods to minimize total weighted earliness and tardiness. To manage uncertainties in production, the study introduces three simulation-optimization algorithms integrating simulation with metaheuristic frameworks. Castaneda et al. [11] tackle the permutation flow-shop problem under both stochastic and fuzzy uncertainties in processing times. The aim is to minimize the expected makespan while also considering additional solution characteristics due to uncertainty. To tackle this complex problem, the paper extends a simheuristic framework to incorporate both stochastic and fuzzy elements. Seiringer et al. [80] present a simheuristic approach designed to optimize material requirements planning parameters. The proposed method combines simulation annealing with an intelligent simulation budget management concept to efficiently minimize overall costs. This concept improves the efficiency by avoiding unnecessary replications of less promising iterations. Yu et al. [88] tackle the challenge of spare parts management by developing a joint optimization model for multi-item, multi-period inventory management and planned maintenance amid uncertain failures. They contrast independent and aggregate inventory policies and integrate predictive maintenance intervals to address uncertain failures. A novel two-stage genetic algorithm is introduced as a simheuristic approach to manage the model's nonlinearity, combinatorial complexity, and stochastic elements, suitable for large-scale instances. Meeß et al. [55] examine the challenge of designing product-service systems by proposing a simheuristic optimization approach to evaluate and select optimal business model configurations during the design phase. The study introduces a proprietary evolutionary algorithm integrated into a simheuristic framework for testing and evaluating different business models. Abu-Marrul et al. [1] focus on a parallel machine scheduling problem with non-anticipatory family setup times and batching, including stochastic processing times and release dates. They present an iterated greedy metaheuristics combined with Monte Carlo simulation to handle stochastic parameters. The study compares this simheuristic approach with a traditional iterated greedy metaheuristics. Grumbach et al. [32] introduce a simheuristic for solving dual resource constrained flexible job shop scheduling problems using a combination of memetic algorithms and deep reinforcement learning. Nessari et al. [58] present a hybrid algorithm for the flexible job shop scheduling problem, focusing on minimizing makespan and total weighted earliness and tardiness in the face of uncertainty. The algorithm integrates the equilibrium optimizer for initial solutions, the non-dominated sorting genetic algorithm for multi-objective optimization, and simulation techniques to handle stochastic variables. Ruiz-Rodríguez et al. [78] examine the effectiveness

of various maintenance scheduling techniques under different levels of uncertainty, such as unexpected machine failures and variable repair times. The study finds that a genetic algorithm simheuristic generally outperforms reinforcement learning and dispatching rules in total machine uptime, especially with high re-optimization frequencies. Zambrano-Rey et al. [89] tackle a stochastic job shop scheduling problem with sequence-dependent setup times, focusing on minimizing the expected maximum lateness. The stochastic elements are modeled through uncertain times between failures and times to repair. The proposed solution is a simheuristic based on tabu search. Rodríguez-Espinosa et al. [77] concentrate on a bi-objective flexible job shop scheduling problem with stochastic processing times. They aim to minimize both deterministic earliness plus tardiness and earliness plus tardiness risk, the latter focusing on robustness in uncertain environments. The proposed solution is a simheuristic combining the non-dominated sorting genetic algorithm with Monte Carlo simulation to generate the Pareto frontier for both objectives.

Recent Applications in Health Care

Recent applications of simheuristics can also be found in health care. Dehghanimohammadabadi and Kabadayi [17] introduce a combined simulation-optimization and multi-criteria decision-making approach to assess the impact of quality improvement initiatives in health care. It uses the analytic hierarchy process to determine the importance of various healthcare criteria from health providers. These weights are then used in a simulation-optimization framework to identify the most effective actions for enhancing quality of care. Datta et al. [15] aim to improve outpatient care delivery by proposing a multi-objective simulation-based decision support model that balances cost and patient dissatisfaction, with the latter addressing service fairness. The model, developed from field data, uses a queuing theory-based discrete event simulation and employs genetic algorithms for optimization. Pandhare et al. [65] introduce a prognostics and health management-enabled digital twin framework designed for robust production scheduling in flow-shop environments. This framework integrates genetic algorithm optimization with data-driven modeling techniques and discrete event simulation to address real-time equipment health. Dehghanimohammadabadi et al. [18] introduce the multi-objective patient appointment scheduling framework to enhance clinic operations and patient satisfaction. The framework integrates multi-objective particle swarm optimization, data exchange, and simulation. It aims to minimize total service time and maximize patient admissions without overtime. Hirpara et al. [37] studied on-scene injury assessment of trauma patients and their allocation to right hospitals by the emergency medical service providers. They utilized Monte Carlo simulation integrated in a genetic algorithm to solve multi-transportation capacitated facility location problem.

Recent Applications in Finance

Regarding recent applications of simheuristics in finance, [62] study the challenge of selecting the best portfolio of projects under limited financial resources, a problem that becomes NP-hard as constraints increase. The authors analyze a stochastic version of the project portfolio selection problem that considers uncertainties in cash flows and discount rates, aiming to maximize the expected net present value while adhering to risk constraints. Kizys et al. [45] explore the challenge of portfolio optimization, specifically minimizing risk for a given expected return, which becomes NP-hard as the number of assets and constraints increase. Traditional metaheuristics often fail to account for the uncertainty in financial markets, such as random returns and noisy covariances. To address this, the authors propose a simheuristic algorithm that combines a variable neighborhood search metaheuristics with Monte Carlo simulation to handle stochastic returns and noisy covariances. Nieto et al. [59] tackle the challenge of efficiently managing assets to cover a firm's liabilities over multiple periods, a task that is particularly complex under uncertainty. The authors propose a simheuristic approach that combines Monte Carlo simulation with a genetic algorithm to maximize expected terminal wealth. This approach is designed to produce effective solutions quickly and includes "smoothing" techniques to make the solutions more practical for real-world application.

Other Recent Applications

Finally, recent applications to other fields are reviewed in this section. Antoniadis et al. [5] focus on enhancing the self-healing capabilities of smart grids by addressing disturbances, such as potential overloads, and ensuring stability for a future planning horizon. The authors propose a simulation-based approach for evaluating the robustness of grid topology reconfigurations after disturbances. Lai et al. [46] explore the application of simheuristics to optimize the operating rule curve of the Klang Gate Dam (Malaysia) in response to future climate change impacts. The research involves selecting a set of general circulation models based on location and data availability, which is then downscaled and analyzed using artificial neural networks and support vector regression. Alvarez Fernandez et al. [2] examine the optimization of a hub-and-spoke telecommunication network where numerous nodes exchange real-time multimedia data, including audio, video, and images. In this scenario, the amount of data exchanged between nodes is modeled as a random variable. The objective is to identify the optimal locations for a fixed number of hubs to minimize the total expected transmission cost, considering the uncapacitated single-allocation p-hub median problem under uncertainty.

Overview of Computational Results

This section provides an overview of previously published results in the literature. These studies have been selected to demonstrate the efficiency of simheuristics in addressing well-known NP-hard and large-scale stochastic optimization problems across different fields of application. Table 1 summarizes the average results obtained for the selected optimization problems. Eleven different problems were chosen to represent a broad spectrum of real-life optimization problems. The first column lists the references from which the results were sourced, while the second column describes the specific type of problem addressed. The subsequent column

Table 1 Summary of different stochastic optimization problems

specifies whether the objective function involves maximization or minimization. The following three columns present the results achieved under various scenarios. The OBD column displays the best solution found without accounting for stochasticity, representing the objective function value in a deterministic scenario, which serves as a lower bound reference in a perfect information scenario. The next column, OBD-S, indicates the expected cost associated with the OBD solution when it is assessed in a stochastic scenario, incorporating the associated level of uncertainty—a simulation is used to estimate the expected cost of the OBD solution under a stochastic scenario. Finally, the OBS column shows the expected cost achieved using a simheuristic approach for the stochastic version of the problem.

Figure 5 presents a graphical representation of the results from Table 1, where the vertical axis shows the percentage gap between OBD-S and OBS with respect to OBD (baseline at 0% gap). The results show that, for all the problems considered, the solutions provided by the simheuristic approach (OBS) outperform those of the deterministic version when the latter is applied under uncertainty conditions (OBD-S). This indicates that optimal or near-optimal solutions for deterministic versions of optimization problems will typically become suboptimal solutions when applied in stochastic scenarios. For instance, the solutions obtained for the arc routing problem with stochastic demands (ARPSD) perform near-optimally under deterministic conditions but become suboptimal in stochastic scenarios, exhibiting a large gap with respect to the OBS provided by the simheuristic. In this case,

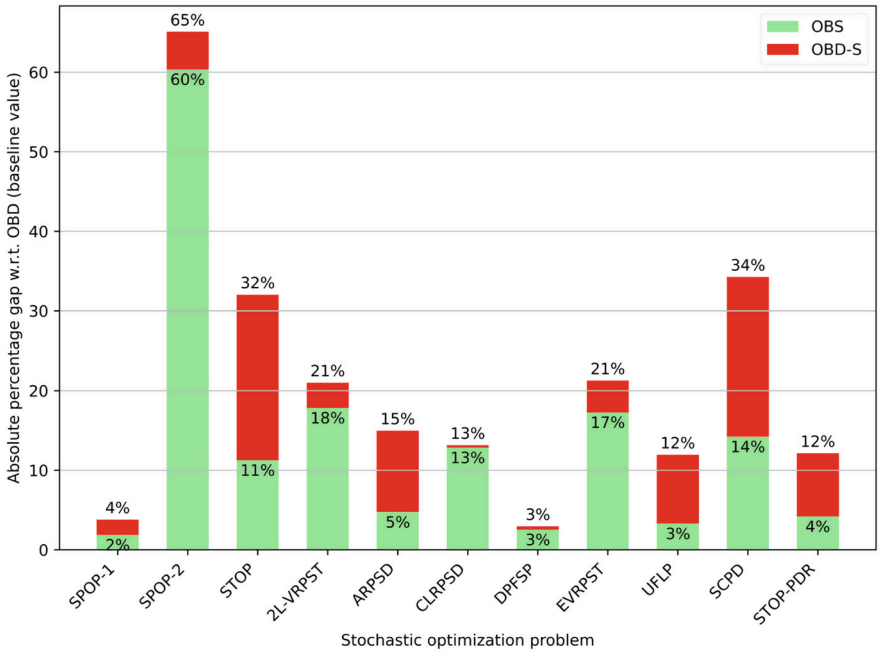

Fig. 5 Gaps of OBD-S and OBS solutions with respect to OBD solution (baseline at 0% gap)

Table 2 Summary of different optimization problems with fuzzy and dynamic components

Publication	Problem	Type of problem	Framework	OBD	OBD-H	OBH
Martin et al. [52]	Time Capacitated Arc Routing Problem (TCARP)	Min.	Fuzzy Sim.	144.80	176.00	169.70
Castaneda et al. [11]	Permutation Flow Shop Problem (PFSP)	Min.	Fuzzy Sim.	6317.67	7400.07	7325.24
Peyman et al. [68]	Team Orienteering Problem (TOP)	Max.	Learn Sim.	352.47	209.73	233.10
Ghorbani et al. [21]	Capacited Dispersion Problem (CDP)	MaxMin.	Learn Sim.	71.50	31.90	61.70

using the OBD-S solution could lead to inefficient decisions, resulting in additional costs. This gap can increase depending on the level of uncertainty in the problem's components, as observed in the SCPD problem, where the gap between the OBS and the OBD-S is quite large due to the high level of uncertainty. Conversely, when the level of uncertainty is low and has less influence on the elements of the problem, the OBD-S solution can still be competitive, providing results close to those of the OBS and even to those of the OBD. An example is the distributed parallel flow-shop problem (DPFSP), where, although the OBS solution outperforms the OBD-S, they are both quite close to the OBD.

Table 2 reports the obtained results for a set of problems solved using extensions of simheuristics, either fuzzy or sim-learnheuristics. Specifically, the first two problems were solved using fuzzy simheuristics to allow for different types of uncertainty (stochastic and fuzzy), while the others were solved using a sim-learnheuristics to handle both stochastic and dynamic elements. Similar to the previous table, this table shows the OBD, the OBD-H value (which indicates the expected cost when the best deterministic solution is assessed in a scenario with different types of uncertainty or dynamics), and the OBH, which indicates the expected cost using a fuzzy or sim-learnheuristic. The gap between the OBD-H and the OBS is depicted in Fig 6. As with the previous simheuristic results, the simheuristic approach outperforms the deterministic solution when applied in dynamic and uncertain scenarios for all tested problems.

Some Open Challenges

Despite being a relatively new approach, simheuristic algorithms have been successfully applied across a variety of fields. Methodologically, numerous research lines remain open that could enhance the efficiency and applicability of these algorithms. For instance, there is no universally accepted method or guidelines for

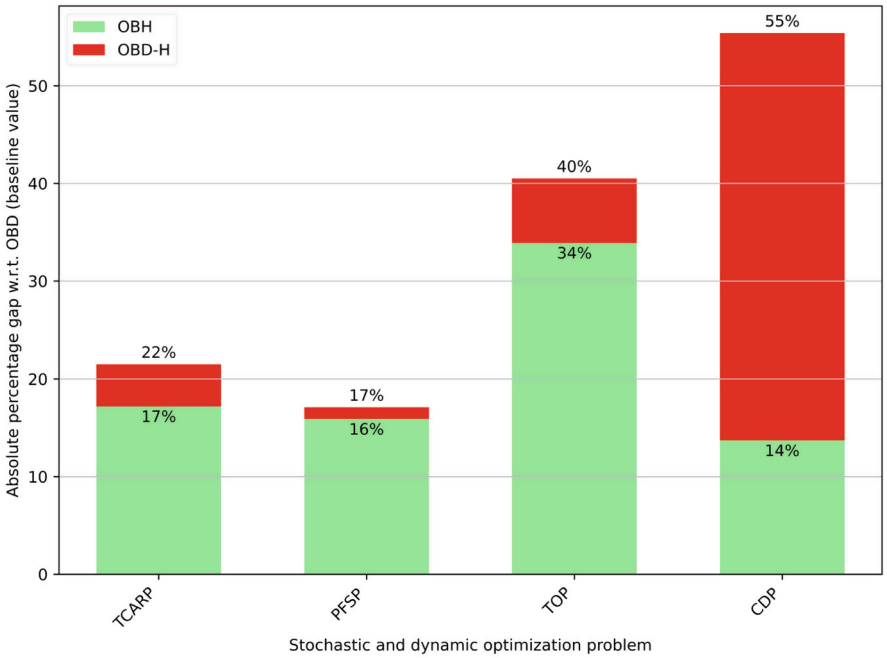

Fig. 6 Gaps of OBD-H and OBH solutions with respect to OBD solution (baseline at 0% gap)

determining the number of simulation executions to use. This decision involves balancing computing time and estimate accuracy. However, techniques like variance reduction can decrease the number of runs required without sacrificing accuracy. The use of parallelization techniques, distributed computing, and high-performance computing to speed up computations is also a promising field to explore in more detail. Another crucial aspect that has not been thoroughly studied is the criteria for labeling a solution as "promising" and thus warranting assessment by the simulation component. The proportion of such solutions depends on available computing time and the time needed to evaluate each solution. A preliminary exploratory study could help estimate the correlation between deterministic and stochastic measures, aiding in setting this proportion.

Integrating machine learning techniques into metaheuristics offers a natural solution for problems with dynamic inputs [9]. Thus, combining simheuristics and machine learning into what we called sim-learnheuristics is a promising approach to handle the increasing stochasticity and dynamism of real-world problems. Furthermore, machine learning techniques can enhance the efficiency of simheuristic algorithms, for example, by determining the number of scenarios or adaptively choosing when to send a solution to the simulation component based on learning from previously visited solutions. Even more, machine learning predictive models can constitute surrogate models for the simulation process, thus saving computational time.

Conclusions

This chapter has emphasized the advantages of combining simulation with metaheuristics to consider real-life optimization problems under uncertain conditions. Pure simulation models, while effective in modeling randomness, fall short in optimizing complex systems on their own. Similarly, deterministic optimization methods fall short in incorporating random inputs and probabilistic constraints commonly encountered in real-world decision-making. As systems in sectors like transportation, production logistics, supply chain management, telecommunication networks, energy, and finance grow more complex and large scale, using simheuristics and similar simulation-optimization methods becomes essential for accounting for uncertainty.

There are multiple ways to integrate simulation into a metaheuristic framework. This chapter has highlighted some best practices, both methodological and computational, that have proven useful in avoiding common pitfalls. Recommendations include allocating a balanced amount of computing time to the simulation component, using simulation results to better guide the metaheuristic search, and making more informed decisions on candidate solutions by conducting risk analyses using various statistics. Current challenges and open research areas were also identified, particularly *(i)* the fuzzy simheuristic extension, which can consider fuzzy uncertainty together with stochastic uncertainty; and *(ii)* the promising combination of simheuristics with learnheuristics for tackling optimization problems that involve both stochastic and dynamic elements, where the ability to adapt to changes and uncertainties in real time can significantly improve outcomes.

Abstract

In this chapter, we describe the Construct, Merge, Solve & Adapt (CMSA) algorithm, a metaheuristic framework designed to address hard combinatorial optimization problems. CMSA combines the probabilistic construction of solutions within an adaptive, iterative process with solution merging and exact optimization techniques. The algorithm probabilistically constructs solutions through heuristic methods, which are then merged into a reduced subproblem. This subproblem is solved using exact optimization approaches, mostly integer programming. Based on the feedback from this solving phase, the algorithm adapts its construction and merging strategies in subsequent iterations,

progressively finding solutions of improving quality over time. CMSA's hybrid nature allows it to balance between the speed of heuristic construction and the accuracy of exact methods, making it particularly effective for large-scale problems. After a general description of standard CMSA, we outline a recent self-adaptive variant and a variant that uses reinforcement learning to improve the search process. All three algorithm variants are applied to the classical maximum independent set problem. Moreover, an experimental evaluation is provided to show their comparative behavior.

Keywords

Hybrid metaheuristic · Combinatorial optimization · Maximum independent set

Introduction

The "Construct, Merge, Solve & Adapt" (CMSA) algorithm [9, 15] is a metaheuristic framework designed to tackle combinatorial optimization problems, especially aiming for problem instances that are hard to solve exactly. It combines constructive heuristics, solution merging, and problem-solving techniques in an iterative process, adapting the search process based on the feedback from previous iterations. Each algorithm iteration consists of the following four steps, also shown in the general CMSA framework depicted in Fig 1. In the first step, solutions are constructed probabilistically using a heuristic approach. These solutions do not necessarily need to be of high quality. Instead, their components are expected to serve as building blocks of high-quality solutions. The heuristic approach may involve greedy algorithms, randomized methods, or other simple techniques that generate solutions quickly. After constructing solutions, the algorithm proceeds to merge

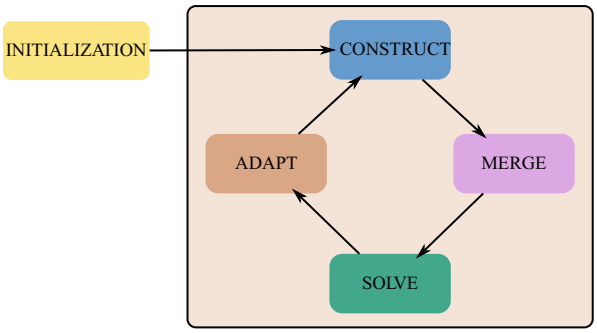

Fig. 1 General framework of CMSA

their components to generate a smaller subproblem, that is, a sub-instance of the original problem instance. In other words, the algorithm employs a bottom-up way of generating a sub-instance by merging components originating from different solutions. The incumbent sub-instance is solved in the third step using an appropriate solver. If the combinatorial optimization problem under consideration can be expressed as an integer linear program (ILP), for example, any ILP solver may be used for this purpose. The principal idea is that the sub-instance is more manageable, making it possible to solve it much more quickly than the original problem instance. Finally, the sub-instance is adapted based on the solution to the incumbent sub-instance returned by the solver. CMSA repeats this cycle, iterating between constructing, merging, solving, and adapting, progressively improving the quality of the obtained solutions. Over time, it generally converges toward a high-quality or near-optimal solution.

The key features of CMSA are as follows. First, as a hybrid approach, it combines the strengths of constructive heuristics (speed) and exact methods (precision). CMSA is particularly suited for large-scale, complex combinatorial optimization problems where exact methods may be too slow or even inviable. It can also be seen as a methodology for using exact techniques in the context of problem instances that are too large for their standalone application.

CMSA Variants

The first and original CMSA variant [15] works as follows. First, the complete set of solution components (C) must be defined. For example, when considering the traveling salesman problem (TSP), each edge between a pair of cities may be considered a solution component. For a second example, consider the one-dimensional bin packing problem where, intuitively, each item to be packed is a solution component. For providing a problem-independent description of CMSA, we henceforth consider a generic set $C = \{c_1, \ldots, c_n\}$ of solution components. We assume that any valid solution $S \in \mathcal{S}$, where $\mathcal{S}$ is the set of all feasible solutions, can be expressed as a subset of C, that is, $S \subseteq C$. Finally, let $f : \mathcal{S} \mapsto \mathbb{N}^+$ denote the objective function we aim to minimize.

Algorithm 1 contains the pseudo-code for this first and original CMSA variant. It begins by initializing the sub-instance (C') to the empty set. Moreover, the age values of the solution components are set to zero. The best-so-far solution S^{bsf} remains uninitialized. Each iteration of CMSA consists of the following four actions.

1. The first step of each iteration consists in the probabilistic construction of n_{a} (generally valid) solutions to the given problem. This is done by calling n_{a} times function ConstructSolutionProbabilistically(C, d_{rate}) in line 6 of Algorithm 1. Note that this action is problem-dependent. A randomized greedy heuristic, whose degree of randomness is determined by parameter d_{rate}, is typically employed for solution construction tailored to the considered optimization problem.

Algorithm 1: Standard CMSA

1: **input 1:** Complete set of solution components (C)
2: **input 2:** Values for n_a, d_{rate}, age_{max}, t_{SOLVER}
3: **initialization:** $C' := \emptyset$, $age[c] := 0\ \forall c \in C$, S^{bsf} is not initialized
4: **while** CPU time limit not reached **do**
5: **for** $i := 1, \ldots, n_a$ **do**
6: $S :=$ ConstructSolutionProbabilistically(C, d_{rate})
7: **if** S^{bsf} not initialized **or** $f(S) < f(S^{bsf})$ **then** $S^{bsf} := S$ **endif**
8: **for** all $c \in S$ **and** $c \notin C'$ **do**
9: $age[c] := 0$
10: $C' := C' \cup \{c\}$
11: **end for**
12: **end for**
13: $S^{SOLVER} :=$ SolveSubinstance(C', t_{SOLVER})
14: **if** $f(S^{SOLVER}) < f(S^{bsf})$ **then** $S^{bsf} := S^{SOLVER}$ **end if**
15: AdaptSubinstance(C', S^{SOLVER}, age_{max})
16: **end while**
17: **output:** S^{bsf}

2. Next, the solution components found in these n_a solutions are added to the incumbent sub-instance C'. Their age value is set to zero if they are not already present in C'. This is shown in lines 8–11 of Algorithm 1.
3. Third, an appropriate solver is applied to the updated sub-instance C' in function SolveSubinstance(C', t_{SOLVER}) (see line 13) to derive the best solution possible within the given time limit of t_{SOLVER} CPU seconds. There are no limitations concerning the nature of this solver. It may be a problem-specific exact or heuristic solver, or it may be, for example, an ILP solver. Note that the feasible search space of C' consists of those solutions to the original (complete) problem instance that only contains components present in C'. Henceforth, the solution returned by the employed solver is called S^{SOLVER}.
4. Finally, the incumbent sub-instance C' is adapted on the basis of solution S^{SOLVER} in function Adapt(C', S^{SOLVER}, age_{max}) at line 15. This is a problem-independent step that works as follows. After incrementing the age values of all solution components in $C' \setminus S^{SOLVER}$ by one, the age values of all components present in S^{SOLVER} are set to zero. In addition, to alleviate the work of the solver, all those solution components in C' whose age value has reached the user-determined upper limit of age_{max} are removed from C'. In this context, note that the age value of a solution component, at any given time, indicates the number of consecutive CMSA iterations in which this component has been part of the sub-instance but has not been included in the solver's solution to that sub-instance.

Note that CMSA is iterated until a predefined CPU time limit is reached. Upon termination, the algorithm returns the best-so-far solution S^{bsf} as output. The generic CMSA parameters include the number of solutions generated per iteration (n_a), the maximum allowable age of solution components (age_{max}), and the time limit for the

utilized solver at each iteration (t_{SOLVER}). However, additional parameters related, for example, to the sub-instance solver may be used.

Self-Adaptive CMSA

The standard CMSA algorithm was shown to be a well-working algorithm across various combinatorial optimization problems; however, certain applications have revealed its sensitivity to parameter settings. To address this issue, a self-adaptive variant of CMSA, named Adapt-CMSA, was proposed in [2]. A key feature of Adapt-CMSA is that it does not require intensive parameter tuning across subsets of the problem instances considered.

Adapt-CMSA (see Algorithm 2) differs from the standard CMSA primarily in how it manages the size of the sub-instance. In the standard CMSA, sub-instance size is controlled using age values in combination with a maximum age limit for solution components. In contrast, Adapt-CMSA does not rely on age values. Instead, after each iteration, all solution components, except those that are part of the best-so-far solution S^{bsf}, are removed from the sub-instance C' (see line 23).

Algorithm 2: Self-adaptive CMSA (Adapt-CMSA)

1: **input 1:** Complete set of solution components (C)
2: **input 2:** Values for Adapt-CMSA parameters t_{prop}, t_{SOLVER}
3: **input 3:** Values for solution construction parameters α^{LB}, α^{UB}, α_{red}
4: **initialization:** $n_{\text{a}} := 1$; $\alpha_{\text{bsf}} := \alpha^{\text{UB}}$; $C' := S^{\text{bsf}}$
5: $S^{\text{bsf}} :=$ GenerateGreedySolution(C)
6: **while** CPU time limit not reached **do**
7: **for** $i := 1, \ldots, n_{\text{a}}$ **do**
8: $S :=$ ConstructSolutionProbabilistically(C, S^{bsf}, α_{bsf})
9: $C' := C' \cup S$
10: **end for**
11: $(S^{\text{SOLVER}}, t_{\text{req}}) :=$ SolveSubinstance(C', t_{SOLVER}) ▷ This function returns two objects: (1) the obtained solution (S^{SOLVER}), (2) the required computation time (t_{req})
12: **if** $t_{\text{req}} < t_{\text{prop}} \cdot t_{\text{SOLVER}}$ and $\alpha_{\text{bsf}} > \alpha^{\text{LB}}$ **then** $\alpha_{\text{bsf}} := \alpha_{\text{bsf}} - \alpha_{\text{red}}$ **end if**
13: **if** $f(S^{\text{SOLVER}}) < f(S^{\text{bsf}})$ **then**
14: $S^{\text{bsf}} := S^{\text{SOLVER}}$
15: $n_{\text{a}} := 1$
16: **else**
17: **if** $f(S^{\text{SOLVER}}) > f(S^{\text{bsf}})$ **then**
18: **if** $n_a = 1$ **then** $\alpha_{\text{bsf}} := \min\{\alpha_{\text{bsf}} + \frac{\alpha_{\text{red}}}{10}, \alpha^{\text{UB}}\}$ **else** $n_a = 1$ **end if**
19: **else**
20: $n_{\text{a}} := n_{\text{a}} + 1$
21: **end if**
22: **end if**
23: $C' := S^{\text{bsf}}$ ▷ Only the solution components of S^{bsf} remain in C'
24: **end while**
25: **output:** S^{bsf}

Sub-instance size in Adapt-CMSA is partially controlled during the probabilistic construction of solutions at each iteration (see function ConstructSolutionProbabilistically(C, S^{bsf}, α_{bsf}) in line 8). This function receives as input not only the set of all possible solution components (C) but also the current best-so-far solution S^{bsf} and a parameter α_{bsf} (where $0 \leq \alpha_{\text{bsf}} < 1$). The parameter α_{bsf} influences the construction of new solutions by biasing them toward the best-so-far solution S^{bsf}; specifically, higher values of α_{bsf} lead to greater similarity between the generated solutions and S^{bsf}.

The self-adaptive nature of Adapt-CMSA is shown in the dynamic adjustment of α_{bsf} over time and depending on the search progress. In particular, the value of α_{bsf} can move between a lower bound α^{LB} and an upper bound α^{UB}, both algorithm parameters. At the beginning of the algorithm, α_{bsf} is initialized to its maximum α^{UB} (see line 4). In other words, at the start of the algorithm, the generated solutions will be most similar to the best-so-far solution S^{bsf}. If the incumbent sub-instance is solved within a computation time t_{req} that is less than a fraction t_{prop} of the maximum allowed computation time t_{SOLVER}, α_{bsf} is reduced by α_{red} (see line 12), where α_{red} is another algorithm parameter. The reasoning behind this adjustment is as follows: When the current sub-instance is solved easily, it suggests a relatively small search space. To expand the search space, the solutions generated in ConstructSolutionProbabilistically(C, S^{bsf}, α_{bsf}) should be more diverse relative to S^{bsf}. This is accomplished by reducing the α_{bsf} value.

Apart from α_{bsf}, the number of solution constructions per iteration (n_a) is also self-adaptive; see lines 13–22. At the start of Adapt-CMSA, n_a is set to 1 (see line 4). If the solution to the sub-instance provided by the solver (S^{SOLVER}) improves over the best-so-far solution S^{bsf}, n_a is reset to one (see line 15). Conversely, if S^{SOLVER} is strictly inferior to S^{bsf}, the corresponding sub-instance was too large (resp., difficult) for the solver to be solved within t_{SOLVER} seconds. If this case coincides with a setting of $n_a = 1$, the α_{bsf} value is marginally increased (by $\frac{\alpha_{\text{red}}}{10}$); otherwise, n_a is reset to one. In the event that $f(S^{\text{SOLVER}}) = f(S^{\text{bsf}})$, n_a is incremented by one (see line 20). This is done because solving the sub-instance failed to produce a solution better than S^{bsf}, even though the sub-instance was still solved to optimality within the allowed computation time of t_{SOLVER} seconds, suggesting that the size of the sub-instance should be increased.

CMSA Extended with Reinforcement Learning

Another potential limitation of standard CMSA is that the probabilistic construction of solutions in each iteration relies on a static, unchanging probability distribution. In other words, the probability of generating any particular valid solution remains constant throughout the algorithm's execution. In principle, this can be changed by adding a learning component to the solution construction phase. The first ones to do so were the authors of [28]. They intertwined CMSA iterations with the running of a population-based metaheuristic. At each iteration of their Learn-CMSA approach, the sub-instance of Learn-CMSA receives input from the incumbent population of

the metaheuristics and vice versa. A somewhat more straightforward approach was recently presented in [29], where the authors present a CMSA variant in which the construction of solutions is based on a simple reinforcement learning (RL) mechanism, with rewards determined on the basis of the solution returned by the solver at each iteration. This CMSA variant is called RL-CMSA and is presented in Algorithm 3.

RL-CMSA maintains a set $Q = \{q_1, \ldots, q_n\}$ of quality values which contains a q_i for each solution component $c_i \in C$. One of the main characteristics of RL-CMSA is that solutions are constructed by sampling solution components depending on these values. At the start of the algorithm, all $q_i \in Q$ are initialized to zero. Moreover, these values change during the algorithm due to cumulating rewards received after the adapt step depending on the solution S^{SOLVER} produced by the solver. In particular, those solution components from C' that form part of S^{SOLVER} receive a reward of one, while those from C' that the solver did not select receive a reward of minus one. In this way, the solver acts as a feedback mechanism for the solution construction process, and the values in Q keep track of the "quality" of the different solution components. The process of determining the rewards and adding them to the quality values is done in UpdateQ(q, C', S^{SOLVER}); see line 17.

Solutions are constructed in function ConstructSolutionProbabilistically(C, q, d_{rate}, β) in line 7 exclusively based on the quality values; that is, no heuristic information is used to bias this solution construction. The use of parameters d_{rate} and β will be outlined later. The only problem-dependent part is to be found

Algorithm 3: Reinforcement learning CMSA (RL-CMSA)

1: **input 1:** Complete set of solution components (C)
2: **input 2:** Values for RL-CMSA parameters n_{a}, $age_{\max}$, t_{SOLVER}, cf_{limit}, b_{reset}
3: **input 3:** Values for solution construction parameters d_{rate}, β
4: **initialization:** $C' := \emptyset$, $age[c] := 0$ and $q[c] := 0$ $\forall c \in C$, S^{bsf} is not initialized
5: **while** CPU time limit not reached **do**
6: **for** $i := 1, \ldots, n_{\text{a}}$ **do**
7: $S :=$ ConstructSolutionProbabilistically(C, q, d_{rate}, β)
8: **if** S^{bsf} not initialized **or** $f(S) < f(S^{\text{bsf}})$ **then** $S^{\text{bsf}} := S$ **endif**
9: **for** all $c \in S$ **and** $c \notin C'$ **do**
10: $age[c] := 0$
11: $C' := C' \cup \{c\}$
12: **end for**
13: **end for**
14: $S^{\text{SOLVER}} :=$ SolveSubinstance(C', t_{SOLVER})
15: **if** $f(S^{\text{SOLVER}}) < f(S^{\text{bsf}})$ **then** $S^{\text{bsf}} := S^{\text{SOLVER}}$ **end if**
16: AdaptSubinstance(C', S^{SOLVER}, $age_{\max}$)

21: **if** $b_{\text{reset}} = true$ **then** $C' := \emptyset$ **end if**
22: **end if**
23: **end while**
24: **output:** S^{bsf}

in determining those solution components that can be selected at each solution construction step.

As the reader might notice, if some quality values become much larger than the rest, the solution construction procedure could lead to highly similar solutions being constructed repeatedly. To avoid this, RL-CMSA implements a reset mechanism. This consists of computing a value cf denoted as the convergence factor, which gives a measure of the level of convergence, as follows. For every solution component c_i of the last solution constructed S, the probability z_i of selecting c_i over all the solution components not forming part of S is calculated. The convergence factor is then defined as $cf = \min_{c_i \in S} z_i$. Once the convergence factor is calculated, the algorithm checks if it is larger than a parameter $cf_{\text{limit}} \in [0, 1]$ known as the convergence factor limit. If this is the case, the algorithm is re-initialized, which consists of setting all quality values back to zero and emptying the sub-instance C' depending on a Boolean parameter b_{reset} (see lines 19-22). This last option allows completely erasing the information learned so far (if $b_{\text{reset}} = true$) or keeping some otherwise, in the form of the sub-instance C'.

Timeline of CMSA Applications

Table 1 provides a timeline of all applications of different CMSA variants found in the related literature to date. The first table column contains the name of the considered combinatorial optimization problem; the second column references the corresponding publication; the third column indicates the year of publication; and the last column provides information about the utilized (or introduced) CMSA variant. For easier visual differentiation between CMSA variants, colored dots are used in the last column, with a gray dot signifying a CMSA approach that does not align with any established CMSA variant. Any such exceptions are explained in the table.

Application of CMSA to Maximum Independent Set

In the final part of this chapter, we demonstrate the application of the three CMSA variants described before (standard CMSA, Adapt-CMSA, and RL-CMSA) to the NP-hard maximum independent set (MIS) problem. The MIS problem is a well-known combinatorial optimization problem in graph theory, which can be described as follows. Given is an undirected graph $G = (V, E)$. The set $N(v_i) \subset V$ denotes the set of neighbors of v_i in graph G, that is, for each $v_j \in N(v_i)$, there exists an edge $e = (v_i, v_j) \in E$. Moreover, $N[v_i]$ is the so-called closed neighborhood of v_i in G defined as follows: $N[v_i] := N(v_i) \cup \{v_i\}$. A set $S \subset V$ is a feasible solution to the MIS problem if for any pair $v_i \neq v_j \in S$ the edge set E of graph G does not contain the edge $e = (v_i, v_j)$. In other words, S is a feasible solution if no two nodes from S are neighbors in G. The optimization goal is to find a feasible solution that is as large as possible.

Table 1 Applications of CMSA until October 2024 (in alphabetical order)

Optimization problem	Publications	Year (first)	CMSA variant
Minimum covering arborescence	[15]	2016	Standard CMSA
Minimum common string partition	[8, 13, 15]	2016	Standard CMSA
Multi-dimensional knapsack	[13, 14, 24]	2016	Standard CMSA
Repetition-free longest common subsequence	[10, 11]	2016	Standard CMSA
Binary optimization	[12]	2019	Problem specific
Project scheduling	[35]	2019	Standard CMSA with ACO for solution construction
Minimum capacitated dominating set	[27]	2019	Standard CMSA
Routing of air-ground robots	[6]	2019	Standard CMSA
Maximum happy vertices problem	[21, 23, 34]	2019	Standard CMSA
Score-constrained packing	[22]	2020	Standard CMSA
Maintenance of nuclear power plants	[18]	2021	Standard CMSA
Test data generation in software product lines	[20]	2021	Standard CMSA
Minimum positive influence dominating set	[2]	2022	Adapt-CMSA
Bus driver scheduling	[30]	2022	Standard CMSA
Electric vehicle routing with time windows, simultaneous pickup and deliveries, and partial vehicle charging	[1]	2022	Adapt-CMSA
Unit disk cover	[5]	2022	Standard CMSA
Closest string problem	[16]	2023	Standard CMSA
Two-echelon electric vehicle routing with simultaneous pickup and deliveries	[3]	2023	Adapt-CMSA
Maximum disjoint dominating set	[31, 32]	2023	Standard CMSA with multiple solution constructors
Multi-way multi-dimensional number partitioning	[17]	2023	Adapt-CMSA
Rooted max tree coverage	[37]	2023	Standard CMSA
Diversity and equity optimization	[26]	2024	Standard CMSA
Minimum dominating set and far from most string problems	[29]	2024	RL-CMSA
Electric vehicle routing with time windows and simultaneous pickups and deliveries	[4]	2024	Standard CMSA
Variable-sized bin packing	[4]	2024	Adapt-CMSA
Far from most string problem	[28]	2024	Learn-CMSA

A typical ILP model for the MIS problem uses a binary variable x_i for each node $v_i \in V$. The formulation of the model is as follows:

$$\max \quad \sum_{v_i \in V} x_i \tag{1}$$

$$\text{subject to} \quad x_i + x_j \leq 1 \qquad \forall\, e = (v_i, v_j) \in V \tag{2}$$

$$x_i \in \{0, 1\} \qquad \forall\, v_i \in V$$

Constraints (2) make sure that any solution contains at most one endpoint of an edge in E.

Definition of the Solution Components

A key step in designing any CMSA algorithm is defining the set of solution components (C). For the MIS problem, we adopt a straightforward approach: The set C includes a component c_i for each node $v_i \in V$ of the input graph $G = (V, E)$. Therefore, it is important to keep in mind that, throughout the following discussion, both v_i and c_i refer to the same node v_i of the input graph G.

Probabilistic Construction of MIS Solutions

The process for constructing a valid MIS solution in standard CMSA is described in Algorithm 4. It begins with an empty solution, $V_{\text{sol}} = \emptyset$. At each step of the construction, $\tilde{V} \subseteq V$ is defined as the set of nodes that do not have a single neighbor included in V_{sol}. Exactly one node is selected from $\tilde{V}$ at each step using the function ChooseFrom($\tilde{V}$, d_{rate}). As mentioned before, the value of d_{rate} determines the randomness of the solution construction process. The selection process for a node is outlined as follows.

Algorithm 4: Function ConstructSolutionProbabilistically(C, d_{rate}) of standard CMSA

1: **input:** a graph $G = (V, E)$
2: $V_{\text{sol}} := \emptyset$
3: $\tilde{V} := V \setminus \bigcup_{v_i \in V_{\text{sol}}} N[v_i]$
4: **while** $\tilde{V} \neq \emptyset$ **do**
5: $\quad v_j :=$ ChooseFrom($\tilde{V}$, d_{rate})
6: $\quad V_{\text{sol}} := V_{\text{sol}} \cup \{v_j\}$
7: $\quad \tilde{V} := V \setminus \bigcup_{v_i \in V_{\text{sol}}} N[v_i]$
8: **end while**
9: **output:** a CMSA-solution S, corresponding to solution V_{sol}

Function ChooseFrom($\tilde{V}, d_{\text{rate}}$): A node $v_j \in \tilde{V}$ is chosen according to the greedy function $\mu(v_j) := |N(v_j)|$, which evaluates the degree of v_j. In this selection process, nodes with lower degrees are preferred. To choose a node v_j from $\tilde{V}$, a random number r is drawn uniformly from [0, 1]. If $r \leq d_{\text{rate}}$, node $v_j \in \tilde{V}$ is chosen such that

$$v_j := \text{argmin}\{\mu(v_i) \mid v_i \in \tilde{V}\} \ . \tag{3}$$

Alternatively, when $r > d_{\text{rate}}$, a set of $\min\{l_{\text{size}}, |\tilde{V}|\}$ nodes from $\tilde{V}$ is selected and added to a candidate set $L \subseteq \tilde{V}$ such that

$$\mu(v_i) \leq \mu(v_k) \quad \text{for all } v_i \in L, v_k \in \tilde{V} \setminus L \ . \tag{4}$$

A vertex $v_j \in L$ is then selected uniformly at random. It is important to highlight that once the construction of a solution V_{sol} is complete, it is converted into a corresponding CMSA-solution S. This conversion entails replacing each node $v_i \in V_{\text{sol}}$ with its corresponding solution component c_i. The obtained CMSA-solution S is then returned by Algorithm 4.

In Adapt-CMSA, solutions are constructed according to the same principle. Function GenerateGreedySolution(C) of line 4 of Algorithm 2, for example, is obtained from Algorithm 4 described above by using a setting of $d_{\text{rate}} = 1.0$. In other words, this function generates a solution deterministically. Next, ConstructSolutionProbabilistically(C, S^{bsf}, α_{bsf}) in line 8 of Algorithm 2 executes the solution construction from Algorithm 4 with the following change in function ChooseFrom($\tilde{V}, d_{\text{rate}}$). For being able to select a node from $\tilde{V}$, a probability $\mathbf{p}(v_k)$ is calculated for all $v_k \in \tilde{V}$ in the following way. For this purpose, first, a value $h(v_k)$ is determined for each vertex $v_k \in \tilde{V}$:

$$h(v_k) := \begin{cases} \frac{\alpha_{\text{bsf}}}{\mu(v_k)} & \text{if } c_k \in S^{\text{bsf}} \\ \frac{(1-\alpha_{\text{bsf}})}{\mu(v_k)} & \text{otherwise} \end{cases} \tag{5}$$

Second, the probabilities are defined as follows:

$$\mathbf{p}(v_k) := \frac{h(v_k)}{\sum_{v_l \in \tilde{V}} h(v_l)} \quad \forall\, v_k \in \tilde{V} \tag{6}$$

Subsequently, a node v_j is selected from $\tilde{V}$ based on these probabilities. Recall that the bias toward the best-so-far solution S^{bsf} is controlled by the parameter $\alpha_{\text{bsf}} \in [0, 1]$, where a higher α_{bsf} value increases this bias. Notably, this bias does not exist in standard CMSA.

Finally, in RL-CMSA, solutions are also constructed as shown in Algorithm 4. However, the choice of a node at each construction step (as done by function ChooseFrom($\tilde{V}, d_{\text{rate}}$)) is performed solely based on the quality values in Q (see the

description of RL-CMSA), in the following way. First, with a probability d_{rate}, this selection is done randomly among those nodes (resp., solution components) from $\tilde{V}$ with the highest quality values; otherwise, this is done probabilistically based on the following probabilities p_i for each $v_i \in \tilde{V}$:

$$p_i = \frac{e^{\beta q_i}}{\sum_{v_k \in \tilde{V}} e^{\beta q_k}}. \tag{7}$$

Hereby, $d_{\text{rate}} \in [0, 1]$ and $\beta \geq 0$ are parameters of the solution construction procedure, which balance between the exploration and exploitation of solution components.

Sub-instance Solving

Sub-instances C' are solved in the same way in all three CMSA variants considered in this chapter. To do so, the MIS ILP model is extended by adding the following set of constraints:

$$x_i = 0 \quad \text{for all } c_i \in C \setminus C' \tag{8}$$

Thus, only solution components (or nodes) that are part of the sub-instance C' can be chosen to appear in solutions. Note that the corresponding functions for sub-instance solving in all three CMSA variants return the ILP solver solution in terms of a set S^{SOLVER} of solution components. Moreover, the application of the ILP solver is subject to a time limit of t_{SOLVER} CPU seconds, which means that the returned solution (S^{SOLVER}) is not necessarily an optimal solution to sub-instance C'.

Experimental Evaluation

The experimental evaluation presented in this section includes the following algorithms:

1. Greedy: A greedy heuristic derived by applying the heuristic from Algorithm 4 in a deterministic manner.
2. CPLEX: The application of CPLEX 22.1 to each problem instance using the default parameter settings of CPLEX.
3. CMSA: The application of standard CMSA
4. Adapt-CMSA: The application of the self-adaptive CMSA variant described before.
5. RL-CMSA: The application of the CMSA variant supported by reinforcement learning.

CPLEX 22.1 is executed sequentially (one thread) in standalone mode and within the CMSA variants. For conducting the experiments, we used the IIIA-CSIC in-house high-performance computing cluster of machines equipped with Intel® Xeon® 5670 CPUs having 12 cores of 2.933 GHz and at least 32 GB of RAM.

Benchmark Set

To ensure a controlled experimentation environment, we chose to create a benchmark set featuring graphs of different sizes and densities, utilizing the following three network models:

1. **The Erdös-Rényi model [19]**. Named after mathematicians Paul Erdös and Alfréd Rényi, this model is one of the earliest and simplest models for generating random graphs. Introduced in 1959, this model is defined by two parameters: the number of nodes (n) and the probability (p) that an edge exists between any pair of nodes.
2. **The Watts-Strogatz model [36]**. This model generates small-world networks, that is, networks that feature a small average shortest path length between vertices while maintaining a high degree of local clustering. This model was introduced by Duncan J. Watts and Steven Strogatz in 1998.
3. **The Barabási-Albert model [7]**. Developed by Albert-László Barabási and Réka Albert in 1999, the main characteristic of this preferential attachment model is its ability to produce networks with a scale-free degree distribution. In such networks, the degrees of nodes follow a power-law distribution, where a few nodes have a very high degree while most nodes have much lower degrees.

Thirty graphs were generated using each of the 3 models for each combination of $|V| \in \{500, 1000, 1500, 2000\}$ and 4 distinct graph densities. In Erdős-Rényi graphs, density is controlled by the edge probability (p), in Watts-Strogatz graphs by the parameter (k) and in Barabási-Albert graphs by the parameter (m). Altogether, this benchmark set includes 480 graphs for each network model. We used the `igraph` library's implementations of these graph models.

ILP Solver Parameters

In addition to the CMSA-specific parameters of the three CMSA variants that will be applied to the MIS problem in this chapter, the following parameters related to the utilized ILP solver are used. Note that these parameters are explained in the context of CPLEX version 22.1 which was used for the implementations.

1. $\text{ilp}_{\text{emphasis}} \in \{\texttt{true}, \texttt{false}\}$ is a Boolean parameter indicating whether or not to utilize "heuristic emphasis." Hereby, $\text{ilp}_{\text{emphasis}} = \texttt{false}$ denotes CPLEX's default setting, while $\text{ilp}_{\text{emphasis}} = \texttt{true}$ refers to setting the emphasis parameter to a value of five, indicating the highest heuristic emphasis level in which the solver strongly favors the improvement of its best solution found over bound calculations.

2. $\text{ilp}_{\text{warmstart}} \in \{\texttt{true}, \texttt{false}\}$ is another Boolean parameter indicating whether or not to provide the solver with the best-so-far solution S^{bsf} of CMSA at the start of each application. This is called a "warm start" in the context of CPLEX.
3. $\text{ilp}_{\text{abort}} \in \{\texttt{true}, \texttt{false}\}$ is a third Boolean parameter indicating whether or not to abort CPLEX whenever a solution is found that is better than the current best-so-far solution S^{bsf} of CMSA.

Note that all three CPLEX-related parameters are used in standard CMSA and in RL-CMSA. However, using $\text{ilp}_{\text{warmstart}}$ and $\text{ilp}_{\text{abort}}$ would not make sense in Adapt-CMSA, as in this CMSA variant, it is important to know if a sub-instance can be solved to optimality within the allotted computation time.

Parameter Tuning

All three CMSA variants underwent parameter tuning with the `irace` tool [25]. Specifically, each CMSA variant was tuned once for the complete benchmark set, with an `irace` budget of 3000 algorithm runs. Additional problem instances were created to serve as tuning instances. Specifically, for each combination of $|V|$ and graph density, exactly one tuning instance was generated by each of the 3 network models, resulting in a total of 24 tuning instances. The computation time limit was set to 150 CPU seconds for all graphs with $|V| = 500$, 300 CPU seconds for graphs with $|V| = 1000$, 450 CPU seconds for graphs with $|V| = 1500$, and 600 CPU seconds for graphs with $|V| = 2000$.

The tuning results of the three CMSA variants are shown in Table 2. An interesting observation in examining these parameter settings is that standard CMSA performs best with the lowest possible determinism rate ($d_{\text{rate}} = 0.0$)

Table 2 Parameters, domains, and tuning results. "n.a." is the abbreviation for "not applicable"

Parameter	Domain	CMSA	Adapt-CMSA	RL-CMSA
n_{a}	$\{1, \ldots, 50\}$	17	n.a.	15
age_{max}	$\{1, \ldots, 10\}$	1	n.a.	4
d_{rate}	$[0.0, 0.99]$	0.0	n.a.	0.43
l_{size}	$\{3, \ldots, 100\}$	81	n.a.	n.a.
t_{SOLVER}	$\{1, \ldots, 20\}$	9	20	20
$\text{ilp}_{\text{emphasis}}$	{`true`, `false`}	`false`	`false`	`true`
$\text{ilp}_{\text{warmstart}}$	{`true`, `false`}	`false`	n.a.	`false`
$\text{ilp}_{\text{abort}}$	{`true`, `false`}	`false`	n.a.	`true`
α^{LB}	$[0.6, 0.99]$	n.a.	0.98	n.a.
α^{UB}	$[0.6, 0.99]$	n.a.	0.99	n.a.
α_{red}	$[0.01, 0.1]$	n.a.	0.04	n.a.
t_{prop}	$[0.1, 0.8]$	n.a.	0.54	n.a.
β	$[0.0, 2.0]$	n.a.	n.a.	0.16
b_{reset}	{`true`, `false`}	n.a.	n.a.	`false`
cf_{limit}	$[0.9, 1.0]$	n.a.	n.a.	0.9

for probabilistic solution construction. This sharply contrasts with the settings $\alpha^{\text{LB}} = 0.98$ and $\alpha^{\text{UB}} = 0.99$ in Adapt-CMSA, which cause newly constructed solutions to be heavily biased toward the best-so-far solution S^{bsf}. In contrast to the requirements of CMSA and Adapt-CMSA, RL-CMSA works best with an intermediate setting of $d_{\text{rate}} = 0.43$ concerning the determinism in constructing solutions. Another interesting observation concerns the setting of the ILP solver parameters. Whereas CMSA and Adapt-CMSA do not utilize any of the CPLEX features (such as heuristic emphasis, warm starts, or early termination upon improvement), RL-CMSA appears to gain an advantage from applying heuristic emphasis and the abort feature.

Results

The five algorithmic techniques (Greedy, CPLEX, CMSA, Adapt-CMSA, and RL-CMSA) were applied once to each problem instance from the benchmark set. The computation time limit for CPLEX and the three CMSA variants were the same as that used for tuning (described earlier). The results are presented as box plots in Figs 2, 3 and 4. Note that each network model has exactly one graphic (Erdös-Rényi, Watts-Strogatz, and Barabási-Albert). Each graphic features a 4×4 grid of box plots, where the rows show results (from top to bottom) for graphs of increasing size, and the columns (from left to right) show results for graphs of increasing density.

To facilitate the analysis of the results concerning statistical significance, critical difference (CD) plots are provided separately for the graphs of each of the three network models in Figs 5, 6 and 7. In short, a CD plot displays the average ranking of several algorithms across a set of problem instances, with the whiskers of two algorithms connected by a bold horizontal bar if their results are statistically equivalent. Each CD plot figure consists of five graphics. The first graphic (at the top) presents statistical information for the entire set of graphs corresponding to the respective network model. The remaining four graphics display statistical information for all graphs of a specific density.

When studying the results, the following main observations can be made:

1. First of all, the three CMSA variants clearly outperform Greedy, which is—as expected—for all network models the worst-performing technique.
2. The three CMSA variants also outperform CPLEX with statistical significance. This is with the exception of rather sparse graphs and, in general, Barabási-Albert graphs where CPLEX performs rather strongly. In fact, CPLEX outperforms standard CMSA with statistical significance on Barabási-Albert graphs (see Fig 7a). Remember that these graphs are scale-free; that is, their node degrees follow a power-law distribution. This means that some hubs are strongly connected to other nodes, while many others have only very few connections.
3. When comparing the three CMSA variants, it is clear that RL-CMSA is the best-performing approach across the graphs of all three network models (different sizes and densities). As shown by the CD plots in Figs 5, 6 and 7, there is only one subset of graphs (the densest Erdös-Rényi graphs) for which RL-CMSA is not the

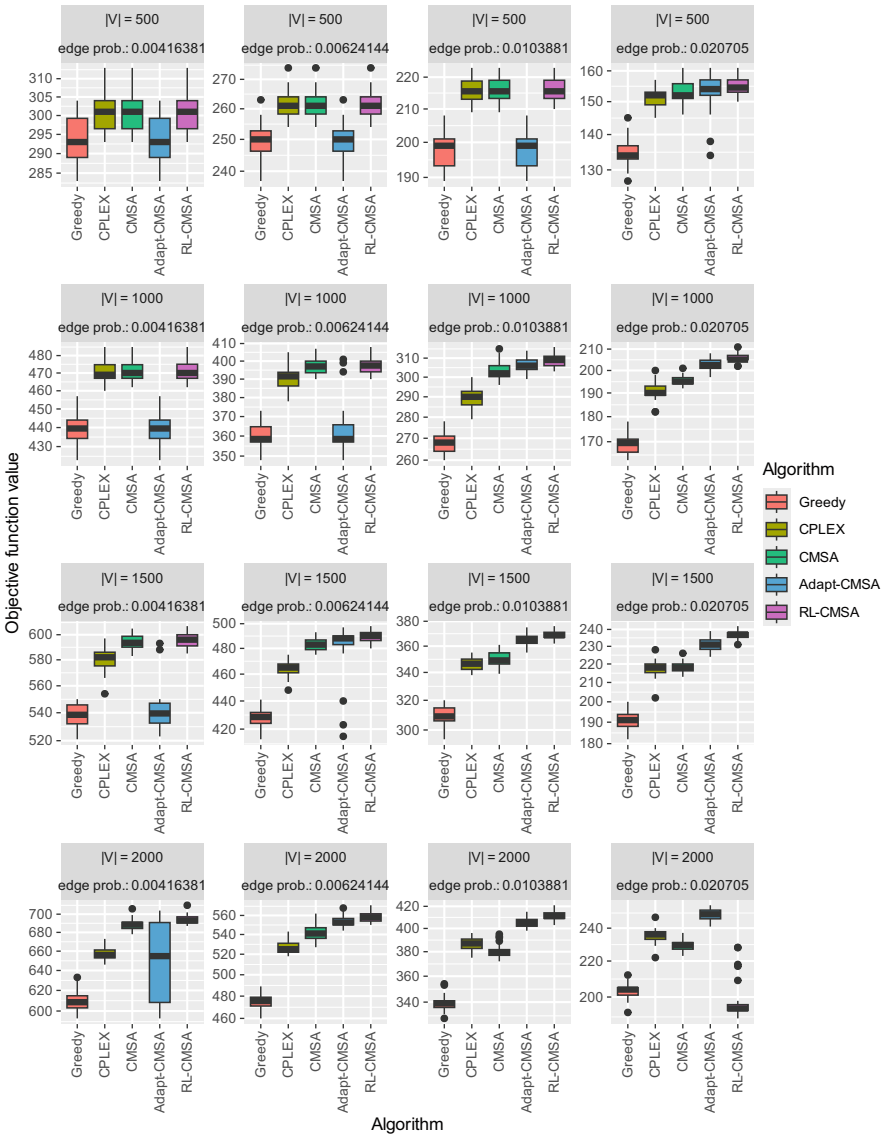

Fig. 2 Results for Erdös-Rényi graphs

best-performing method. This is because, for some reason, RL-CMSA does not work well for the largest and densest Erdös-Rényi graphs (see the bottom-right box plot in Fig 2.

4. Another interesting aspect is that Adapt-CMSA outperforms standard CMSA in the context of Watts-Strogatz and Barabási-Albert graphs. This is with statistical

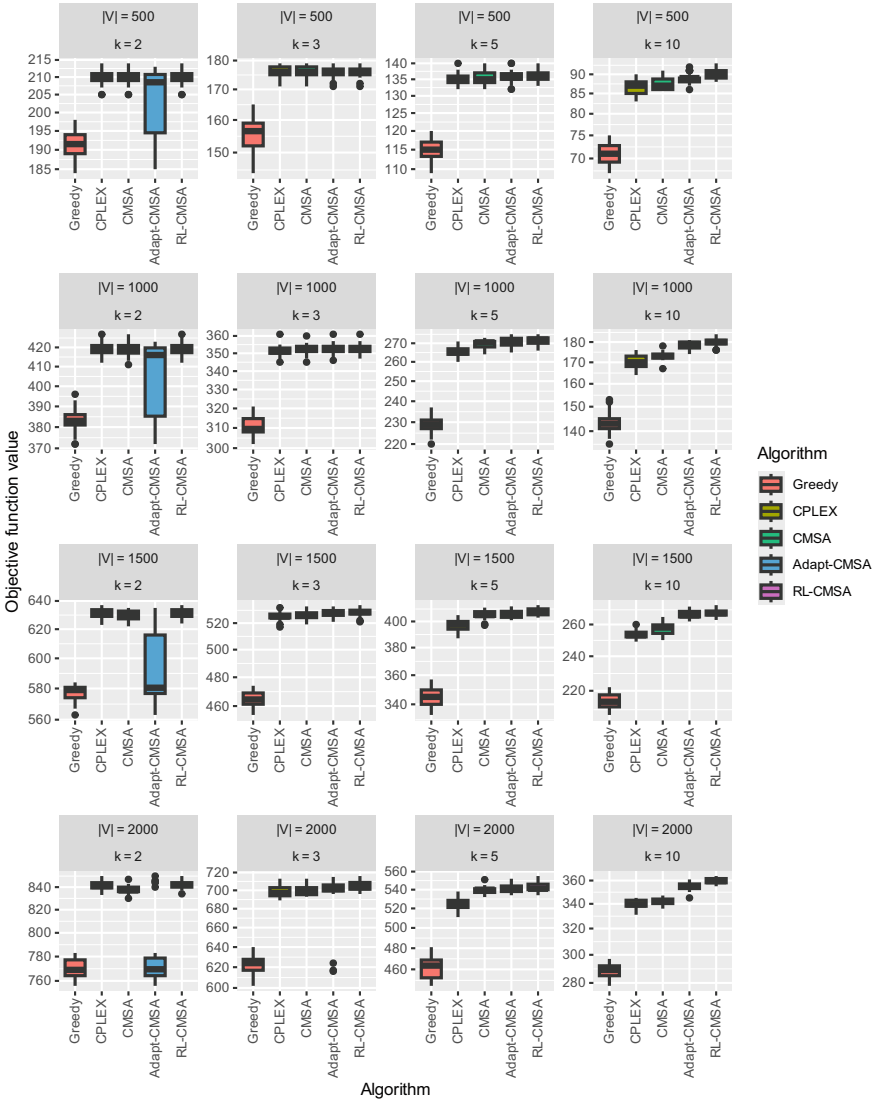

Fig. 3 Results for Watts-Strogatz graphs

significance as shown in Figs 6 and 7. However, in the case of Erdös-Rényi graphs, Adapt-CMSA—when considering all of these graphs—is outperformed by CMSA. When studying the box plots from Fig 2, it becomes clear that this is the case due to a very low performance of Adapt-CMSA for the sparsest graphs (see the boxplots in the first column of that graphic). Remember that the parameter setting of Adapt-CMSA chosen by `irace` was such that the construction of new solutions is very much biased toward the best-so-far solution.

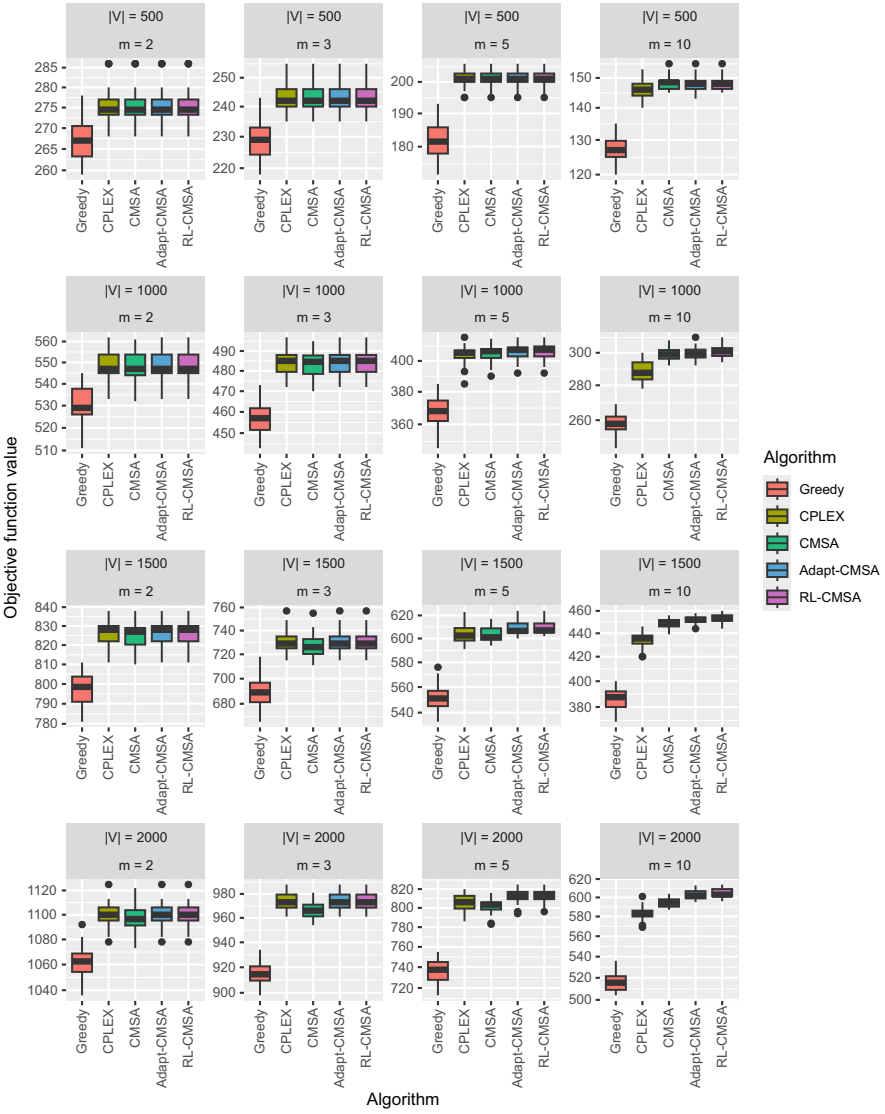

Fig. 4 Results for Barabási-Albert graphs

This setting, even though working very well for the three groups of graphs of higher density (regardless of the network model), does not seem to work well at all when sparse graphs (at least the ones produced by the Erdös-Rényi and the Watts-Strogatz models) are concerned. We assume that, with a rather greedy solution construction, it is very hard to escape from local minima in these cases.

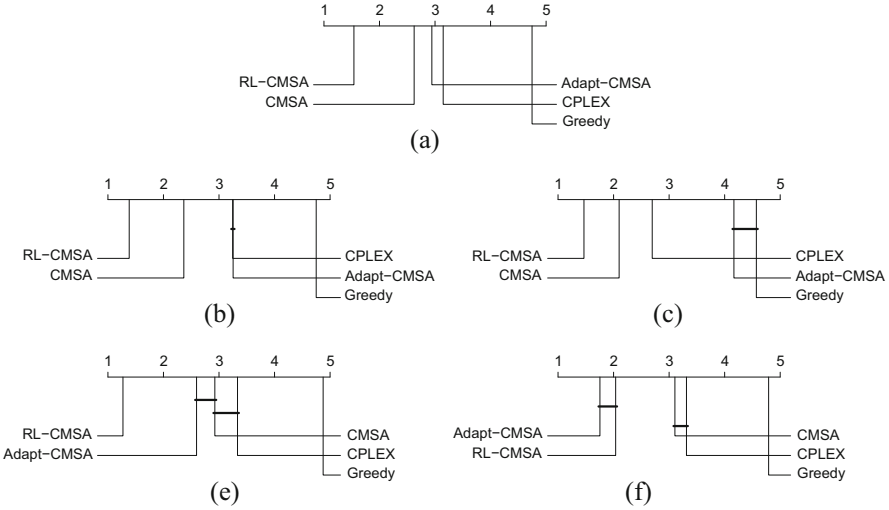

Fig. 5 Critical Difference (CD) plots concerning Erdös-Rényi graphs. (**a**) All graphs. (**b**) Density $p = 0.00624144$. (**c**) Density $p = 0.00416381$. (**d**) Density $p = 0.0103881$. (**e**) Density $p = 0.020705$

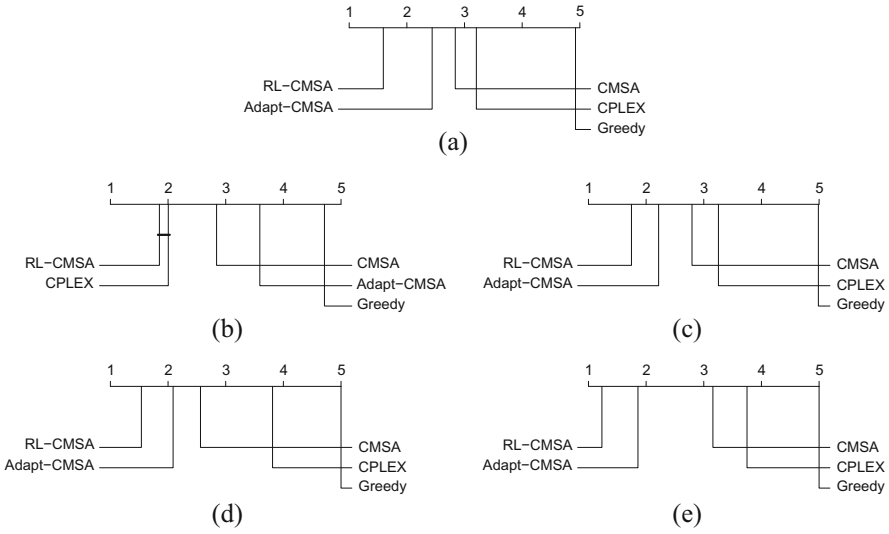

Fig. 6 Critical Difference (CD) plots concerning Watts-Strogatz graphs. (**a**) All graphs. (**b**) Density $k = 2$. (**c**) Density $k = 3$. (**d**) Density $k = 5$. (**e**) Density $k = 10$

Finally, the `STNWeb` tool [33] was used in an attempt to learn something about the changing behavior of the three CMSA variants when applied to graphs created with different network models. This tool produces graphics—called STN graphics—that visualize the trajectories of algorithms in the search space. We

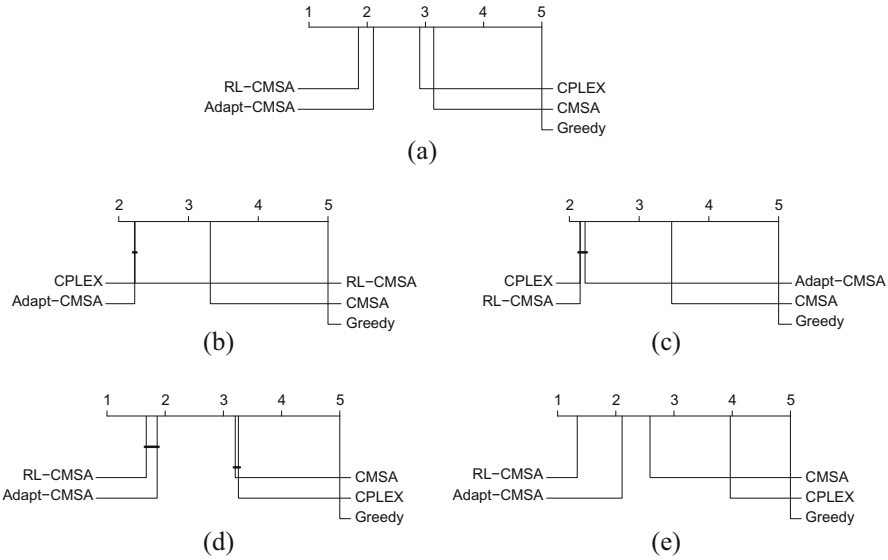

Fig. 7 Critical Difference (CD) plots concerning Barabási-Albert graphs. (**a**) All graphs. (**b**) Density $m = 2$. (**c**) Density $m = 3$. (**d**) Density $m = 5$. (**e**) Density $m = 10$

applied CMSA, Adapt-CMSA, and RL-CMSA ten times to all problem instances and recorded every new best-so-far solution to produce these trajectories. In Fig 8, we show the resulting STN graphics for the first (out of 30) graphs with 2000 nodes from the third density level as a representative example. The three graphics in this figure refer to the corresponding Erdös-Rényi graph (see Fig 8a), the Watts-Strogatz graph (see Fig 8b), and the Barabási-Albert graph (see Fig 8c). Before delving into the analysis, please note that the displayed graphics result from—in STN jargon—search space partitioning, meaning that each node (dot, square, triangle) in these graphics might represent a single solution or clusters of similar solutions. Firstly, it is evident that the STN graphics for the Erdös-Rényi and Watts-Strogatz graphs display far more similarities with each other than they do with the STN graphic for the Barabási-Albert graph. In particular, they show that both CMSA and Adapt-CMSA start their search trajectories in a common area of the search space. However, while some CMSA trajectories are attracted to the same search space region, this does not hold true for Adapt-CMSA. Moreover, they show that RL-CMSA trajectories start in different search space regions. These two observations make sense as CMSA and Adapt-CMSA, in contrast to RL-CMSA, are biased by the same greedy heuristic that favors low-degree nodes. In general, both graphics do not show any overlaps between the search trajectories of different algorithms. This suggests that, in Erdös-Rényi and Watts-Strogatz graphs, good solutions might be very different from each other. In contrast, in the context of the

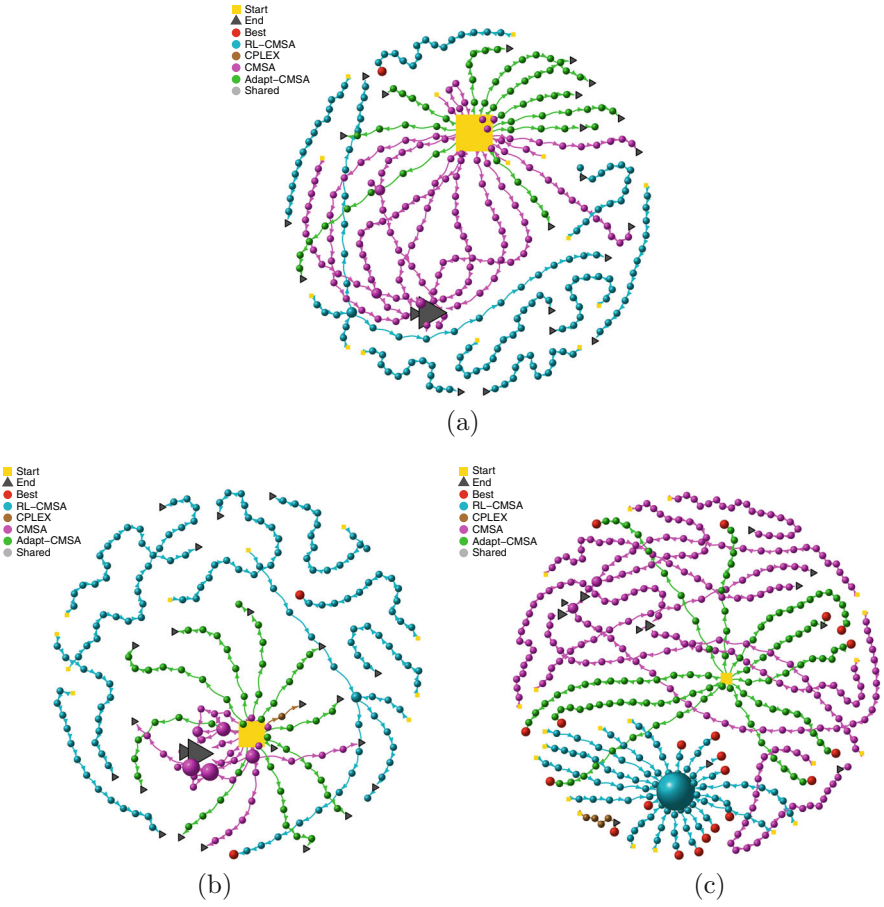

Fig. 8 STNWeb graphics. The three graphics show ten runs of all CMSA variants (in addition to the deterministic CPLEX run) for the first graph with 2000 nodes and the third density level. (**a**) shows results for the corresponding Erdös-Rényi graph, (**b**) for the Watts-Strogatz graph, and (**c**) for the Barabási-Albert graph

Barabási-Albert graph, the search trajectories of RL-CMSA seem to be attracted by a common area of the search space. After passing through this area, all of them find different solutions of the same quality (red dots). This behavior suggests that, in contrast to Erdös-Rényi and Watts-Strogatz graphs, in Barabási-Albert graphs, the MIS problem is characterized by a common backbone of nodes that must form part of high-quality solutions. As RL-CMSA is the only CMSA variant with a learning component, it is also the only one to learn to include the nodes from the backbone into solutions before finding the best solutions in each run.

Conclusion

This chapter introduced three variants of one of the most recent hybrid metaheuristics called "Construct, Merge, Solver & Adapt" (abbreviated as CMSA), which uses problem-specific solvers at each iteration to solve smaller sub-instances of the tackled problem instances. In addition to the standard CMSA variant, we described a self-adaptive CMSA variant called Adapt-CMSA and a CMSA variant called RL-CMSA that uses reinforcement learning. To showcase an application, these three CMSA variants were applied to solve the maximum independent set problem, a classical NP-hard problem in Computer Science. The RL-CMSA variant emerged as the best-performing technique, followed by the Adapt-CMSA variant. However, it was also evident that Adapt-CMSA might have problems escaping from local minima in case of an overly strong bias toward the best-so-far solution. In contrast, RL-CMSA showed a strong performance over the whole benchmark set of graphs produced by different network models.

We believe that one of the main research lines around CMSA in the near future will be concerned with strengthening the learning component of the algorithm. Recent applications of RL-CMSA [29] and Learn-CMSA [28] show the potential of this type of research. Another possibly fruitful research line concerns using specialized exact techniques (instead of black-box ILP solvers) for solving sub-instances.

Abstract

Constraint-Based Local Search emerged in the last decade as a framework for declaratively expressing hard combinatorial optimization problems and solving them with local search techniques. It delivers tools to practitioners that

enable them to quickly experiment with multiple models, heuristics, and meta-heuristics, focusing on their application rather than the delicate minutiae of producing a competitive implementation. At its heart, the declarative models are reminiscent of the modeling facilities familiar to constraint programming, while the underlying computational model heavily depends on incrementality. The net result is a platform capable of delivering competitive local search solutions at a fraction of the efforts needed with a conventional approach delivering model-and-run to local search users.

Keywords

Local Search · Model · Declarative · Incremental · Solver

Introduction

Complete techniques such as Integer Programming and Constraint Programming typically offer optimality guarantees on the results they deliver but do not always scale to large instances. This explains the appeal of local search methods that deliver a different trade-off in the algorithmic design space, favoring scalability at the expense of guarantees. Local search algorithms apply to diverse application domains such as routing, scheduling, resource allocation, or rostering to name just a few. In most cases, local search techniques scale to truly large problem instances that are often out of scope for complete techniques and are capable of producing streams of solutions of improving quality.

Yet, while modeling and high-level tools are ubiquitous for Mixed -Integer Programming and Constraint Programming, they have been relatively unexplored for local search until recently. This is primarily due to the fact that the separation of models and algorithms is not as simple in local search compared to MIP and CP which are declarative in nature. Indeed, the vast majority of papers discussing local search describe their solution in *algorithmic* terms rather than *declarative* terms like models, decision variables, and constraints. The 90s witnessed a shift in interest and the emergence of multiple tools expressly dedicated to local search techniques. GSAT [13, 15] and WalkSAT [14] offered the initial impetus behind formulating problems with a simple language (in clausal form) and using generic local search algorithms operating on that encoding. Integer Optimization by Local Search [25] generalized this line of work to the richer language of integer programming.

Localizer [8, 9] took a different approach, providing a first step to build a general-purpose modeling language for local search. It introduced the concept of *invariants* to express arbitrary one-way constraints that are automatically and incrementally updated under variable assignments. These invariants can then encode, in a declarative fashion, the incremental data structures typically needed in the implementation of meta-heuristics such as Tabu Search [5], Min-Conflict Search [10], Simulated Annealing [6], Scatter Search [7], or GRASP [4] to name just a few.

Constraint-Based Local Search is the culmination of this line of work. It complements the constraint programming efforts typically focused on complete

search techniques and delivers a "model and search" framework in which one uses decision variables and constraints to model a problem and relies on search procedures to explore the underlying search space. COMET is an optimization platform that embodies Constraint-Based Local Search and is a direct descendant of LOCALIZER. It is an object-oriented programming language with explicit support for modeling problems declaratively and solving them with local search techniques. The contributions underlying COMET span from the incremental computation model, the modeling abstractions, and the control mechanisms to specify and execute local search heuristics and meta-heuristics easily, efficiently, and compactly.

Foundations Constraint-Based Local Search aims at implementing the vision captured by the equation

$$LocalSearch = Model + Search$$

that expresses the belief that a local search algorithm is best viewed as the composition of a *declarative model* with a *search* component. This separation of concerns is central: It postulates the importance of expressing the structures of the problem being solved declaratively and compositionally and providing a search component which *exploits* those structures and guides the search toward high-quality local optima.

The Constraint-Based Local Search architecture delivers several key benefits:

Rich Language Constraints are declarative and capture the problem substructures. They range from simple arithmetic constraints, the indexing of arrays of variables with variables, meta-constraints (constraints on the truth value of other constraints) and logical constraints, to combinatorial constraints such as cardinality, sequence, or alldifferent constraints to name just a few. Constraints (and combinators) for local search were introduced in [23].

Rich Search Programming meta-heuristics is supported by a wealth of language combinators and control abstractions to automate the most tedious and error-prone aspects of an actual implementation. The abstractions foster the decoupling of neighborhood, heuristics, and meta-heuristics specifications while leveraging the incrementality exposed by the constraints present in the declarative model. Control abstractions were introduced in [20].

Separation The untangling of model and search promotes the independent design and evolution of these two components. With Constraint-Based Local Search, it is possible to explore alternative models independently of refinements to the search procedures.

Versatility The ability to specify meta-heuristics orthogonally to the model also enables a collection of *generic* search routines which are highly reusable and promote the experimental process to design an effective CBLS program. This versatility further promotes the reuse of highly generic "canned" search procedures.

Extensibility New constraints and objective functions can be added to the system library and used in conjunction with native constraints. Perhaps even more interestingly, the new constraints can be implemented directly in the host language (i.e., COMET), and the bulk of the implementation is often cast in terms of invariants. New heuristics and meta-heuristics can also be easily added to the system as the implementation of *any* heuristic or meta-heuristic relies on a few key concepts such as closures, continuations, selectors, and neighbors.

Performance Finally, the architecture heavily relies on incrementally maintaining the computational state over time. This capability is compositional and a direct by-product of the declarative model. The approach enables the platform to deliver constraint-based local search *programs* that are a fraction of the size and complexity of handcrafted code, yet deliver performance comparable, and sometime exceeding, manually crafted implementations.

The rest of this chapter starts with an illustration of Constraint-Based Local Search through the modeling and resolution of the classic n-queens problem in section "Getting Started." Section "Foundations" discusses the theoretical underpinnings of Constraint-Based Local Search starting with models and concluding with programs. Section "Case Studies" focuses on how to model applications with a rich language that goes beyond boolean formulas or linear equations. Section "Implementation" explores the implementation issues, starting with the support for incremental computation through invariants and proceeding with a discussion of differentiation. Section "Empirical Results" gives a brief survey of the type of performance that can be expected from Constraint-Based Local Search systems and section "Conclusion" concludes the chapter.

Getting Started

To introduce Constraint-Based Local Search, it is valuable to start with the modeling and resolution of a simple well-known problem. The examples presented in this chapter use the COMET platform.

The Problem The n-queens problem is to place n queens on a chess board of size $n \times n$ so that no two queens can attack each other. While the problem is polynomial, its simplicity is appealing to illustrate Constraint-Based Local Search. The COMET program is shown in Fig. 1 and features two clear components that are discussed next.

The Model The model definition spans lines 4–9, is declarative, and exclusively focuses on defining an array of decision variables $queen$ in line 6 and three combinatorial constraints on lines 7–9. Variable $queen_i$ models the row on which the queen in column i is to be placed. Each decision variable has a domain $Size$ representing the set of permissible values for that variable. Each combinatorial `alldifferent` constraint takes as input an array of expressions and requires that

```
1 import lssolver;
2 int n = 8;
3 range Size = 1..n;
4 Solver<LS> m();
5 ConstraintSystem<LS> S(m);
6 var{int} queen[Size](m,Size);
7 S.add(alldifferent(queen));
8 S.add(alldifferent(all(i in Size) (queen[i] + i)));
9 S.add(alldifferent(all(i in Size) (queen[i] - i)));
10
11 while(S.violations() > 0)
12   selectMin(i in Size,v in Size: queen[i]!=v)(S.getAssignDelta(queen[i],v))
13     queen[i] := v;
```

Fig. 1 A constraint-based local search model for the queens problem

the values of all entries in the array be pairwise distinct. For instance, line 7 states that no two queens can be assigned to the same row. The constraints on lines 8 and 9 play a similar role but for the upward and downward diagonals. Note how an operator `all` is used on line 8 to create an array of expressions

$$(queen_1 + 1, queen_2 + 2, queen_3 + 3, \cdots, queen_7 + 7, queen_8 + 8),$$

which is the input of the combinatorial constraint.

The Search A classic constraint-based local search starts from a tentative assignment of values to the decision variables and iteratively transforms it, moving from tentative assignments to tentative assignments using a *local* move operator. The local move used in this specific case is the assignment of a single variable to a new value. Namely, with n decision variables, each with a domain of size n, one could consider up to $\Theta(n^2)$ such moves. To illustrate the search process, consider the left board in Fig. 2a which depicts a tentative assignment. The bottom row of numbers conveys, for each column, the number of constraints violated by the queen placement in that column. For instance, the value in column 2 reports the number of constraints violated by the queen in that column (on row 4). Namely, the number of violations attributed to $queen_2$ is 2 since there is a queen on the same row (violating the row constraint) and a queen on the same up diagonal (in the next column). The numbers in the last column focus on $queen_4$ and therefore are replicas of column 4 of the delta matrix. Namely, they show how the total number of violations would change if $queen_4$ was to be reassigned to another row. Naturally, the fourth value in that column (from the bottom) is zero since it amounts to not moving the queen at all. The third value is -2 since $queen_4$ currently violates three constraints (one horizontal as well as one up and one down diagonal), and the move to row 3 would eliminate all three conflicts (-3) but introduce a new one with the queen in column 8 currently placed on row 3 as well for a net violation gain of -2. Finally, the 7 in

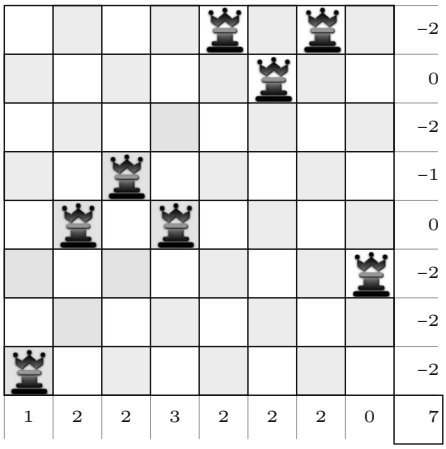

Fig. 2 The first step of the CBLS algorithm for the queens problem. (**a**) Starting point. (**b**) Delta matrix

the bottom-right corner is the overall violations for the entire board. Indeed, there are two rows with more than one queen, three upward diagonals with more than one queen and two downward diagonals ($7 = 2 + 3 + 2$). Here, a move consists of relocating a queen to a new row, and the algorithm chooses the best such move. The right side, Fig. 2b, shows the reduction in violations for each possible move. Therefore, a viable move is to relocate $queen_4$ to row 3, reducing the total number of conflicts (violations) from 7 to 5. The delta matrix shows that quite a few moves would deliver a -2 gain.

The search outlined above is a classic greedy search. The implementation spanning lines 11–14 obtains the set of constraints present in the model (line 11) and starts from a randomly initialized tentative assignment σ_0. It proceeds through a sequence of moves aimed at satisfying the three softened constraints present in S. The underlying neighborhood function N defined as

$$N(\sigma) = \{\sigma' \mid \exists j \in 1..8\ \forall i \in 1..8, i \neq j : \sigma'(queen_i) = \sigma(queen_i) \wedge \sigma'(queen_j) \in D(queen_j) \setminus \{\sigma(queen_j)\}\}$$

spells out a set of $\Theta(n^2)$ neighbors and is implemented with the `select` statement on line 12 that considers the reassignment of a single decision variable at a time. Overall, the search produces a sequence of tentative assignments

$$\sigma_0, \sigma_1 \in N(\sigma_0), \sigma_2 \in N(\sigma_1), \cdots, \sigma_k \in N(\sigma_{k-1})$$

delivering a solution σ_k that satisfies all the softened constraints (the number of violations of S is 0).

Foundations

This section reviews the foundations of Constraint-Based Local Search, covering both models and programs. It introduces the main concepts behind the declarative and operational models.

Models

From an end-user perspective, constraints and objective functions are at the heart of Constraint-Based Local Search. They provide the declarative bricks needed to construct models describing requirements and properties of the solution being sought. They also support the underlying computational model. This section first reviews the key concepts of constraints, and objective functions before finishing with a presentation of the underlying semantics.

Basics Constraint-Based Local Search is the process of looking for an assignment of values to decision variables that meets specific requirements. Decision variables are central to the modeling process as they characterize solutions. This chapter focuses on integer variables only for simplicity. Extensions to more complex variables (i.e., set, paths, and trees) have been proposed in [12, 22]. The chapter also assumes that Constraint-Based Local Search models are defined over a set X of decision variables.

Definition 1 (Assignment). An assignment σ is a mapping $X \rightarrow D(X)$ from variables to values in their domain. The value assigned to x in σ is denoted by $\sigma(x)$. The set of all possible assignments is denoted by Σ.

For convenience, the expression $\sigma[x/v]$ denotes a new assignment σ' which is similar to σ except that variable x is assigned to v, i.e.,

$$\forall y \in X \setminus \{x\} \ : \ \sigma'(y) = \sigma(y) \wedge \sigma'(x) = v.$$

Constraints are used to impose requirements on the decision variables. Constraints are naturally declarative, can be expressed in a variety of ways, and always capture a relation over a subset of variables from X.

Definition 2 (Constraint). A constraint $c(x_1, \cdots, x_n)$ is a n-ary relation over variables $x_1 \cdots x_n \in X$. The set $vars(c)$ is the set of n variables appearing in c, i.e., $vars(c) = \{x_1, \cdots, x_n\}$.

Constraints can be expressed through algebraic expressions, logical statements, or combinatorial structures.

Example 1. In the queens example, the requirement that any two variables cannot lay on the same row, i.e., `alldifferent(x)`, is semantically equivalent to the conjunction of constraints

$$\bigwedge_{i \in 1..8, j \in i+1..8} x_i \neq x_j.$$

Operationally however, the `alldifferent` maintains its state and violations more efficiently than the naive reformulation above.

Example 2. A constraint system S is a set of constraints, and its truth value is equivalent to the truth value of $\wedge_{c \in S}\ c$.

Evaluations and Violations The driving force behind Constraint-Based Local Search rests on the ability to assess how badly constraints are violated. This is captured by the concept of violation degrees (or violations for short).

Definition 3 (Violation Degree). The violation degree of $c(x_1, \cdots, x_n)$ is a function $v_c : \Sigma \to \mathbb{R}^+$ such that, for any assignment σ such that $\sigma(x_1) \in D(x_1)$, $\cdots, \sigma(x_n) \in D(x_n)$, it holds that

$$c(\sigma(x_1), \cdots, \sigma(x_n)) \equiv v_c(\sigma) = 0.$$

The violation degree definition depends critically on the structure conveyed by constraint c. The definition of violation is constraint-dependent but is derived systematically for algebraic and logical expressions. For completeness, consider the specification of expression evaluation.

Definition 4 (Expression Evaluation). Let $e \in \mathcal{E}$ be an arithmetic expression and $\sigma \in \Sigma$ be an assignment. The evaluation of e with respect to (wrt) σ is specified by the function $\mathbb{E}(\sigma, e) : \mathcal{E} \times \Sigma \to \mathbb{Z}$, which is defined inductively on the structure of e in Fig. 3.

Algebraic *constraints* are based on relations and logical combinators. To reason about the violations of relational and logical constraints, it is useful to derive an *expression* modeling the violations of constraint c from the structure of c.

Fig. 3 The evaluation of an expression with respect to an assignment

$$\begin{aligned}
\mathbb{E}(\sigma, v) &= v \Leftrightarrow v \in \mathbb{R} \\
\mathbb{E}(\sigma, x) &= \sigma(x)(x \in X) \\
\mathbb{E}(\sigma, e_1 + e_2) &= \mathbb{E}(\sigma, e_1) + \mathbb{E}(\sigma, e_2) \\
\mathbb{E}(\sigma, e_1 - e_2) &= \mathbb{E}(\sigma, e_1) - \mathbb{E}(\sigma, e_2) \\
\mathbb{E}(\sigma, e_1 \times e_2) &= \mathbb{E}(\sigma, e_1) \times \mathbb{E}(\sigma, e_2) \\
\mathbb{E}(\sigma, \textsc{Abs}(e)) &= \textsc{Abs}(\mathbb{E}(\sigma, e)) \\
\mathbb{E}(\sigma, \min(e_1, e_2)) &= \min(\mathbb{E}(\sigma, e_1), \mathbb{E}(\sigma, e_2))
\end{aligned}$$

Definition 5 (Constraint Conversion). Let c be a logical or relational constraint. The constraint conversion of c is an expression $\mathbb{V}(c)$ which can be evaluated to determine the violations of c with respect to some assignment. It is specified by the function $\mathbb{V}(c) : \mathcal{E} \to \mathcal{E}$ which is defined by induction on the structure of c as specified in Fig. 4.

The conversion for the conjunction of two constraints is none other than the sum of the converted relation violations.

Example 3. The conversion of $x = 5 \wedge y \neq 10$ where $x, y \in X$ is derived as follows:

$$\mathbb{V}(x = 5 \wedge y \neq 10) = \mathbb{V}(x = 5) + \mathbb{V}(y \neq 10) = \textsc{Abs}(x-5)+1-\min(1, \textsc{Abs}(y-10)).$$

It is now possible to compose both functions to obtain the actual violations of an algebraic constraint c with respect to an assignment σ.

Example 4. The violation of an arithmetic constraint $c \equiv l \geq r$ is given by

$$\mathbb{E}(\sigma, \mathbb{V}(l \geq r)).$$

The violation degree function for c is then given by

$$v_c(\sigma) = \mathbb{E}(\sigma, \max(r - l, 0)) = \max(\mathbb{E}(\sigma, r) - \mathbb{E}(\sigma, l), 0).$$

Example 5. The violation of a conjunction $c = c_1 \wedge c_2$ is defined as

$$v_c(\sigma) = \mathbb{E}(\sigma, \mathbb{V}(c_1 \wedge c_2)).$$

While the above mechanics are appropriate to obtain the violations of algebraic constraints, combinatorial constraints define their own notion of violations that capture the combinatorial substructure at hand. Consider the `alldifferent` constraint again.

Example 6. The violation function of $c = \texttt{alldifferent}(x_1, \cdots, x_n)$ simply counts the number of values used more than once by variables $x_1, \ldots, x_n$. More precisely, given an assignment σ and $vars(c) = \{x_1, \cdots, x_n\}$,

Fig. 4 The constraint conversion function

$$\begin{aligned}
\mathbb{V}(e_1 = e_2) &= \textsc{Abs}(e_1 - e_2) \\
\mathbb{V}(e_1 \leqslant e_2) &= \max(e_1 - e_2, 0) \\
\mathbb{V}(e_1 \geqslant e_2) &= \max(e_2 - e_1, 0) \\
\mathbb{V}(e_1 \neq e_2) &= 1 - \min(1, \textsc{Abs}(e_1 - e_2)) \\
\mathbb{V}(r_1 \wedge r_2) &= \mathbb{V}(r_1) + \mathbb{V}(r_2) \\
\mathbb{V}(r_1 \vee r_2) &= \min(\mathbb{V}(r_1), \mathbb{V}(r_2)) \\
\mathbb{V}(\neg r) &= 1 - \min(1, \mathbb{V}(r))
\end{aligned}$$

$$v_c(\sigma) = \sum_{i \in S} \max(0, |\{x_j \in vars(c) | \sigma(x_j) = i\}| - 1),$$

where $S = \bigcup_{i \in 1..n} D(x_i)$. Consider the `alldifferent` constraint on the rows for the board in Fig. 2a. The assignment is $\sigma = [1, 4, 5, 4, 8, 7, 8, 3]$: It has two variables using value 4 and two variables using value 8, giving a violation of 2 for the row constraints.

Differentiation The infrastructure covered so far enables the incremental assessment of the satisfaction, and the number of violations, of a constraint c. However, it does not specify how to assess the impact of a local move on the satisfiability or violations of constraints. *Gradients* are the cornerstone of this process.

Definition 6 (Gradient). Given an assignment σ and an arithmetic expression e, $\uparrow_x(\sigma, e)$ denotes the maximum increase for the evaluation of e over all possible values in $D(x)$ wrt σ, whereas $\downarrow_x(\sigma, e)$ denotes the largest decrease for the evaluation of e over all possible values in $D(x)$ wrt σ, i.e.,

$$\uparrow_x (\sigma, e) = \max_{v \in D(x)} \mathbb{E}(\sigma[x/v], e) - \mathbb{E}(\sigma, e)$$

$$\downarrow_x (\sigma, e) = \mathbb{E}(\sigma, e) - \min_{v \in D(x)} \mathbb{E}(\sigma[x/v], e).$$

Note that gradients are nonnegative in this specification. An efficient implementation can be derived inductively on the structure of expression e. Figure 5 gives an abridged version of such derivation. The definition for $\uparrow_x(\sigma, x)$ is an interesting

$$\begin{aligned}
\uparrow_x (\sigma, v) &= 0 \Leftrightarrow v \in \mathbb{R} \\
\uparrow_x (\sigma, y) &= 0 \Leftrightarrow y \in X \backslash \{x\} \\
\uparrow_x (\sigma, x) &= \max_{v \in D(x)} v - \sigma(x) \\
\uparrow_x (\sigma, e_1 + e_2) &= \uparrow_x (\sigma, e_1) + \uparrow_x (\sigma, e_2) \\
\uparrow_x (\sigma, e_1 - e_2) &= \uparrow_x (\sigma, e_1) + \downarrow_x (\sigma, e_2) \\
\uparrow_x (\sigma, \text{ABS}(e)) &= \max(\text{ABS}(\mathbb{E}(\sigma, e) + \uparrow_x (\sigma, e)), \text{ABS}(\mathbb{E}(\sigma, e) - \downarrow_x (\sigma, e))) - \mathbb{E}(\sigma, \text{ABS}(e)) \\
\uparrow_x (\sigma, \min(e_1, e_2)) &= \min(\mathbb{E}(\sigma, e_1) + \uparrow_x (\sigma, e_1), \mathbb{E}(\sigma, e_2) + \uparrow_x (\sigma, e_2)) - \mathbb{E}(\sigma, \min(e_1, e_2))
\end{aligned}$$

$$\begin{aligned}
\downarrow_x (\sigma, v) &= 0 \Leftrightarrow v \in \mathbb{R} \\
\downarrow_x (\sigma, y) &= 0 \Leftrightarrow y \in X \backslash \{x\} \\
\downarrow_x (\sigma, x) &= \sigma(x) - \min_{v \in D(x)} v \\
\downarrow_x (\sigma, e_1 + e_2) &= \downarrow_x (\sigma, e_1) + \downarrow_x (\sigma, e_2) \\
\downarrow_x (\sigma, e_1 - e_2) &= \downarrow_x (\sigma, e_1) + \uparrow_x (\sigma, e_2) \\
\downarrow_x (\sigma, \text{ABS}(e)) &= \texttt{if } \mathbb{E}(\sigma, e) \geqslant 0 \\
&\quad \texttt{then } \min(\mathbb{E}(\sigma, e), \downarrow_x (\sigma, e)) \\
&\quad \texttt{else } \min(-\mathbb{E}(\sigma, e), \uparrow_x (\sigma, e)) \\
\downarrow_x (\sigma, \min(e_1, e_2)) &= \mathbb{E}(\sigma, \min(e_1, e_2)) - \min(\mathbb{E}(\sigma, e_1) + \downarrow_x (\sigma, e_1), \mathbb{E}(\sigma, e_2) + \downarrow_x (\sigma, e_2))
\end{aligned}$$

Fig. 5 Expression gradients

base case. Indeed, $\uparrow_x(\sigma, x) = \max_{v \in D(x)} v - \sigma(x)$, which has the effect of picking up the largest increase as the distance between the value currently assigned to x in σ and the largest value of the domain. Similarly, note how $\uparrow_x(\sigma, e_1 - e_2)$ combines the largest increase in e_1 with the largest decrease in e_2.

The next concept, variable violation, is interesting: It captures how many violations can be attributed to a specific variable for a given assignment. Variable violations are specified in terms of gradients.

Definition 7 (Variable violations). Given a constraint c, the variable violations of c wrt $x \in vars(c)$ and assignment σ is specified by $\downarrow_x(\sigma, \mathbb{V}(c))$.

The concepts of violation degrees and variable violations are generic, and hence they enable the specification of a common API for all constraints. This API makes it possible to implement the slogan

$$LocalSearch = Model + Search$$

mentioned in the introduction. In particular, the API of a constraint is specified in Fig. 6. For instance, the method call `violations()` simply returns the evaluation of $v_c(\sigma)$, while the method call `violations(x)` returns $\downarrow_x(\sigma, \mathbb{V}(c))$, for the current variable assignment σ. Finally, the call to method `getAssignDelta(x,v)` returns the variation in violation degree when using the assignment $\sigma[x/v]$ instead of σ, i.e., it returns

$$v_c(\sigma) - v_c(\sigma[x/v]).$$

Combinatorial constraints like `alldifferent` also conform to this interface, and the implementation of the last two methods takes advantage of the constraint semantics to implement the specification incrementally.

Objective Functions Objective functions play an equally critical role within Constraint-Based Local Search. Objectives provide the necessary mechanics to express and exploit objective functions. Interestingly, once gradients are available, objectives do not add much complexity. Objective functions must conform to the interface depicted in Fig. 7.

```
1 interface Constraint<LS> {
2   bool holds();
3   var{int} violations();
4   var{int} violations(var{int} x);
5   int getAssignDelta(var{int} x,int v);
6 }
```

Fig. 6 The constraint interface

```
1 interface Objective<LS> {
2   var{int} evaluation();
3   var{int} increase(var{int} x);
4   var{int} decrease(var{int} x);
5   int getAssignDelta(var{int} x,int v);
6 }
```

Fig. 7 The objective interface

Given the current variable assignment σ, the call `evaluation()` returns $\mathbb{E}(\sigma, e)$, while the call `increase(x)` returns $\uparrow_x(\sigma, e)$ and the call `decrease(x)` returns $\downarrow_x(\sigma, e)$.

Models and Constraint Hardness From a purely pragmatic and operational standpoint, it is often convenient to partition the actual constraint set C in two

$$C = S \cup R \quad (S \cap R = \varnothing),$$

where R represents a set of *required* but easy-to-solve constraints and S represents a set of *softened* constraints that are typically much harder to satisfy. The intent is to handle both types of constraints differently. Intuitively, required constraints are always satisfied during the search, while softened constraints may be violated. In the n-queens examples introduced earlier, $R = \varnothing$ and all the constraints are softened in S. In general, however, R may contain some constraints that are not worth relaxing in S. The membership in S or R is clearly a design decision for the modeler to consider.

Definition 8 (Constraint Model). A constraint-based local search model M for a constraint optimization problem is a quintuplet $M = \langle X, D, F, R, S \rangle$, where:

- Every $x \in X$ is a decision variable taking its value from $D(x)$.
- F is, without loss of generality, a minimization function.
- R is a set of required constraints (easy to satisfy).
- S is a set of soft constraints (difficult to satisfy).

Declaratively, the semantics of a Constraint-Based Local Search model is given by the optimization problem

$$\min_{\sigma \in \Sigma} \mathbb{E}(\sigma, F) + \sum_{c \in S} v_c(\sigma)$$

subject to

$$v_c(\sigma) = 0 \quad : \forall c \in R.$$

Namely, the objective is to minimize the sum of the violations over the softened constraints and the original objective function subject to the required constraints. In

the case of constraint satisfaction, $\mathbb{E}(\sigma, F) = 0$ for every σ as the objective is absent. Note that constraints can be weighted, which makes it possible to balance the two terms of the objective. It is simple to write a combinator to weight a constraint in a generic way [22].

Definition 9 (Feasible Solution). A feasible solution σ to a Constraint-Based Local Search model $M = \langle X, D, F, R, S \rangle$ satisfies

$$\sum_{c \in S} \nu_c(\sigma) = 0.$$

$\mathcal{F}(M)$ denotes the set of feasible solutions to M.

Note that, by definition, every assignment σ also satisfies all the required constraints ($\nu_c(\sigma) = 0 \ : \ \forall c \in R$).

Definition 10 (Optimal Solution). An optimal solution σ^* to a Constraint-Based Local Search model $M = \langle X, D, F, R, S \rangle$ is a feasible solution $\sigma^* \in \mathcal{F}(M)$ such that

$$\forall \sigma \in \mathcal{F}(M) : \mathbb{E}(\sigma^*, F) \leq \mathbb{E}(\sigma, F).$$

Definition 11 (Search Procedure). A search procedure produces a sequence of assignments $\sigma_0, \cdots, \sigma_k$, where $\forall i \in 0..k \ : \ \nu_c(\sigma_i) = 0 \ (c \in R)$, and returns σ satisfying

$$\min_{\sigma \in \{\sigma_0, \cdots, \sigma_k\}} \mathbb{E}(\sigma, F) + \sum_{c \in S} \nu_c(\sigma).$$

A Constraint-Based Local Search procedure succeeds if $\sigma \in \mathcal{F}(M)$.

Programs

The model specifies the properties satisfied by assignments appearing in a trace $s_0, s_1, \cdots, s_k$; it does not dictate how the assignments in the trace are generated. This is the prerogative of concrete search procedures which are often viewed as the composition of a *neighborhood* function, a *legality* restriction function, and a candidate *selection* function.

Definition 12 (Neighborhood). The neighborhood of an assignment σ_k, denoted $N(\sigma_k)$, is the set of assignments reachable from σ_k via a local move.

Local moves can be *microscopic* changes to the candidate solution such as the reassignment of a single variable or the swap of the values associated with

two distinct variables. In specific domains, e.g., in scheduling, the move can be *macroscopic* and involve changing several variables to capture moves in more complex neighborhood, e.g., moving a task in a job sequence.

Example 7. In the 8-queens example outlined in section "Getting Started," the neighborhood is based on the reassignment of a single queen to a new row. The neighborhood consists of $\Theta(n^2)$ assignments. It could be further restricted to $\Theta(n)$ assignments by only considering the queen appearing in the largest number of conflicts and its possible reassignments. Given a model $M = \langle X, D, 0, \varnothing, S\rangle$, where S is the set consisting of three softened `alldifferent` constraints, the quadratic neighborhood function is

$$N(\sigma_k) = \{\sigma_k[x/v] \mid x \in X \wedge v \in D(x) \setminus \{\sigma_k(x)\}\},$$

while the linear neighborhood function is

$$N(\sigma_k) = \left\{\sigma_k[x/v] \mid x \in \arg\max_{y \in X} \downarrow_y (\sigma_k, \mathbb{V}(\bigwedge_{c \in S} c)) \wedge v \in D(x) \setminus \{\sigma_k(x)\}\right\}.$$

Definition 13 (Legal neighbors). The legal neighborhood of an assignment σ_k is a restriction of $N(\sigma_k)$, namely $L(N(\sigma_k), \sigma_k) \subseteq N(\sigma_k)$, and the legal subset is required to at least satisfy all the required constraints R.

Note that the legal subset of $N(\sigma_k)$ may even be more restrictive and reject neighbors that are feasible with respect to R but fail to exhibit other characteristics. The *full* characterization of the function L is part of the definition of a meta-heuristic. For instance, the tabu meta-heuristic excludes neighbors that were seen in the recent past.

Definition 14 (Neighbor Selection). The selection function S is responsible for choosing the next assignment among legal neighbors. Namely

$$\sigma_{k+1} = S(L(N(\sigma_k), \sigma_k), \sigma_k) \in L(N(\sigma_k), \sigma_k).$$

For instance, a greedy selection chooses the best neighbor, i.e.,

$$\sigma_{k+1} \in \arg\min_{\sigma \in N(\sigma_k)} \mathbb{E}(\sigma, \mathbb{V}(S)).$$

A heuristics or meta-heuristics specifies the three functions N, L, and S that parameterize the computation model.

Control Primitives To support these abstractions, Constraint-Based Local Search programs rely on a handful of control primitives designed to automate tedious and error-prone implementation details.

While the specification of a program relies on three distinct functions N, L, and S, any implementation concerned with performance produces code that fuses the three functions often degrading the readability and maintainability in the process. Key considerations such as randomization and tiebreaking add another layer of complexity to the code. The implementation of meta-heuristics induces its share of complexity by refining move legality and selection further.

COMET attempts to strike a delicate balance between efficiency, code readability, and ease of maintenance by decoupling these aspects as much as possible. The language introduces *selectors*, *neighbors*, and *randomized choosers* as control abstractions.

Neighborhood Selectors The concept of *neighborhood selector* is a cornerstone for the specification of complex local searches. A simplified version of its interface is presented below:

```
1 interface Neighborhood {
2   void insert(int q,Closure c);
3   boolean hasMove();
4   Closure getMove();
5 }
```

The key idea is that a neighbor is defined as a pair $\langle q, c\rangle$ consisting of a quality measure q and a closure c. The intuition is that, in general, the closure c defines the move which, when executed, will produce an objective value of q for the resulting assignment. Method `insert` adds a neighbor c of quality q (line 2), method `hasMove` checks whether the neighborhood is non-empty, and method `getMove` returns the selected move.

Concrete implementations of this interface commit to a specific selection policy. For instance, the concrete selector `MinNeighborSelector` implements the neighborhood interface and retains only a neighbor minimizing the quality measure. Namely, if the set of inserted neighbors is $N = \{\langle q_1, c_1\rangle, \cdots, \langle q_n, c_n\rangle\}$, the selector retains *one* neighbor

$$\langle q, c\rangle \in \underset{\langle q_j, c_j\rangle \in N}{\arg\min}\ q_j$$

and produces it as its selection when `getMove` is called. Alternative selector includes `KMinNeighborSelector` that returns one of the top-k best neighbors (k being a parameter of the selector).

The `neighbor` *Control Primitive* Neighborhood selectors work in conjunction with the `neighbor` control primitive. The primitive has the following syntax:

`neighbor(`$\langle expr\rangle, \langle N\rangle$`)` $\langle Body\rangle$

where $\langle expr \rangle$ refers to an arbitrary arithmetic expression, $\langle N \rangle$ is an expression referring to a selector, and $\langle Body \rangle$ is a statement (or block of statements). From a semantics standpoint, the control primitive creates a closure c of the body code responsible for producing the assignment σ_{k+1} from the current assignment σ_k. It then associates the closure with a quality measure q and submits the pair $\langle q, c \rangle$ to the selector denoted by N. What makes `neighbor` particularly attractive is the syntactic closeness between the code specifying the quality of the move and the code carrying out the move even if, in practice, there is a strong temporal disconnection between the time when the closure is recorded with the selector and the time it gets executed.

The search procedure in Fig. 8 illustrates an alternative implementation of the greedy search presented in Fig. 1. The loop on lines 3–4 scans all variables and values accumulating the reassignments in the selector N and associating with each one a quality measure based on the delta. The 1-instruction block `queen[i] := v;` on line 4 is automatically wrapped in a closure that is entrusted by `neighbor` to the selector N. The beauty in the construction lies in the ability to easily accumulate in the same selector the union of multiple neighborhoods, all defined with different move operators. This capability will be illustrated in the Progressive Party Problem use case in section "Progressive Party."

Randomized Choosers To support developers, COMET provides control abstractions to make greedy, semi-greedy, and randomized choices. The abstractions encapsulate the necessary state to deliver independent pseudorandom streams in each such instruction appearing in the program. For instance, the $\Theta(n)$-sized neighborhood that considers reassigning the queen with the most violations to a new row is easily modeled with instructions in lines 3–7 below.

```
1 MinNeighborSelector N();
2 while(S.violations()!=0) {
3    selectMax[2](i in Size)(S.violations(queen[i])) {
4       forall(v in queen[i].getDomain() : queen[i] != v)
5          neighbor(S.getAssignDelta(queen[i],v),N)
6             queen[i] := v;
7    }
8    if (N.hasMove()) call(N.getMove());
9 }
```

```
1 MinNeighborSelector N();
2 while(S.violations()!=0) {
3    forall(i in Size,v in queen[i].getDomain() : queen[i] != v)
4       neighbor(S.getAssignDelta(queen[i],v),N) queen[i] := v;
5    if (N.hasMove()) call(N.getMove());
6 }
```

Fig. 8 An alternative greedy search for n-queens

The bracketed 2 on line 3 simply requests the selector to retain any value i among the best two (according to the violation measure).

Discussion The Constraint-Based Local Search model appearing in Fig. 1 highlights the key features of the framework. It features a complete separation between a declarative model and a procedural search component. The declarative model relies on combinatorial constraints specifying the properties of solutions, while the search is exclusively devoted to the selection of a heuristic and meta-heuristic. In this model, the search remains problem specific. Yet, both the model and the search can evolve independently. One can add constraints without changing the search or choose a different search strategy without modifying the model. All these characteristics, when blended with the performance of an incremental computation, deliver an appealing architecture for producing local search solutions.

The program in Fig. 1 can still be improved. In particular, it is tempting to provide syntactic sugar to automatically handle the boiler plate code and support the notion of *constraint annotations* to partition the constraint set into soft and required constraints $S \cup R$. The resulting program is shown in Fig. 9. The model m is now attaching a *soft* annotation to each constraint to dictate its addition to S, while line 10 is used to extract the set of soft constraints from m. Perhaps even more interestingly, the adoption of an explicit first-class model concept enables the authoring of completely generic search procedures. Indeed, the code in lines 10–13 can be packaged as the reusable min-conflict procedure depicted in Fig. 10.

Naturally, lines 10–13 from Fig. 9 disappear from the model in favor of a single line calling the generic `minConflictSearch` on model m program, i.e.,

```
1 minConflictSearch(m);
```

This leaves us with a 10-line Constraint-Based Local Search implementation.

```
1  import lssolver;
2  int n = 8;
3  range Size = 1..n;
4  model m {
5     var{int} queen[Size](Size);
6     soft: alldifferent(queen);
7     soft: alldifferent(all(i in Size) (queen[i] + i));
8     soft: alldifferent(all(i in Size) (queen[i] - i));
9  }
10 ConstraintSystem<LS> S = m.getSoftConstraintSystem();
11 while(S.violations() > 0)
12   selectMin(i in Size,v in Size : queen[i]!=v)(S.getAssignDelta(queen[i],v))
13     queen[i] := v;
```

Fig. 9 A revised constraint-based local search model for n-queens

```
1 void function minConflictSearch(Model<LS> m) {
2    ConstraintSystem<LS> S = m.getSoftConstraintSystem();
3    var{int}[] X = S.getIntVariables();
4    while(S.violations() > 0)
5      selectMin(i in X.getRange(),
6                v in X[i].getDomain() : X[i]!=v)(S.getAssignDelta(X[i],v))
7        X[i] := v;
8 }
```

Fig. 10 A reusable Min-Conflict Procedure

Case Studies

To explore Constraint-Based Local Search, it is desirable to consider a few applications that are elegantly and effectively solved with COMET. The next three subsections consider the progressive party problem [16], car sequencing [3], and scene allocation [18] as each application illustrates a different aspect.

Progressive Party

The progressive party problem is a standard benchmark in combinatorial optimization, and it illustrates two important features. It shows a rich model with many combinatorial constraints as well as constraints on the truth value of relations. It also shows how soft constraints may be instrumental in obtaining a neighborhood. The goal in this problem is to assign guest parties to boats (the hosts) over multiple time periods. Each guest can visit the same boat only once and can meet every other guest at most once over the course of the party. Moreover, for each time period, the guest assignment must satisfy the capacity constraints of the boats.

Figure 11 depicts the declarative part of the model. The decision variable `boat[g,p]` specifies the boat visited by guest `g` in period `p`. Lines 8–9 specify the alldifferent constraints for each guest, lines 10–11 specify the capacity constraints, and lines 12–13 state that two guests meet at most once during the evening. The `soft(2)` annotations added on lines 9 and 11 are not only specifying that the constraint must be softened, but they also associate a fixed static weight of 2 with each constraint. The weights can be easily incorporated in the inductive definition of $\mathbb{V}(c)$ shown in Fig. 4

$$\mathbb{V}(\texttt{soft}(w) : c) = w \cdot \mathbb{V}(c)$$

to handle *statically weighted* soft constraints.

```
1 range Hosts = 1..13;
2 range Guests = 1..29;
3 range Periods = 1..up;
4 set{int} config[1..6];
5
6 model m {
7    var{int} boat[Guests,Periods](Hosts);
8    forall(g in Guests)
9       soft(2): alldifferent(all(p in Periods) boat[g,p]);
10   forall(p in Periods)
11      soft(2): knapsack(all(g in Guests) boat[g,p],crew,cap);
12   forall(i in Guests, j in Guests : j > i)
13      soft: atmost(1,all(p in Periods) boat[i,p] == boat[j,p]);
14 }
```

Fig. 11 The progressive party problem

The Neighborhood The first sensible neighborhood to consider focuses on reassigning a single variable `boat[g,p]` to a new value. This can follow the same template used for the queens problem. These moves impact the violations of *all* the constraints. However, these moves may also prove too to be restrictive. When an instance is near satisfaction, one can expect most of the bins in any given knapsack to be near full. A single variable reassignment amounts to moving an item from one bin into another and that may prove fruitless from a violation standpoint. A natural idea is to include a *second neighborhood* that considers the exchange of values between two variables appearing in the same constraint. While such swaps have no effects on the `alldifferent` constraints, they can more easily lead to violation improvements for the `knapsack` constraints. Formally, the neighborhood is therefore

$$\begin{aligned} N = \{\sigma[x/v] \quad & | \; x = \arg\max_{z \in X} \downarrow_z (\sigma, \mathbb{V}(S)) \wedge v \in D(x) \setminus \{\sigma(x)\}\} \bigcup \\ \{\sigma[x/c, y/d] \; & | \; x = \arg\max_{z \in X} \downarrow_z (\sigma, \mathbb{V}(S)) \wedge \\ & \quad y \in \bigcup_{c \in S \wedge x \in vars(c)} vars(c) \wedge c = \sigma(y) \wedge d = \sigma(x)\}, \end{aligned}$$

where S is the set of soft constraints.

The code in Fig. 12 implements that idea. The main loop (lines 7–30) seeks to improve the overall violations of the soft constraints. The selector on line 9 picks a variable `boat[g,p]` that induces the most violations. Once the variable is selected, the two *nested* selectors (lines 10–15 and lines 16–22) implement the two parts of the neighborhood structure. Lines 10–15 select the variable with the most violations and choose a new value that decreases its violations the most. The second selector is more interesting. It picks a second variable `boat[g1,p]` in the same

```
1  int tenure = 2;
2  int it = 0;
3  int tabu[Guests,Periods,Hosts] = 0;
4
5  ConstraintSystem<LS> S = m.getSoftConstraintSystem();
6  MinNeighborSelector N();
7  while (S.violations() > 0) {
8     int old = S.violations();
9     selectMax(g in Guests, p in Periods)(S.violations(boat[g,p])) {
10       forall(h in Hosts : tabu[g,p,h] <= it) {
11          neighbor(S.getAssignDelta(boat[g,p],h),N) {
12             tabu[g,p,boat[g,p]] = it + tenure;
13             boat[g,p] := h;
14          }
15       }
16       selectMin(g1 in Guests,d=S.getSwapDelta(boat[g,p],boat[g1,p]))(d) {
17          neighbor(d,N) {
18             tabu[g,p,boat[g1,p]] = it + tenure;
19             tabu[g1,p,boat[g,p]] = it + tenure;
20             boat[g,p] :=: boat[g1,p];
21          }
22       }
23    }
24    if (N.hasMove()) {
25       call(N.getMove());
26       if (violations < old && tenure > 2) tenure = tenure - 1;
27       if (violations >= old && tenure < 10) tenure = tenure + 1;
28    }
29    it = it + 1;
30 }
```

Fig. 12 The search procedure for the progressive party problem

period p as the first variable `boat[g,p]` in such a way that the swap between the two variables has the largest impact on the overall violations of S. Note that both variables appear in the knapsack constraint stated over period p. The remainder of the code (lines 24–28) executes the best move in N (if one exists) and updates the variable tabu tenure. Indeed, it marks assignment moves involving either $boat[g, p]$ or $boat[g1, p]$ and their current host assignment as tabu. (The tabu filter is used on line 10.) The swap operator used on line 20 (`:=:`) atomically exchanges the value of the two variables.

The 30 lines of code are compact and elegant: They benefit from the automation provided by the neighborhood selector, the selectors, and the neighbor construction. Yet, they still require some effort to analyze the model and produce a code template that follows a standard recipe. In addition, this code skeleton must still be updated with classic ideas like search intensification around high-quality local minima and diversification to escape from basins of attraction. However, the steps applied in deriving this search procedure are rather systematic: They rely on an analysis of the

model to recognize the presence of specific types of constraints that then suggest a particular neighborhood structure. That is the idea behind the synthesis of search procedures that is described next.

The Synthesized Search Given that models are first-class objects, COMET can manipulate and analyze them. Here, COMET recognizes the presence of knapsack constraints and generates a *composite* neighborhood consisting of the union of variable assignments and of the variable swaps appearing in violated knapsack constraints, an idea first articulated by Van Hentenryck [19]. The synthesis process per se was described in detail in [24].

The skeleton of a synthesized tabu search is depicted in Fig. 13. It uses the fact that all variables have the same domains. Lines 7–9 associate with each decision variable x_i the set of constraints mentioning x_i and susceptible to benefit from

```
1  function bool refersTo(var{int}[] av,var{int} x) {
2     return or(i in av.rng()) (av[i].getId() == x.getId());
3  }
4  function void minConflictWithSwap(Model<LS> m) {
5     ConstraintSystem<LS> S = m.getSoftConstraintSystem();
6     var{int}[] X = S.getVariables();
7     set{Constraint<LS>} cx[i in X.rng()] =
8                    collect(j in S.rng() : S[j].canUseSwap() &&
9                                 refersTo(S[j].getVariables(),X[i])) S[j];
10    MinNeighborSelector N();
11    int k = 0,tenure = 20;
12    int at[X.rng()] = 0;
13    int mat[X.rng(),X.rng()] = 0;
14    for(int k=0;S.violations() != 0;k++) {
15       selectMax(i in X.getRange())(S.violations(X[i])) {
16          forall(v in X[i].getDomain() : at[i] <= k)
17             neighbor(S.getAssignDelta(X[i],v),N) {
18                X[i] := v;
19                at[i] = k + tenure;
20             }
21          forall(c in cx[i]) {
22             var{int}[] Y = c.getVariables();
23             forall(j in Y.getRange() : mat[i,j] <= k)
24                neighbor(S.getSwapDelta(X[i],Y[j]),N) {
25                   X[i] :=: Y[j];
26                   mat[i,j] = mat[j,i] = k + tenure;
27                }
28          }
29       }
30       if (N.hasMove()) call(N.getMove());
31    }
32 }
```

Fig. 13 The synthesized search procedure for the progressive party problem

exchanging (swapping) the values of two of its variables. This initial step is a straightforward projection of the constraint array in S that only retains constraints that refer to x_i and *can use a swap*. Line 10 defines a neighborhood selector. Line 15 selects the variable x_i with the most violations among the softened constraints S. Lines 16–20 focus on the first part of the neighborhood and consider simple reassignments that lead to the largest violation decrease. All the potential neighbors are submitted to N. Lines 21–29 consider all the constraints referring to variable x_i and for which swaps can be of potential benefit. For each such constraint, the code retrieves the variables of the constraint and accumulates in the selector N all the closures modeling swaps (along with their impact on violations).

It is appealing to notice the similarities between the manual and synthetic implementation. In essence, they both capture the same idea. Yet, the generic code adapts to the model and considers exploiting all the constraints susceptible to profit from swaps. The COMET extension required to do so is a minimal extension to query the capabilities of the constraint in the model.

As shown later, the synthesized search outperforms all published results on this problem. Note that, if the set of required constraints R was not empty (it is empty in this application), the two neighborhoods would have to discard assignments and swaps that yield nonzero values for the calls to `getAssignDelta` and `getSwapDelta` to implement the legality requirement correctly. Finally, observe that this skeleton implementation contains a very simply tabu condition to further restrict the legal moves to those that were not recently attempted; this is achieved with two simple data structures (one per neighborhood) that record the last iteration number when a move was performed. Supporting generic intensification and diversification is equally easy.

Car Sequencing

Figure 14 presents a model for car sequencing. In this application, n cars must be sequenced on an assembly line of length n. The customer demands for car configurations are specified in an array $demand$ and the total demand is, of course, n. Each car configuration may require a different set of options, while capacity constraints on the production units restrict the possible car sequences. For a given option o, these constraints are of the form k out of m meaning that, out of m successive cars, at most k can require o. The model declares the decision variables specifying which type of car is assigned to each slot in the assembly line (line 12). It states a hard constraint specifying which cars must be produced (line 13) and then states the soft capacity constraints for each option (lines 14–15).

The handcrafted search procedure, illustrated in Fig. 15, is modeled after a conflict minimization structure. The initialization satisfies the cardinality constraint by using a random permutation of an array of values that already meet the cardinality requirement (lines 4–7). The main loop (lines 10–27) minimizes the number of violations by selecting the slot of the assembly line causing the most violations

```
// ... read parameters nbCars, nbConfigs, nbOptions
range Cars = 1..nbCars;
range Configs = 0..nbConfigs-1;
range Options = 1..nbOptions;
boolean requires[Configs,Options];
int demand[Configs];
int lb[Options],ub[Options];
// ... read the data ...

set{int} options[o in Options] = setof(c in Configs) requires[c,o];
model m {
   var{int} line[Cars](Configs);
   hard: atmost(demand,line);
   forall(o in Options)
      soft: sequence(line,options[o],lb[o],ub[o]);
}
```

Fig. 14 The car sequencing model

```
ConstraintSystem<LS> S = m.getSoftConstraintSystem();
Solver<LS> ls = m.getLocalSolver();
int best = System.getMAXINT();
int cars[Cars];
int nb = 0;
forall(c in Configs, n in 1..demand[c])
   cars[++nb] = c;
RandomPermutation perm(Cars);
forall(c in Cars) lines[c] := cars[perm.get()]; // Satisfy required constraint
while (S.violations() != 0) {
   selectMax(i in Cars)(S.violations(X[i])) {
      selectMin(j in Cars : line[i] != line[j] && t[i,j] <= it)
         (S.getSwapDelta(line[i],line[j])) {
         X[i] :=: X[j];
         t[i,j] = t[j,i] = it + tenure;
      }
   }
   if (S.violations() < best) { best = S.violations();stable = 0;}
   if (stable == 500) {
      with atomic(ls)
         forall(k in 1..5)
            select(a in Cars,b in Cars : line[a] != line[b]) line[a] :=: line[b];
      stable := 0;
      best = S.violations();
   } else stable++;
   it++;
}
```

Fig. 15 The handcrafted search procedure for car sequencing

and swapping its content with another slot that delivers the most improvements. The move itself appears on line 14. The search features a *diversification* component (lines 19–25) that randomly swaps a subset of slots in the assembly line when no improvement took place for a number of iterations. Each time an improving move is found, the stability counter is reset and the best value for this stage is recorded (line 18).

It is possible to recognize the combinatorial structure present in the model thanks to the presence of global `sequence` constraints and to automatically synthesize a search procedure that matches the ideas present in the handcrafted search procedure. The result is shown in Fig. 16. It depicts a generic tabu search procedure featuring several key components. Note how line 6 of the model retrieves the required

```
1  function void tabuSearch(Model<LS> m) {
2     ConstraintSystem<LS> S = m.getSoftConstraintSystem();
3     ConstraintSystem<LS> R = m.getHardConstraintSystem();
4     Solver<LS> ls = m.getLocalSolver();
5     var{int}[] X = R.getVariables();
6     forall(i in R.getRange()) with atomic(ls) R.getConstraint(i).initialize();
7     Counter it(ls) := 0;
8     Counter stable(ls) := 0;
9     int tenure = 20;
10    int t[X.rng(),X.rng()] = 0;
11    Integer best(System.getMAXINT());
12    whenever S.violations()@changes(int o,int n)
13       if (n < best) { best := n;stable := 0;}
14    whenever it@changes() stable++;
15    whenever stable@changes()
16       if (stable == 500) {
17          with atomic(ls)
18             forall(k in 1..5)
19                select(a in X.rng(),b in X.rng() : X[a] != X[b]) X[a] :=: X[b];
20          stable := 0;
21       }
22    while (S.violations() != 0) {
23       selectMax(i in X.rng())(S.violations(X[i])) {
24          selectMin(j in X.rng() : X[i] != X[j] && t[i,j] <= it)
25             (S.getSwapDelta(X[i],X[j])) {
26             X[i] :=: X[j];
27             t[i,j] = t[j,i] = it + tenure;
28          }
29       }
30       it++;
31    }
32 }
```

Fig. 16 The synthesized tabu search for car sequencing

constraints (line 3) and initializes the start assignment by delegating to each required constraint the task of picking a suitable assignment. A basic requirement for achieving this is the following independence property of the required constraints:

$$\forall c_i, c_j \in R \text{ s.t. } i \neq j : vars(c_i) \cap vars(c_j) = \varnothing.$$

In this case, $R = \{$`atmost(demand,line)`$\}$, and the sole cardinality constraint can create, in polynomial time, an array of values that meet the cardinality requirement and randomly permute it to produce the initial assignment to the variables in $vars(c)$. The algorithm for the cardinality constraint uses a (randomized) feasible flow algorithm to match values to variables. As all variables appear in the cardinality constraint, swapping two variables is feasibility-preserving (the number of cars of each type is unchanged). Moreover, the cardinality constraint is tight, meaning that there is a bijection from variable to value occurrences. The core of the search spans lines 22–31 and features the selection of the most conflicting variable (line 23) together with the variable that yields the largest decrease in violations through a swap (lines 24–25). The actual move is performed on line 26, and the move is marked tabu in line 27.

The implementation of the diversification is more interesting. To modularize the capability, it relies on *events*. In COMET, objects like `Counter`, `Integer`, or `var{int}` are capable of dispatching *notifications* when specific events occur. For instance, a counter issues a *change* event when its value is modified. COMET provides the ability to associate a code fragment with events: The code is then executed in response to these events. This is illustrated on line 14 that states that, each time the iteration counter `it` changes, the stability counter `stable` must increase. Similarly, lines 15–21 specify that, when the stability counter changes, one should check whether it has reached a critical value, 500 in this example, in which case a diversification step is undertaken. This architecture promotes the separation of the diversification logic from the main heuristic. Indeed, the code for the diversification simply dictates how to react to changes to the stability counter, and the COMET platform automatically *weaves* that code in the proper place. Finally, note how recording improvements in the violations is also done through an event hooked on the violations of the entire soft system S.

Scene Allocation

Figure 17 features a model for the scene allocation problem that is sometimes used to compare CP and MIP solvers since it is highly symmetric. The problem consists of assigning specific days for shooting scenes in a movie. There can be at most five scenes shot per day and all actors of a scene must be present. Each actor has a fee and is paid for each day she/he plays in a scene. The goal is to minimize the production cost. The decision variable *scene* (line 12) represents the day a scene is shot. The hard cardinality constraint (line 13) specifies the maximum number of scenes shot

```
1 int maxScene = ...; // read the data
2 int maxDay = ...; // read the data
3 range Scenes = 1..maxScene;
4 range Days = 1..maxDay;
5 enum Actor = ... ; // read the data
6 int pay[Actor] = ...; // read the data
7 set{Actor} appears[Scenes] = ...; // read the data
8 set{int} which[a in Actor] = setof(s in Scenes) member(a,appears[s]);
9 int occur[Days] = ...; // read the data
10
11 model m {
12    var{int} scene[Scenes](Days);
13    hard: atmost(occur,scene);
14    minimize: sum(a in Actor) pay[a]*
15                  (sum(d in Days) (or(s in which[a]) (scene[s] == d)));
16 }
17 generatedTabuSearch(m);
```

Fig. 17 Scene allocation model

on any one day. The objective function minimizes the sum of actor compensations, which is the actor fee times the number of days he/she appears in a scene shot on that day.

The model in Fig. 17 is now a constraint optimization model featuring an objective function that demands a different strategy to obtain a suitable search procedure. In general, it is necessary to juggle three considerations. First, one should maintain the feasibility of the required constraints through a suitable initialization and the selection of moves that never violate the constraints in R. Second, one may have to deal with softened difficult constraints (S) for whom one searches for a feasible solution by driving down the violations. Third, it is essential to drive down the value of the objective function. The latter two considerations (true objective and softened constraint) are naturally conflicting as it is easier to drive the objective function down if one violates difficult constraints and vice versa. The practical response is to rely on a statically or a dynamically weighted sum of the two objectives where the search shifts the emphasis on either considerations by altering the weights.

In this application, $S = \varnothing$ and $R = \{\texttt{atmost}(occur, scene)\}$; hence, the task is somewhat simpler as there is only one component to the objective function. In this case, the generated tabu search is driven by the sole required constraint, but with a significant difference. In the previous example, the soft constraint was tight, a fact detected by the model analysis. Indeed, the cardinality constraint in car sequencing is tight because the assembly line has as many slots as the number of cars to produce. This is not the case here: There are typically fewer scenes than the number of slots in which they can be scheduled, and thus the required constraint is not a bijection between variables and value occurrences. As a result, limiting the neighborhood

only to swaps would preserve the feasibility of the cardinality constraint at the expense of a significant decrease in solution quality. This is not surprising since the neighborhood would no longer be connected. The model analysis however recognizes that the `atmost` constraint is not tight and also considers feasibility-preserving assignments.

The generated skeleton is depicted in Fig. 18. As before, line 5 uses the required constraints to initialize the search to a feasible assignment (once again, the task is delegated to the required constraints and the model analysis ensures that $vars(c_i) \cap vars(c_j) = \varnothing \ \forall\, c_i, c_j \in R$ before generating code). The core of the search spans lines 11–24 and relies on the union of two neighborhoods. Line 12 starts by selecting a variable x_i that can lead to the largest decrease in the objective function. Lines 13–15 consider all the swaps that include x_i and lead to the largest decrease in the objective function (i.e., the most negative delta). The selector on line 13 is semi-greedy and will select, uniformly at random, one of the top-3 such moves. Lines 16–19 are devoted to the second neighborhood and collect the best value to reassign x_i. Line 17 shows the conjunct that eliminates assignments that are not feasible with respect to R. The skeleton search uses a vanilla tabu data structure and omits the diversification component for simplicity.

```
1  function void generatedTabuSearch(Model<LS> m) {
2     Function<LS> obj = m.getObjective();
3     ConstraintSystem<LS> R = m.getHardConstraintSystem();
4     Solver<LS> ls = m.getLocalSolver();
5     forall(i in R.getRange()) with atomic(ls) R.getConstraint(i).initialize();
6     int it = 0,tenure = 20,best = System.getMAXINT();
7     var{int}[] X = obj.getVariables();
8     int tm[X.rng(),X.rng()] = 0;
9     int t[X.rng()] = 0;
10    MinNeighborSelector N();
11    while (it < 10000) {
12       selectMax(i in X.rng())(obj.decrease(X[i])) {
13          selectMin[3](j in X.rng() : i != j && tm[i,j] <= it,
14                       d = obj.getSwapDelta(X[i],X[j]))(d)
15             neighbor(d,N) { X[i] :=: X[j];tm[i,j] = tm[j,i] = it + tenure;}
16          selectMin(v in X[i].getDomain() : t[i] <= it && v != X[i] &&
17                                            R.getAssignDelta(X[i],v)==0,
18                    d = obj.getAssignDelta(X[i],v))(d)
19             neighbor(d,N) { X[i] := v;t[i] = it + tenure;}
20       }
21       if (N.hasMove()) call(N.getMove());
22       if (obj.evaluation() < best) best = obj.evaluation();
23       it++;
24    }
25 }
```

Fig. 18 Generated search for scene allocation

Implementation

The implementation of a Constraint-Based Local Search system critically depends on incremental computation. Constraints and objective functions must respond to their APIs like `violations`, `increase`, `decrease`, or `getAssignDelta` extremely fast in order to consider large neighborhoods and long traces of assignment within an allotted time.

To deliver this performance, the implementation is presented in two distinct layers. The `invariant` layer is responsible for the basic incremental computation that occurs when an assignment is changed through a local move operator. The `differentiability` layer is responsible for implementing the response mechanism behind the constraints and objective function. Their implementation is primarily framed in terms of invariants. Both are highlighted in this section, starting with invariants (section "Invariants") and finishing with differentiation (section "Differentiation").

Invariants

Invariants provide a declarative concept that relieves programmers from the tedious task of maintaining complex data structures incrementally. By focusing on what to maintain, rather than how to maintain assignments under changes, programmers are relieved of an error-prone, yet critical, aspect of implementing constraints and objective functions. In essence, invariants capture the so-called *one-way constraints* [1,2,11,17], namely, they capture the value of an expression that must be maintained over time under changes to the value of its variables. An acyclic network of dependencies connects all the variables of the problems and is responsible for scheduling the evaluations. This subsection reviews examples and outlines the underlying implementation.

Definition 15 (Invariant). An invariant $\mathcal{I}$ is a one-way constraint

$$\langle x_1, \ldots, x_n \rangle \leftarrow f(y_1, \ldots, y_m),$$

where $x_1, \ldots, x_n$ are called invariant variables and $y_1, \ldots, y_m$ are either decision or invariant variables. The set $O = \{x_1, \ldots, x_n\}$ is the output variables of $\mathcal{I}$. The set $I = \{y_1, \ldots, y_m\}$ is the input variables of $\mathcal{I}$. We often abuse notation and rewrite the one-way constraints as

$$O \leftarrow f(I).$$

$\mathcal{I}_O$, $\mathcal{I}_I$, and $\mathcal{I}_f$ denote the output variables, the input variables, and the function of invariant $\mathcal{I}$.

Since invariants are one-way constraints, there are some necessary syntactic restrictions. One such restriction is that no two invariants have a common output variable. This ensures that every invariant variable is defined at most once.

The declarative semantics of an invariant specifies that the one-way constraints always hold.

Definition 16 (Declarative Semantics of an Invariant). Let σ be an assignment before or after any atomic instruction of a program for which the invariant $\mathcal{I}$ has been posted. Then, it follows that

$$\langle \sigma(x_1), \ldots, \sigma(x_n) \rangle \leftarrow f(\sigma(y_1), \ldots, \sigma(y_m)),$$

where $\mathcal{I}_O = \{x_1, \ldots, x_n\}$ and $\mathcal{I}_I = \{y_1, \ldots, y_m\}$. The narrative abuses notation and sometimes writes

$$\sigma(\mathcal{I}_o) \leftarrow \mathcal{I}_f(\sigma(\mathcal{I}_I)).$$

Example 8 (Expression Invariant). The numerical invariant

$$x \leftarrow y + 3 * z$$

stating that, at any point in time, the value of x in an assignment σ, i.e., $\sigma(x)$, should be the value $\sigma(y)$ plus three times the value of $\sigma(z)$.

Operationally, an invariant must maintain the link between its output and input variables under assignments to its input variables. The invariant maintains this link by keeping a local assignment of its input variables and by implementing an update function which updates the global and local assignments to reflect the change in one of its input variables.

Definition 17 (Operational Semantics of an Invariant). Let $\mathcal{I}$ be an invariant. Operationally, $\mathcal{I}$ maintains a local store $\mathcal{I}_\sigma$ over variables $\mathcal{I}_I$ and implements an update procedure $\mathcal{I}_u : \Sigma \times X$. Let $\sigma_l = \mathcal{I}_\sigma$ be the local store of $\mathcal{I}$, σ be an assignment, and $y \in \mathcal{I}_I$. The update procedure $\mathcal{I}_u(\sigma, y)$ performs the following assignments:

$$\begin{aligned} \sigma(\mathcal{I}_O) &:= \mathcal{I}_f(\sigma_l[\sigma(y)/y](\mathcal{I}_I)); \\ \sigma_l(y) &:= \sigma(y); \end{aligned}$$

To propagate a collection of invariants effectively, the implementation constructs an incremental graph.

Definition 18 (Incremental Graph). An incremental graph $G(X \cup I, A)$ is a directed acyclic graph whose vertices coincide with decision variables and invariants,

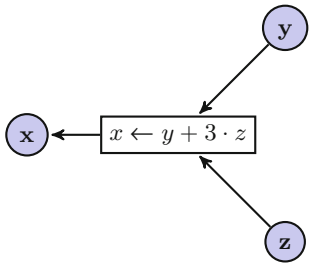

Fig. 19 The dependencies of an arithmetic invariant

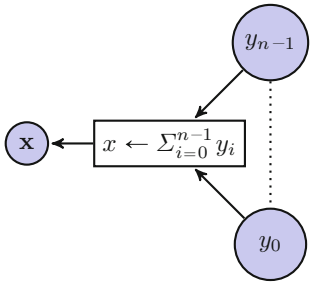
and whose arc set corresponds to the dependencies induced by the invariant. Each invariant $\mathcal{I}$ introduces a dependency $\mathcal{I} \leftarrow y$ for each $y \in \mathcal{I}_I$ and a dependency $x \leftarrow \mathcal{I}$ for each $x \in \mathcal{I}_O$.

Figure 19 depicts the dependencies of the arithmetic invariant presented earlier.

Example 9 (Summation Aggregate). A summation invariant captures the relation

$$x \leftarrow \sum_{i=0}^{n-1} y[i],$$

where n is a constant and y denotes an array of n variables. The dependencies are shown below:



The update function $\mathcal{I}_u(\sigma, y)$ implements the following code:

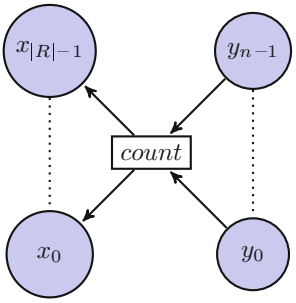
```
1 σ(x) := σ(x) + σ(y) − σ_l(y);
2 σ_l(y) := σ(y);
```

where $\sigma_l = \mathcal{I}_\sigma$.

Example 10 (Counting). A counting invariant $x \leftarrow count(y)$ defined over an array of variables y yields an array of variables x indexed by $R = \bigcup_{i=0}^{n-1} D(y_i)$ that maintains the relations

$$\forall\, v \in R \;:\; x_v = \sum_{i \,\in\, range(y)} (y_i = v)\,.$$

Namely, x_v counts the number of variables in y currently assigned to v. The dependencies are as follows:



and there are $|R| - 1 + n$ of them. The update function $\mathcal{I}_u(\sigma, y)$ implements the following code:

```
1 σ(x_{σ_l(y)}) := σ(x_{σ_l(y)}) − 1;
2 σ(x_{σ(y)}) := σ(x_{σ(y)}) + 1;
3 σ_l(y) := σ(y);
```

where $\sigma_l = \mathcal{I}_\sigma$.

Incremental computation Given $G(X \cup I, A)$, one can obtain a topological sort r of its vertices. Indeed, each dependency $y \leftarrow x$ imposes the constraint

$$1 + r(x) \leq r(y).$$

The partial ordering expressed in r drives the propagation algorithm that updates all the variables following an assignment of new values to decision variables.

Figure 20 shows the pseudo-code for the invariant propagation algorithm. The `propagate` algorithm is invoked with the incremental graph $G(X, A)$, an assignment σ, and the set of decision variables Y that have been updated. Line 3 initializes a priority queue PQ with all the invariants mentioning any member of Y as one of its sources. The priority associated with invariant $\mathcal{I}$ is its topological

```
1  propagate(G(X, A),σ,Y)
2  {
3     PQ = ⋃_{y∈Y} {⟨I ← y, r(I)⟩ ∈ A};
4     while (PQ ≠ ∅) {
5        σ_o := σ;
6        ⟨I ← y, r(I)⟩ := extractMin(PQ);
7        I_u(σ, y);
8        C = {x ∈ I_O : σ_o(x) ≠ σ(x)};
9        forall(x ∈ C)
10          PQ = PQ ∪ {⟨I ← x, r(I)⟩ ∈ A};
11    }
12 }
```

Fig. 20 The invariant propagation

number $r(\mathcal{I})$. The main loop spanning lines 6–11 considers the invariants in priority order (see Line 7). The update function of the selected invariant is executed in Line 8. Line 9 collects in C the modified output variables, and Line 10 enqueues the new invariant to reconsider.

The correctness of the `propagate` algorithm hinges on the facts that $G(X, A)$ is acyclic. The use of topological numbers guarantees that the invariant considered in iteration i is handled only after its sources have reached final values in σ. As long as u meets its specification, the assignment σ is guaranteed to satisfy all the invariants considered in iterations $1..i$. Computing the affected variables in C and scheduling any invariant depending on them cannot possibly schedule an earlier invariant since the graph is acyclic.

Differentiation

The implementation of constraints and objective functions relies on the foundation provided by invariants as first described in [21]. As indicated earlier, the implementation of the constraint API

```
1 interface Constraint<LS> {
2   bool holds();
3   var{int} violations();
4   var{int} violations(var{int} x);
5   int getAssignDelta(var{int} x,int v);
6 }
```

depends on an efficient, incremental evaluation of violations, variable violations, and gradients. The functions $\mathbb{E}(\sigma, e)$, $\mathbb{V}(e)$, $\uparrow_x(\sigma, e)$, $\downarrow_x(\sigma, e)$ are essential to the evaluation of expressions and the definition of violation and gradient expressions from algebraic definitions. Yet, none of them is incremental and therefore unsuitable

for *direct* use in, for instance, Example 5. Likewise, this is true for combinatorial constraints such as `alldifferent`. Invariants do provide the solution, and the subsection focuses on the implementation when constraints are expressed algebraically or combinatorially.

Algebraic and Logical Constraints The key insight to an incremental implementation is to forsake the evaluation function $\mathbb{E}$ and adopt instead a *compilation* approach, generating invariants that evaluate an expression incrementally. This is achieved by Function $\mathbb{I} : \mathcal{E} \rightarrow X \times 2^I$ which is partly shown in Fig. 21 and defined inductively on the structure of expressions. Specifically, a call $\mathbb{I}(e)$ on an expression e produces a decision variable holding the value of the expression and a set of invariants that define this variable.

Note how each line of the inductive definition obtains the variable and invariants supporting the operand and produces a fresh variable alongside an additional invariant based on the variables obtained from the inductive calls on the operands. For instance, the last line of Fig. 21 shows that the compilation of a summation expression inductively obtains a fresh decision variable i_k for each term e_k, as well as the invariants supporting i_k's definition in S_k. It then creates a new fresh variable i_Σ and the summation aggregate invariant that defines it. It finally adds all the invariants in S_k.

Relations simply give rise to arithmetic expressions through the function $\mathbb{V}$ whose definition is in Fig. 3. To obtain an incremental evaluation of the violations of an arbitrary relation $e_1 \diamond e_2$, one can simply obtain the violation expression and compile it with:

$$\langle i_{e_1 \diamond e_2}, S_{e_1 \diamond e_2} \rangle = \mathbb{I}(\mathbb{V}(e_1 \diamond e_2))$$

to retrieve a set of invariants (which it states) and an output variable $i_{e_1 \diamond e_2}$ whose value $\sigma(i_{e_1 \diamond e_2})$ denotes the violations of $e_1 \diamond e_2$ with respect to σ. At this point, the implementation of method `violation()` is straightforward and reduces to

Fig. 21 Compiling expression evaluations to invariants

$$
\begin{array}{ll}
\mathbb{I}(v) & = \langle i_v, \{i_v \leftarrow v \Leftrightarrow v \in \mathbb{R}\}\rangle \\
\mathbb{I}(x) & = \langle i_x, \{i_x \leftarrow x\}\rangle \\
\mathbb{I}(e_1 + e_2) & = \text{let } \langle i_1, S_1\rangle = \mathbb{I}(e_1), \langle i_2, S_2\rangle = \mathbb{I}(e_2) \\
 & \quad \text{in } \langle i_+, \{i_+ \leftarrow i_1 + i_2\} \cup S_1 \cup S_2\rangle \\
\mathbb{I}(e_1 - e_2) & = \text{let } \langle i_1, S_1\rangle = \mathbb{I}(e_1), \langle i_2, S_2\rangle = \mathbb{I}(e_2) \\
 & \quad \text{in } \langle i_-, \{i_- \leftarrow i_1 - i_2\} \cup S_1 \cup S_2\rangle \\
\mathbb{I}(e_1 \times e_2) & = \text{let } \langle i_1, S_1\rangle = \mathbb{I}(e_1), \langle i_2, S_2\rangle = \mathbb{I}(e_2) \\
 & \quad \text{in } \langle i_\times, \{i_\times \leftarrow i_1 \times i_2\} \cup S_1 \cup S_2\rangle \\
\mathbb{I}(\textsc{Abs}(e)) & = \text{let } \langle i_e, S_e\rangle = \mathbb{I}(e) \\
 & \quad \text{in } \langle i_{abs}, \{i_{abs} \leftarrow \textsc{Abs}(i_e)\} \cup S_e\rangle \\
\mathbb{I}(\min(e_1, e_2)) & = \text{let } \langle i_1, S_1\rangle = \mathbb{I}(e_1), \langle i_2, S_2\rangle = \mathbb{I}(e_2) \\
 & \quad \text{in } \langle i_{min}, \{i_{min} \leftarrow min(i_1, i_2)\} \cup S_1 \cup S_2\rangle \\
\mathbb{I}(\sum_{k=0}^{n} e_k) & = \text{let } \langle i_k, S_k\rangle = \mathbb{I}(e_k) \ \forall \ k \ \in 0..n \\
 & \quad \text{in } \langle i_\Sigma, \{i_\Sigma \leftarrow \sum_{k=0}^{n} i_k\} \cup \bigcup_{k=0}^{n} S_k\rangle
\end{array}
$$

returning $\sigma(i_{e_1 \diamond e_2})$. The incremental evaluation of gradients proceeds similarly with the generation of an expression modeling the gradient of e and its compilation with $\mathbb{I}$, i.e.,

$$\langle i_{\downarrow_x(e)}, S_{\downarrow_x(e)} \rangle = \mathbb{I}(\downarrow_x (e)),$$

and $\downarrow_x(e)$ is an expression (independent of σ) whose evaluation wrt σ would yield $\downarrow_x(\sigma, e)$. Similarly a method call `violations(x)` must simply return $\sigma(i_{\downarrow_x(e)})$. Finally, objective functions make a direct use of expressions as well as $\uparrow_x$ and $\downarrow_x$ and are therefore handled exactly like constraints.

Combinatorial Constraints While combinatorial constraints could be implemented in terms of expressions, it is often preferable to exploit the semantics of the constraints to directly produce an incremental implementation. To illustrate the idea, consider the `alldifferent(x)` constraint used in the introductory example and responsible for ensuring that no two entries in x have the same value.

Fundamentally, the constraint should maintain the cardinality of each value used in x and require that no two values have a cardinality larger than 1 to satisfy the constraint. The variable violation for x_i would, in this case, simply be the excess in the number of variables assigned to $\sigma(x_i)$. In essence, when the constraint `alldifferent(x)` is added on an array x with n variables where $\bigcup_{j=1}^{n} D(x_j) = V$, it is sufficient to state the following invariants:

$$\begin{aligned} c &\leftarrow count(x) \\ v_i &\leftarrow \max(0, c_i - 1) \ \forall i \in V \\ cv &\leftarrow \textstyle\sum_{k \in V} v_i \\ vv_j &\leftarrow v_{x_j} \qquad\qquad \forall j \in 1..n. \end{aligned}$$

The implementation of the constraint then reduces to

```
1  class alldifferent implements Constraint<LS> {
2    bool holds() { return σ(cv) == 0;}
3    var{int} violations() { return cv;}
4    var{int} violations(var{int} x) { return vv_id(x);}
5    int getAssignDelta(var{int} x,int v) {
6      if σ(x) == v
7        return 0;
8      else
9        return (σ(c_v) ≥ 1) − (σ(x) ≥ 2);
10   }
11 }
```

where the function `id` is used to identify the variable x by an integer. Note the simplicity of the method implementations that simply leverage the work done

by invariants. Additionally, the implementation does not have to provide any imperative code to handle the changes of decision variables as all of this logic is handled through the invariants. Finally, even the `getAssignDelta(x,v)` implementation remains straightforward. When the current value assignment to variable x is identical to the tentative assignment (v), the function returns 0. Otherwise, it returns the amount of change. Namely, if value v is already used once or more, the number of violations will increase by 1. Similarly, if $\sigma(x)$ is used twice or more, a violation is necessarily lost.

Empirical Results

Offering a comprehensive empirical evaluation of COMET is beyond the scope of this chapter. Yet, the monograph [22] contains an extensive empirical evaluation on many problems and discusses the impact of modeling techniques and search.

Instead, this section focuses on demonstrating the potential behind the synthesis of search procedures. In particular, it explores the performance of the search procedures shown in Figs. 13, 16, and 18 and contrasts them with the results obtained from purely synthesized search procedures in the spirit of [24]. In all cases, the results were obtained on a Core i7 machine clocked at 1.8 Ghz and running OSX 10.10, and the reported results are based on averages collected from 100 runs of each algorithm.

Progressive Party Two instances of the problem (5–7 and 6–7) were used in the evaluation in the following table.

Type	*Choice*	$\|P\|$	μ_{iter}	σ_{iter}	$\mu_T(ms)$	$\sigma_T(ms)$
Manual	5	7	2,360.9	1,386.1	723.9	377.3
Synthetic	5	7	2,282.2	1,495.9	842.5	476.1
Manual	6	7	6,847.8	5,714.7	1,683.0	1,324.4
Synthetic	6	7	4,532.2	4,724.5	1,338.1	1,281.6

The search procedures are extremely similar and only differ in the presence of an adaptive tabu list within the synthetic implementation. It is not surprising to note that both implementations are very close with a slight win for the synthetic search without having to invest any effort in parameter tuning.

Car Sequencing One instance (4–72) was used for car sequencing. In this case, the two implementations seem to exhibit significantly different behaviors as the number of iterations is almost 4 times as high (on average) for the manual implementation. This is most likely due to the difference in parameters and in the components of the meta-heuristics within the synthetic search. It also shows that, without exploring variants of the search procedure, it is not obvious to produce high-quality results.

Yet, the ability to easily exploit, without further ado, restarts, diversification, and intensification components is quite valuable. Lastly, note that the times per iteration of the two searches are quite close ($\frac{19.9}{162{,}944} \approx 1.2 \cdot 10^{-4}$ and $\frac{5.4}{49{,}598.8} \approx 1.1 \cdot 10^{-4}$ with σ_{iter} values of the same order of magnitude as the averages μ_{iter}) showing that the differences only come from the search heuristic and meta-heuristic, not the incremental computation.

Type	*Instance*	μ_{iter}	σ_{iter}	$\mu_T(s.)$	$\sigma_T(s.)$
Manual	4-72	162,944.3	164,853.9	19.9	20.5
Synthetic	4-72	49,598.8	57,815.4	5.4	6.3

Scene Allocation The scene allocation benchmark was used to compare three variants. The manual implementation is in Fig. 18, and two synthetic search procedures are with different parameters, namely, one of them uses 10,000 iterations and no restarts, while the other uses 10 restarts and 1000 iterations per restart. Here, the synthetic search relying on restarting is very close to the custom implementation. Its success rate is 99/100, just shy of a perfect 100 like the custom search. While the synthetic search uses more iterations (on average) to get to the optimum, the runtimes are very close. An examination of the synthesized search reveals that the root cause of the difference is the search heuristic. The equivalent of lines 13 and 17 in Fig. 18 in the synthesized search relies on a purely random selector rather than the more aggressive semi-greedy and greedy selectors used in the custom implementation. This difference explains the loss in greediness and explains the positive impact of restarts.

Type	μ_{iter^*}	σ_{iter^*}	μ_{f^*}	σ_{f^*}	$\#Opt$	$\mu_T(ms)$	$\sigma_T(ms)$
Manual	860	982	334,144	0	100	567.4	46.9
Synthetic (10,000 iters, 1 restart)	2,254	3,104	334,960	1,093	64	731.8	175.6
Synthetic (1000 iters, 10 restarts)	1,954	2,212	334,167	227	99	730.1	71.7

Conclusion

Constraint-based local search is an appealing framework for the design and implementation of local search models for any number of applications. It adopts the core practices of constraint programming through the support of separated components for expressing a declarative model and for programming the search. The declarative models rely on a rich language seamlessly blending algebraic, logical, and combinatorial constraints. The search component itself is exclusively devoted to the automation of the most tedious and error-prone activities that arise when implementing a variety of heuristics and meta-heuristics. Perhaps even more

crucially, search procedures can be written completely independently of the model, making them highly reusable and generic. The culmination of this effort is the availability of synthetic search procedures that take advantage of an analysis of the declarative model to produce sensible search procedures that often compete with tailored, hand-written implementations.

The entire framework competitiveness relies on incremental implementations that are constructed on top of invariants and differentiable abstractions such as constraints and objectives. The net result is a platform for practitioners who would to take advantage of the capabilities of local search techniques without the significant investment necessary to produce an efficient implementation.

Abstract

Guided local search (GLS) is a meta-heuristic method proposed to solve combinatorial optimization problems. It is a high-level strategy that applies an efficient penalty-based approach to interact with the local improvement procedure. This interaction creates a process capable of escaping from local optima, which improves the efficiency and robustness of the underlying local search algorithms. Fast local search (FLS) is a way of reducing the size of the neighborhood to improve the efficiency of local search. GLS can be efficiently combined with FLS in the form of guided fast local search (GFLS). This chapter describes the principles of GLS and provides guidance for implementing and using GLS, FLS, and GFLS. It also surveys GLS' extensions, hybrids, and applications to optimization, especially in routing, including promising emerging approaches on combining GLS with AI.

Introduction

Many practical problems are NP-hard in nature, which means complete, constructive search is unlikely to satisfy our computational demand. Many real-life problems cannot be realistically and reliably solved by complete search. This motivates the development of local search, or heuristic methods.

Local search (LS) is the basis of most heuristic search methods. It searches in the space of candidate solutions.The solution representation issue is significant, though it is not the subject of our discussion here. Starting from a (possibly randomly generated) candidate solution, LS moves to a "neighbor" that is "better" than the current candidate solution according to the objective function. LS stops when all neighbors are inferior to the current solution.

LS can find good solutions very quickly. However, it can be trapped in local optima – positions in the search space that are better than all their neighbors, but not necessarily representing the best possible solution (the global optimum). To improve the effectiveness of LS, various techniques have been introduced over the years. Simulated annealing (SA), Tabu search (TS), and Guided local search (GLS) all attempt to help LS escape local optimum. This chapter focuses on GLS [100], a general meta-heuristic algorithm and its applications. GLS sits on top of other heuristic methods with the aim to improve their efficiency or robustness. GLS has been applied to a nontrivial number of problems and found to be efficient and effective. It is relatively simple to implement and apply, with only a few parameters to tune.

GLS was inspired by GENET [30, 97], a neural network architecture which was developed for constraint satisfaction problems. GLS's and GENET's mechanism for escaping from local minima resembles model-free reinforcement learning [97]. GLS also relates to ideas from the area of search theory on how to distribute the search effort. In particular, incremental distribution of the search effort according to information in a probabilistic framework can be found in a class of methods deriving themselves from the optimal search theory of Koopman [54, 88].

The principles of GLS can be summarized as follows. As a meta-heuristic method, GLS sits on top of LS algorithms. To apply GLS, one defines a set of features for the candidate solutions. When LS is trapped in local optima, certain features are selected and penalized. LS searches the solution space using the objective function augmented by the accumulated penalties.

The novelty of GLS is in the way that it selects features to penalize. GLS effectively distributes the search effort in the search space, favoring promising areas. Penalty modifications regularize the solutions generated by local search to be in accordance to prior or gathered during search information. The approach taken by GLS is similar to that of regularization methods for "ill-posed" problems [95]. The idea behind regularization methods and GLS up to an extent is the use of prior information to help in solving an approximation problem. Prior information translates to constraints which further define our problem reducing so the number of candidate solutions to be considered.

The structure of the chapter is as follows. In section "Guided Local Search," we describe GLS with details about implementing its components. Similarly, the implementation of combining GLS with fast local search is discussed in section "Guided Fast Local Search." Next, in section "GLS Extensions, Hybrids, and Variations," we review other algorithms that extend GLS or hybridize it with other techniques. The section "GLS and Artificial Intelligence" examines emerging and promising approaches combining GLS with AI techniques. GLS's ability to handle multi-objective optimization problems is explored in section "GLS for Multi-objective Optimization." The applications of GLS to the traveling salesman problem and a workforce scheduling problem are explained in sections "GLS Implementation on the Traveling Salesman Problem" and "GLS/GPLS Implementation on a Workforce Scheduling Problem," respectively. We give comprehensive references to the applications of GLS and its variants in section "Overview of GLS Applications" with special focus on recent advances in tackling routing problems, and we conclude in section "Conclusion."

Guided Local Search

As mentioned earlier, GLS augments the given objective function with penalties. To apply GLS, one needs to define features for the problem. For example, in the traveling salesman problem [37], a feature could be *"whether the candidate tour travels immediately from city A to city B."* GLS associates a cost and a penalty with each feature. The costs can often be defined by taking the terms and their coefficients from the objective function. For example, in the traveling salesman problem, the cost of the above feature can simply be the distance between cities A and B. The penalties are initialized to 0 and will only be increased when the local search reaches a local optimum. Given an objective function g that maps every candidate solution s to a numerical value, GLS defines a function h that will be used by LS (replacing g):

$$h(s) = g(s) + \lambda \times \sum_{\text{i is a feature}} (p_i \times I_i(s)) \tag{1}$$

where s is a candidate solution, λ is a parameter of the GLS algorithm, i ranges over the features, p_i is the penalty for feature i (all p_i's are initialized to 0), and I_i is an indication of whether s exhibits feature i:

$$I_i(s) = 1 \text{ if } s \text{ exhibits feature } i; 0 \text{ otherwise.} \tag{2}$$

Sitting on top of local search algorithms, GLS helps them to escape local optima in the following way. Whenever the local search algorithm settles in a local optimum, GLS augments the cost function by adding penalties to selected features. The novelty of GLS is mainly in the way that it selects features to penalize. The intention is to penalize "unfavorable features" or features that "matter most" when a local search settles in a local optimum. A feature with high cost has more impact on the overall cost. Another factor that should be considered is the current penalty value of that feature. The utility of penalizing feature i, $util_i$, under a local optimum s_*, is defined as follows:

$$util_i(s_*) = I_i(s_*) \times \frac{c_i}{1 + p_i} \tag{3}$$

where c_i is the cost and p_i is the current penalty value of feature i. In other words, if a feature is not exhibited in the local optimum (indicated by I_i), then the utility of penalizing it is 0. The higher the cost of this feature (the greater c_i), the greater the utility of penalizing it. Besides, the larger the number of times it has been penalized (the greater p_i), the lower the utility of penalizing it again. In a local optimum, the feature with the greatest $util$ value will be penalized. When a feature is penalized, its penalty value is always increased by 1. The scaling of the penalty is adjusted by λ.

By taking the cost and current penalty into consideration in selecting the feature to penalize, GLS focuses its search effort on more promising areas of the search space: areas that contain candidate solutions that exhibit "good features,"

i.e., features involving lower cost. On the other hand, penalties help to prevent the search from directing all effort to any particular region of the search space.

Naturally the choice of the features, their costs, and the setting of λ may affect the efficiency of a search. Experience shows that the features and their costs normally come directly from the objective function. In many problems, the performance of GLS is not too sensitive to the value λ. It means that not too much effort is required to apply GLS to a new problem. In certain problems, one needs expertise in selecting the features and the λ parameter. Research aiming to reduce the sensitivity of the λ parameter in such cases is reported in [68].

Implementation Guideline

A local search procedure for the particular problem is required for the algorithm to be implemented. Guided local search is repeatedly using this procedure to optimize the augmented objective function of the problem. Each time the local search procedure reaches a local minimum, the augmented objective function is modified by increasing the penalties of one or more of the features present in the local minimum. These features are selected by using the utility function (3). The section below presents and explains the pseudo-code for implementing a guided local search method.

The pseudo-code for the guided local search procedure is depicted in Fig. 1, where p is the problem, g is the objective function, h is the augmented objective function, λ is a parameter, I_i is the indicator function of feature i, c_i is the cost of feature i, M is the number of features, p_i is the penalty of feature i, $CONSTRUCTIONMETHOD(p)$ is the method for constructing an initial solution for problem p, and $IMPROVEMENTMETHOD(s_k, h)$ is the method for improving solution s_k according to the augmented objective function h.

To understand the pseudo-code, let us first explain the methods for constructing and improving a solution, as they are both prerequisites for building a GLS algorithm.

Construction Method

As with other meta-heuristics, GLS requires a construction method to generate an initial (starting) solution for the problem. In the pseudo-code, this is denoted by $CONSTRUCTIONMETHOD$. This method can generate a random solution or a heuristic solution based on some known technique for constructing solutions for the particular problem. GLS is not very sensitive to the starting solution given that sufficient time is allocated to the algorithm to explore the search space of the problem.

Improvement Method

A method for improving the solution is also required. In the pseudo-code, this is denoted by $IMPROVEMENTMETHOD$. This method can be a simple local search algorithm or a more sophisticated one such as variable neighborhood search

```
begin GUIDEDLOCALSEARCH(p, g, λ, [I_1, ..., I_M], [c_1, ..., c_M], M)
1   k ← 0;
2   s_0 ← CONSTRUCTIONMETHOD(p);
3   for i = 1, ..., M do
4       p_i ← 0;
5   end-for;
6   h ← g + λ * ∑ p_i * I_i;
7   while stopping criterion not satisfied do
8       s_{k+1} ← IMPROVEMENTMETHOD(s_k, h);
9       for i = 1, ..., M do
10          util_i ← I_i(s_{k+1}) * c_i/(1 + p_i);
11      end-for;
12      forall i such that util_i is maximum do
13          p_i ← p_i + 1;
14      end-for;
15      k ← k + 1;
16  end-while;
17  s* ← best solution found with respect to objective function g;
18  return s*;
end GUIDEDLOCALSEARCH.
```

Fig. 1 The guided local search algorithm

[44], variable depth search [61], ejection chains [41], or combinations of local search methods with exact search algorithms [77].

It is not essential for the improvement method to generate high-quality local minima. Experiments with GLS and various local heuristics reported in [103] have shown that high-quality local minima take time to produce, resulting in less intervention by GLS in the overall allocated search time. This may sometimes lead to inferior results compared to a simple but more computationally efficient improvement method.

Note also that the improvement method is using the augmented objective function instead of the original one.

Indicator Functions and Feature Penalization

Given that a construction and an improvement method are available for the problem, the rest of the pseudo-code is straightforward to apply. The penalties of features are initialized to zero and they are incremented for features that maximize the utility formula, after each call to the improvement method.

The indicator functions I_i for the features rarely need to be implemented. Looking at the values of the decision variables can directly identify the features present in a local minimum. When this is not possible, data structures with constant time deletion/addition operations (e.g., based on double-linked lists) can incrementally maintain the set of features present in the working solution, thus avoiding the need for an expensive computation when GLS reaches a local minimum.

The selection of features to penalize can be efficiently implemented by using the same loop for computing the utility formula for features present in the local minimum (the other features can be ignored) and also placing features with maximum utility in a vector. With a second loop, the features with maximum utility contained in this vector have their penalties incremented by one.

Parameter λ

Parameter λ is the only parameter of the GLS method (at least in its basic version) and in general is instance dependent. Fortunately, for several problems, it has been observed that good values for λ can be found by dividing the value of the objective function of a local minimum with the number of features present in it. In these problems, λ is dynamically computed after the first local minimum and before penalties are applied to features for the first time. The user only provides parameter α, which is relatively instance independent. The recommended formula for λ as a function of α is the following:

$$\lambda = \alpha * g(x^*)/(\text{no. of features present in } x^*) \tag{4}$$

where g is the objective function of the problem and x^* is a local minimum. Tuning α can result in λ values, which work for many instances of a problem class. Another benefit from using α is that, once tuned, it can be fixed in industrialized versions of the software, resulting in ready-to-use GLS algorithms for the end user.

Augmented Objective Function and Move Evaluations

With regard to the objective function and the augmented objective function, the program should keep track of the actual objective value in all operations related to storing the best solution or finding a new best solution. Keeping track of the value of the augmented objective value (e.g., after adding the penalties) is not necessary since local search methods will be looking only at the differences in the augmented objective value when evaluating moves.

However, the move evaluation mechanism needs to be revised to work efficiently with the augmented objective function. Normally, the move evaluation mechanism is not directly evaluating the objective value of the new solution generated by the move. Instead, it calculates the difference Δg in the objective function. This difference should be combined with the difference in the amount of penalties. This can be easily done and has no significant impact on the time needed to evaluate a move. In particular, we have to take into account only features whose state changes (being deleted or added). The penalties of the features deleted are summed together. The same is done for the penalties of added features. The change in the amount of penalties due to the move is then simply given by the difference:

$$\sum_{\text{over all features j added}} p_j - \sum_{\text{over all features k deleted}} p_k \tag{5}$$

which then has to be multiplied by λ and added to Δg.

Another minor improvement is to monitor the actual objective value not only for the solutions accepted by the local search but also for those evaluated. Since local search is using the augmented objective function, a move that generates a new best solution may be missed. From our experience, this modification does not improve significantly the performance of the algorithm although it can be useful when GLS is used to find new best-known solutions to hard benchmark instances.

Stopping Criterion

There are many choices possible for the stopping criterion. Since GLS is not trapped in local minima, it is not clear when to stop the algorithm. Like other meta-heuristics, we usually resort to a measure related to the length of the search process. For example, we may choose to set a limit on the number of moves performed, the number of moves evaluated, or the CPU time spent by the algorithm. If a lower bound is known, we can utilize it as a stopping criterion by setting the gap to be achieved between the best-known solution and the lower bound. Criteria can also be combined to allow for a more flexible way to stop the GLS method. For practical applications of the algorithm such as the optimal routing of vehicles, the stopping criterion tends to be based on running times and the ability to generate near optimal solutions within seconds given the dynamic nature of these problems [86].

Possible Features for Common Applications

Applying guided local search to a problem requires identifying a *suitable* set of features to guide the search process. Features provide the heuristic search expert with quite a powerful tool since any solution property can be potentially captured and used to guide local search. Usually, we are looking for solution properties, which have a direct impact on the objective function. These can be modeled as features with feature costs equal or analogous to their contribution to the objective

function value. By applying penalties to features, GLS can guide the improvement method to avoid costly ("bad") properties, converging faster towards areas of the search space, which are of high quality.

Features are not necessarily specific to a particular problem and they can be used in several problems of similar structure. Real-world problems, which sometimes incorporate elements from several academic problems, can benefit from using more than one feature set to guide the local search in better optimizing the different terms of a complex objective function.

Below, we provide examples of useful features for several representative problems from various domains.

Routing/Scheduling Problems

In routing/scheduling problems, one is seeking to minimize the time required by a vehicle to travel between customers or for a resource to be set up from one activity to the next. Problems in this category include the traveling salesman problem, vehicle routing problem, machine scheduling with sequence-dependent setup times, and others.

Travel or setup times are modeled as edges in a path or graph structure commonly used to represent the solution of these problems. The objective function (or at least part of it) is given by the sum of lengths for the edges used in the solution.

Edges are ideal GLS features. A solution either contains an edge or not. Furthermore, each edge can be considered to have a feature cost equal to its length. We can define a feature for each possible edge and assign a cost to it equal to the edge length. GLS quickly identifies and penalizes long and costly edges guiding local search to high-quality solutions, which use as much as possible the short edges available.

Assignment Problems

In assignment problems, a set of items has to be assigned to another set of items (e.g., airplanes to flights, locations to facilities, people to work, etc.). Each assignment of item i to item j usually carries a cost, and depending on the problem, a number of constraints are required to be satisfied (e.g., capacity or compatibility constraints). The assignment of item i to item j can be seen as a solution property which is either present in the solution or not. Since each assignment also carries a cost, this is another good example of a feature to be used in a GLS implementation.

In some variations of the problem such as the quadratic assignment problem, the cost function is more complicated and assignments have an indirect impact on the cost. Even in these cases, we found that GLS can generate good results by assigning the same feature costs to all features (e.g., equal to 1 or some other arbitrary value). Although GLS is not guiding the improvement method to good solutions (since this information is difficult to extract from the objective function), it can still diversify the search because of the penalty memory incorporated and it produces results comparable to popular heuristic methods.

Resource Allocation Problems

Assignment problems can be used to model resource allocation applications. A special but important case in resource allocation is when the resources available are not sufficient to service all requests. Usually, the objective function will contain a sum of costs for the unallocated requests, which is to be minimized. The cost incurred when a request is unallocated will reflect the importance of the request or the revenue lost in the particular scenario.

A possible feature to consider for these problems is whether a request is unallocated or not. If the request is unallocated, then a cost is incurred in the objective function, which we can use as the feature cost to guide local search. The number of features in a problem is equal to the number of requests that may be left unallocated, one for each request. There may be hard constraints which state that certain requests should always be allocated a resource, in which case there is no need to define a feature for them. Problems in this category include the path assignment problem [10], maximum channel assignment problem [87], and workforce scheduling problem [13, 22]. Allocation of workloads to data centers in the context of cloud infrastructure using GLS, which represents a more complex real-world application, is discussed in [74].

Constrained Optimization Problems

Constraints are very important in capturing processes and systems in the real world. A number of combinatorial optimization problems deal with finding a solution, which satisfies a set of constraints or, if that is not possible, minimizes the number of constraint violations (relaxations). Constraint violations may have costs (weights) associated with them; in which case the sum of constraint violation costs is to be minimized.

Local search usually considers the number of constraint violations (or their weighted sum) as the objective function even in cases where the goal is to find a solution which satisfies all the constraints. Constraints by their nature can be easily used as features. They can be modeled by indicator functions and they also incur a cost (i.e., when violated/relaxed), which can be used as their feature cost. Problems which can benefit from this modeling include the constraint satisfaction and partial constraint satisfaction problem, the famous SAT and its MAX-SAT variant, graph coloring, various frequency assignment problems [1, 70], and others.

Packing and Placement Problems

GLS has been applied to packing and placement problems where the goal is generally to place or pack as many as possible two-dimensional or three-dimensional shapes or boxes into a set of surfaces or bins [33, 35, 36, 98]. The application of GLS to these problems is often taking a similar approach to constraint optimization problems where local search is attempting to minimize and ultimately eliminate the number of overlaps between shapes or objects (equivalent to constraint violations) by either altering their location, orientation, or allocation to the containing surfaces or bins.

The overall size of the surface or number of bins utilized is typically the overarching optimization criterion. GLS has been tested beyond classical problems in the context of practical applications such as strip packing of irregular shapes [33, 98] and also circuit module placement in VLSI design [36].

Features utilized represent the overlaps to be eliminated with feature cost reflecting the degree of overlap between objects and also the size of the objects where it is assumed that larger objects overlapping are less desirable than smaller ones [35]. In certain problems such as VLSI design, the rectilinear distance between shapes may also be used as feature to minimize the overall wiring required to connect the individual modules of an overall circuit [36].

Guided Fast Local Search

In this section, we look at the combination of guided local search with fast local search, a generalized algorithm for speeding up local search, resulting in the guided fast local search method. Guided fast local search addresses the issue of slow local search procedures and it is particularly useful when applying GLS to tackle large-scale problem instances.

One factor which affects the efficiency of a local search algorithm is the size of the neighborhood. If too many neighbors are considered, then the search could be very costly. This is especially true if the search takes many steps to reach a local optimum, and/or each evaluation of the objective function requires a significant amount of computation. Bentley presented in [19] the *approximate 2-opt* method to reduce the neighborhood of 2-opt in the TSP. We have generalized this method to a method called *fast local search* (FLS). The principle is to use heuristics to identify (and ignore) neighbors that are unlikely to lead to improving moves in order to enhance the efficiency of a search.

The neighborhood chosen for the problem is broken down into a number of small sub-neighborhoods and an activation bit is attached to each one of them. The idea is to scan continuously the sub-neighborhoods in a given order, searching only those with the activation bit set to 1. These sub-neighborhoods are called active sub-neighborhoods. Sub-neighborhoods with the bit set to 0 are called inactive sub-neighborhoods and they are not being searched. The neighborhood search process does not restart whenever we find a better solution but it continues with the next sub-neighborhood in the given order. This order may be static or dynamic (i.e., change because of the moves performed).

Initially, all sub-neighborhoods are active. If a sub-neighborhood is examined and does not contain any improving moves, then it becomes inactive. Otherwise, it remains active and the improving move found is performed. Depending on the move performed, a number of other sub-neighborhoods are also activated. In particular, we activate all the sub-neighborhoods where we expect other improving moves to occur as a result of the move just performed. As the solution improves, the process dies out with fewer and fewer sub-neighborhoods being active until all the sub-neighborhood

bits turn to 0. The solution formed up to that point is returned as an approximate local optimum.

The overall procedure could be many times faster than conventional local search. The bit setting scheme encourages chains of moves that improve specific parts of the overall solution. As the solution becomes locally better, the process is settling down, examining fewer moves and saving enormous amounts of time which would otherwise be spent on examining predominantly bad moves.

Although FLS procedures do not generally find very good solutions, when they are combined with GLS, they become very powerful optimization tools. Combining GLS with FLS is straightforward. The key idea is to associate features to sub-neighborhoods. The associations to be made are such that for each feature we know which sub-neighborhoods contain moves that have an immediate effect upon the state of the feature (i.e., moves that remove the feature from the solution).

By reducing the size of the neighborhood, one may significantly reduce the amount of computation involved in each local search iteration. The idea is to enable more local search iterations in a fixed amount of time. The danger of ignoring certain neighbors is that some improvements may be missed. The hope is that the gain in "search speed" outweighs the loss in "search quality."

Implementation Guideline

Guided fast local Search (GFLS) is more sophisticated than the basic GLS algorithm as it uses a number of sub-neighborhoods, which are enabled/disabled during the search process. The main advantage of GFLS lies in its ability to focus the search after the penalties of features are increased. This can dramatically shorten the time required by an improvement method to re-optimize the solution each time the augmented objective function is modified.

The following provides the pseudo-code for the method and also some suggestions on how to achieve an efficient implementation. We first look at the pseudo-code for fast local search, which is part of the overall guided fast local search algorithm.

Fast Local Search

The pseudo-code for fast local search is given in Fig. 2, where s is the solution, h is the augmented objective function, L is the number of sub-neighborhoods, bit_i is the activation bit for sub-neighborhood i, $MOVESFORSUBNEIGHBOURHOOD(i)$ is the method which returns the set of moves contained in sub-neighborhood i, and $SUBNEIGHBOURHOODSFORMOVE(m)$ is the method which returns the set of sub-neighborhoods to activate when move m is performed.

As explained earlier, the problem's neighborhood is broken down into a number of sub-neighborhoods and an activation bit is attached to each one of them. The idea is to examine sub-neighborhoods in a given order, searching only those with the activation bit set to 1. The neighborhood search process does not restart whenever we find a better solution but it continues with the next sub-neighborhood in the given

```
begin FASTLOCALSEARCH(s, h, [bit_1, ..., bit_L], L)
1   while ∃bit, bit = 1 do
2       for i = 1, ..., L do
3           if bit_i = 1 then
4               MOVES ← MOVESFORSUBNEIGHBOURHOOD(i);
5               forall move m in MOVES do
6                   s' ← m(s);
7                   if h(s') < h(s) then
8                       ACTIVATESET ← SUBNEIGHBOURHOODSFORMOVE(m);
9                       forall sub-neighbourhood j in ACTIVATESET do
10                          bit_j ← 1;
11                      end-for;
12                      s ← s';
13                      GOTO: IMPROVINGMOVEFOUND;
14                  end-if;
15              end-for;
16              bit_i ← 0;
17          end-if;
18      IMPROVINGMOVEFOUND: continue
19      end-for;
20  end-while;
21  return s;
end FASTLOCALSEARCH.
```

Fig. 2 The fast local search algorithm

order. The pseudo-code given above is flexible since it does not specify which bits are initially switched on or off, something which is an input to the procedure. This allows the procedure to be focused to certain sub-neighborhoods and not the whole neighborhood, which may be a large one.

The procedure has two points that need to be customized. The first is the breaking down of the neighborhood into sub-neighborhoods (*MOVESFORSUBNEIGHBOURHOOD* method in pseudo-code). The second is the mapping from moves to sub-neighborhoods for spreading activation (*SUBNEIGHBOURHOODSFORMOVE* method in pseudo-code). Both points are strongly dependent on the move operator used.

In general, the move operator depends on the solution representation. Fortunately, several problems share the same solution representation which is typically based on some well-known simple or composite combinatorial structure (e.g., selection, permutation, partition, composition, path, cyclic path, tree, graph, etc.). This allows us to use the same move operators for many different problems (e.g., 1-opt, 2-opt, swaps, insertions, etc.).

The method for mapping sub-neighborhoods to moves, which is denoted in the pseudo-code by *SUBNEIGHBOURHOODSFORMOVE*, can be defined by looking at the implementation of a typical local search procedure for the problem. This implementation, at its core, will usually contain a number of nested for-loops for generating all possible move combinations. The variable in the outermost loop in the move generation code can be used to define the sub-neighborhoods. The moves in each sub-neighborhood will be those generated by the inner loops for the particular sub-neighborhood index value at the outermost loop.

In general, the sub-neighborhoods can be overlapping. Fast local search is usually examining a limited number of moves compared to exhaustive neighborhood search methods, and therefore, duplication of moves is not a problem. Moreover, this can be desirable sometimes to give a greater range to each sub-neighborhood. Since not all sub-neighborhoods are active in the same iteration, if there is no overlapping, some improving moves may be missed.

The method for spreading activation, denoted by *SUBNEIGHBOURHOODSFORMOVE*, returns a set of sub-neighborhoods to activate after a move is performed. The lower bound for this set is the sub-neighborhood where the move originated. The upper bound (although not useful) is all the sub-neighborhoods in the problem.

A way to define this method is to look at the particular move operator used. Moves will affect part of the solution directly or indirectly while leaving other parts unaffected. If a sub-neighborhood contains affected parts, then it needs to be activated since an opportunity could arise there for an improving move as a result of the original move performed.

The fast local search loop is settling down in a local minimum when all the bits of sub-neighborhoods turn to zero (i.e., no improving move can be found in any of the sub-neighborhoods). Fast local search in that respect is similar to other local search procedures. The main differences are that the method can be focused to search particular parts of the overall neighborhood, and secondly, it is working in an opportunistic way looking at parts of the solution which are likely to contain improving moves rather than the whole solution. In the next section, we look at guided fast local search, which uses fast local search as its improvement method.

Guided Fast Local Search

The pseudo-code for guided fast local search is given in Fig. 3, where *FASTLOCALSEARCH* is the fast local search method as described in section "Fast Local Search," *SUBENEIGHBORHOODSFORFEATURE* is the method which returns the set of sub-neighborhoods to activate when feature i is penalized, and the rest of the

```
begin GUIDEDFASTLOCALSEARCH(p, g, λ, [I_1, ..., I_M], [c_1, ..., c_M], M, L)
1   k ← 0;
2   s_0 ← CONSTRUCTIONMETHOD(p);
3   for i = 1, ..., M do
4       p_i ← 0;
5   end-for;
6   for i = 1, ..., L do
7       bit_i ← 1;
8   end-for;
9   h ← g + λ * Σ p_i * I_i;
10  while stopping criterion not satisfied do
11      s_{k+1} ← FASTLOCALSEARCH(s_k, h, [bit_1, ..., bit_L], L);
12      for i = 1, ..., M do
13          util_i ← I_i(s_{k+1}) * c_i/(1 + p_i);
14      end-for;
15      forall i such that util_i is maximum do
16          p_i ← p_i + 1;
17          ACTIVATESET ← SUBNEIGHBORHOODSFORFEATURE(i);
18          forall sub-neighbourhood j in ACTIVATESET do
19              bit_j ← 1;
20          end-for;
21      end-for;
22      k ← k + 1;
23  end-while;
24  s* ← best solution found with respect to objective function g;
25  return s*;
end GUIDEDFASTLOCALSEARCH.
```

Fig. 3 The guided fast local search algorithm

definitions are the same than those used in the pseudo-code for GLS described in section "Implementation Guideline."

This pseudo-code is similar to that of guided local search explained in section "Implementation Guideline." All differences relate to the manipulation of activation

bits for the purpose of focusing fast local search. These bits are initialized to 1. As a result, the first call to fast local search is examining the whole neighborhood for improving moves. Subsequent calls to fast local search examine only part of the neighborhood and in particular all the sub-neighborhoods that relate to the features penalized by GLS.

Identifying the sub-neighborhoods that are related to a penalized feature is the task of the *SUBENEIGHBORHOODSFORFEATURE* method. The role of this method is similar to that of the *SUBNEIGHBOURHOODSFORMOVE* method in fast local search (see section "Fast Local Search"). The *SUBENEIGHBORHOODSFORFEATURE* method is usually defined based on an analysis of the move operator. After the application of penalties, we are looking for moves which remove or have the potential to remove penalized features from the solution. The sub-neighborhoods, which contain such moves, are prime candidates for activation. Specific examples will be given later in the chapter and in the context of GLS applications.

GLS Extensions, Hybrids, and Variations

GLS is closely related to other heuristic and meta-heuristic methods. In this section, we shall review the different variations, hybrids, and extensions of GLS and FLS that have been developed over the years.

Extensions to GLS

GLS is closely related to other heuristic and meta-heuristic methods. This motivates the adoption of ideas borrowed from other meta-heuristics in GLS. For example, taboo lists and aspiration ideas from tabu search have been used in versions of GLS. Resembling the tabu list idea, a limited number of penalties are used when GLS is applied to the radio link frequency assignment problem [70]. When the list is full, old penalties are overwritten [102]. The motive is that if too many penalties are built up during the search, the local search could be misguided. In another GLS work, aspiration is used to favor promising moves [68].

Tairan and Zhang in [91] studied how to enhance the performance of GLS through designing a cooperative mechanism based on the proximate optimality principle (POP). The idea is to run multiple agents of GLS and during the search the agents exchange their obtained information about the previous search to make their further search more rational. Based on POP, they suggested that common features that appear in many locally optimal solutions of GLS agents are more likely to be parts of the globally optimal solution. Thus, this property should be taken into consideration in the penalization stage during the search. The effectiveness of the proposed cooperative method was demonstrated through high-quality results obtained in the TSP. A similar approach, again in the context of the TSP, is presented in [2] where the agents exchange information utilizing the crossover operator to preserve the good components of the best solutions found by the agents during the search.

GLS Hybrids

Being simple and general, GLS ideas can easily be combined with other techniques. GLS has been hybridized with several meta-heuristics creating efficient frameworks which were successfully applied to several applications. Below, we review and comment on some of these hybrids of GLS.

As a meta-heuristic method, GLS can also sit on top of genetic algorithms (GA). This has been demonstrated in the guided genetic algorithm (GGA) [57–59]. GGA is a hybrid of GA and GLS. It is designed to extend the domain of both GA and GLS. One major objective is to further improve the robustness of GLS. It can be seen as a GA with GLS to bring it out of local optima: if no progress has been made after specific iterations (this number is a parameter of GGA), GLS modifies the fitness function (which is the objective function) by means of penalties, using the criteria defined in (Eq. 3). GA will then use the modified fitness function in future generations. The penalties are also used to bias crossover and mutation in GA – genes that contribute more to the penalties are more likely to be changed by these two GA operators. This allows GGA to be more focused in its search.

On the other hand, GGA can roughly be seen as a number of GLSs running in parallel from different starting points and exchanging material in a GA manner. The difference is that only one set of penalties is used in GGA, whereas parallel GLSs could have used one independent set of penalties per run. Besides, learning in GGA is more selective than parallel GLS: the updating of penalties is only based on the best chromosome found at the point of penalization.

GLS was hybridized with two major evolutionary computation (EC) techniques, namely, estimate distribution algorithm (EDA) and evolution strategy (ES). The hybrid of GLS with EDA was introduced by Zhang et al. [112]. They proposed a framework that incorporates GLS within EDA, in which GLS is applied to each solution in the population of EDA. The framework is successfully applied to the quadratic assignment problem. The results show the superiority of EDA/GLS over GLS alone.

The hybrid of GLS with ES was first studied by Mester and Braysy [65]. The resulting framework combines GLS and ES into an iterative two-stage procedure called active guided evolution strategies (AGES). GLS is used in both phases to improve the local search in the first stage and to regulate the objective function and the neighborhood of the modified ES in the second stage. The principle of FLS is also incorporated into the idea of penalty variable neighborhood in which the neighborhood considered by the local search is limited to a small set of the neighbors of the penalized feature.

GLS has also been hybridized with variable neighborhood search (VNS) and large neighborhood search (LNS). Kytojoki et al. [55] combine GLS with VNS in an efficient variable neighborhood search heuristic, named guided VNS (GVNS), which was applied to the vehicle routing problem. The addition to VNS is the use of GLS to escape local minima. The idea of threshold value borrowed from threshold accepting (TA) is used as a termination condition for every GLS stage. The hybrid of GLS with LNS is introduced in [106]. In the proposed framework, LNS is applied when the GLS cannot escape a local optimum after a number of

penalizations, with the aim of increasing the diversity and exploring more promising parts of the search space. The effectiveness of this hybrid was demonstrated through high-quality results obtained in a planning optimization problem.

Guided tabu search (GTS) is a hybrid meta-heuristic which combines GLS with TS proposed by Tarantilis et al. [93, 94] to solve the vehicle routing problem with heterogeneous fleet and then extended to solve another variant of the same general problem. The basic idea is to control the exploration of TS by a guiding mechanism, based on GLS, that continuously modifies the objective function of the problem. The authors propose a new arc (as a feature) selection strategy which considers the relative arc length according to the rest of the customers ($d_{i,j}/avg_{i,j}$ rather than $d_{i,j}$, where $avg_{i,j}$ is the average value of all outgoing arcs from i and j). They argue that this would lead to a more balanced arc selection, which should improve upon the most frequently employed strategy based on $d_{i,j}$ only. Experimental results confirm the effectiveness of GTS, producing new best results for several benchmarks. De Backer et al. [14] also proposed a guided tabu search hybrid in their work on the vehicle routing problem (VRP). Bai et al. [15] proposed a multi-start GLS variant assisted by tabu search for the freight service design problem.

GLS has been also successfully hybridized with ant colony optimization (ACO) by Hani et al. [43]. This hybrid algorithm was applied to the facility layout problem, a variant of the quadratic assignment problem (QAP). The basic idea is simple: GLS sits on top of the basic LS in the ACO.

The hybridization of GLS and constraint programming (CP) was introduced by Gomes et al. [42]. This method, named guided constraint search, borrows ideas from GLS to improve the efficiency of pure CP methods. The basic principle is to use a fitness function to choose at each iteration only the N most promising values of each variable's domain, defining a subspace for the CP method. The selection strategy is inspired from GLS; for each pair, a utility function, penalty parameter, and cost are defined. At each iteration, those features (variable/value pairs) which were considered but did not belong to new best solution are deemed bad features and they are penalized.

Variations of GLS

The success of GLS motivated researchers to invent new algorithms inspired from GLS, borrowing the ideas of features, penalties, and utilities. Below, we briefly describe such GLS-inspired algorithms.

Partially based on GLS, which is a centralized algorithm, Basharu et al. [18] introduce an improved version for solving distributed constraint satisfaction problems. The distributed guided local search (Dis-GLS) incorporates additional heuristics to enhance its efficiency in distributed scenarios. The algorithm has been successfully applied to the distributed version of the graph coloring problem producing promising results compared to other distributed search algorithms.

Hifi et al. [46] introduced a variant of GLS by proposing a new penalization strategy. The principle is to distinguish two phases in the search process, namely, the

penalty and normal phases. The search process switches between the two phases in order to either escape local optima or diversify the search to explore another feasible space. The computational results confirm the high quality of solutions obtained by the proposed variant.

Tamura et al. [92] propose an improved version of GLS, named the objective function adjustment (OA) algorithm which incorporates the idea of features (from GLS) alongside the concept of energy function.

Shi et al. [85] modified the penalization mechanism of GLS in the form of elite-based GLS (EB-GLS). EB-GLS records and updates an elite solution, which is the best solution found so far during the search. Features present in the recorded elite solution are more likely to be part of a global optimum; thus, EB-GLS reduces the probabilities of these features being penalized. This introduces an additional intensification mechanism which according to the authors of [85] may perform well for problems where high-quality solutions are closely clustered together.

Vansteenwegen et al. [99] introduced a diversification modification instead. In addition to penalizing features included in the current local optimum, features not included undergo an inverse version of the penalizing mechanism rewarding them instead.

In the GLS variant proposed by Zhong and Cole [113] for the vehicle routing problem, only features whose utilities are larger than a certain value are penalized. Furthermore, penalties have an upper bound introduced.

GLS and Artificial Intelligence

The GLS algorithm has its roots in artificial intelligence. It was inspired by GENET [30, 97] a neural network architecture for solving constrain satisfaction problems. Furthermore, both GLS and GENET adopt an approach to escaping local minima which is closing resembling reinforcement learning [97]. With the resurgence of AI and in particular developments in deep learning and large language models, there has been recent research on leveraging GLS in combination with AI approaches.

GLS features and associated costs can be the subject and outcome of a learning process with the view of optimizing algorithmic performance. More specifically, GNNGLS by Hudson et al. [49] and neural-GLS by Sui et al. [89] both adopt neural network models to learn the feature costs (referred to as "regret) ahead of applying GLS to random and classic TSP instances. In [49], a graph neural network is deployed for this task, while in [89] a graph convolutional network is considered alongside a more complicated strategy with better overall performance. Considering the reverse paradigm, GLS can be utilized to improve the training performance of neural networks. An example of such an approach is present in [45] in the context of a robotic-assisted intelligence system.

Variants of GLS based on different feature definitions, feature costs, construction heurists, and local search methods can be synthesized by LLMs evolving the structure of the algorithm and subsequently altering and optimizing further its performance. Liu et al. [62] proposed such a large language model framework

named AEL-GLS to maintain a population of GLS algorithms for the TSP. AEL-GLS utilizes a general evolutionary framework, comprising initialization, crossover, and mutation, to evolve new algorithms. The generation of novel GLS algorithms occurs during population initialization, as well as through crossover and mutation operations in the evolutionary process. The introduction of LLM enables such algorithm-level creations. The algorithm evolution process is entirely automated, without any human intervention.

In another example of this approach, ReEvo presented in [108] also maintains and evolves a population of GLS variants for the TSP, where insights and knowledge are verbalized as long-term reflections and accumulated throughout iterations to accelerate and improve heuristic design. The more elaborate approach of ReEvo compared to AEL-GLS claims to reduce running times from days in [62] to less than an hour in [108] with ability to generate a GLS variant that outperforms both human-designed and machine-designed variations of the method.

Another promising direction, not fully explored, is that of combining software agents and GLS. In a typical setup (e.g., see [16,91]), a collection of software agents using GLS cooperate to solve a problem by evolving a population of solutions. The approach has found application in the context of the dynamic VRP which requires periodic re-optimization of static subproblems, including requests, which have already arrived to the system as this is explained in [17].

We expect more research to emerge combining agents with deep learning and LLMs to evolve and apply GLS variants (or variants of other meta-heuristics for that matter) in the context of addressing large-scale and dynamic real-world problems. Individual agents could be seen applying deep learning and LLMs to improve the search heuristics they deploy as they gain experience from solving a series of problems within a specific domain while, in parallel, they also collaborate with other agents to share the search workload. This is essential so that rapid responses are achieved against even the largest and most dynamic real-world problems.

GLS for Multi-objective Optimization

Most real-world optimization problems are multi-objective in nature. The multi-objective optimization problem (MOP) concerns the optimization of two or more objectives simultaneously. Instead of searching for a global optimum solution as in single-objective optimization problems, the search in MOPs targets a set of solutions representing the optimum set of trade-offs between the objectives. This set is known interchangeably as the Pareto optimum set or the efficient solutions, and the objective values of these solutions are located at the Pareto front (PF). Efficient solutions are nondominant solutions in the sense that improving the value of any one of their objectives must be at the expense of degrading the quality of one or more of the other objectives. Thus, all efficient solutions are considered equivalent as long as there is no further information regarding the relative importance of each of the objectives.

Pareto Local Search

A simple, intuitive adaptation of local search to contain multiple objectives is to apply the Pareto domination as an acceptance criterion when comparing the current solution to the new one. An archive of nondominant solutions discovered during the search is maintained in order to produce an approximation to the PF. The algorithm stops when the neighborhood of all solutions in the archive have been explored, i.e., the archive is a Pareto local optimum set. Recently, this idea was termed Pareto local search (PLS) and has been developed and extended by several researchers such as in [73]. PLS can be outlined, from a high-level perspective, as follows:

1. It starts with a randomly or heuristically generated solution that is added to the $archive$.
2. A non-visited candidate solution in the $archive$ is randomly chosen, and its neighborhood is explored while applying a first-improvement strategy (i.e., any better solution found is accepted immediately, and its neighborhood is explored for further improvement). This is an iterative step which is applied every time a new better solution is found and accepted.
3. The $archive$ is updated with any non-dominated neighbor, i.e., the new neighbor is added to the $archive$ only if it is non-dominated by another solution in the $archive$, and then all existing solutions that are dominated by the new neighbor are removed from the $archive$.
4. The exploration of the neighborhood of the current solution stops when all of the neighbors are visited. When the exploration stops, the current solution is considered as a Pareto local optimum.
5. The current solution is marked as being visited.
6. The procedure continues at step 2, while there is a solution in the $archive$ that is not visited.

The PLS returns the $archive$, which is a *Pareto local optimal set*.

Guided Pareto Local Search

Guided Pareto local search (GPLS) [6, 7] extends the guidance approach in GLS to guide PLS to escape Pareto local optimum sets. The only change that GPLS makes to the underlying PLS is the replacement of each objective function g_i with an augmented objective function h_i during the evaluation of neighbor solutions. The augmented functions are not used in the updating procedure of the *archive*, which always depends only on the original objective functions.

In GPLS, the definition of features has to be derived from all objectives. Thus, a set (or multiple sets) of features has to be defined, which will be shared by all solutions. In multi-objective optimization problems, one should take into consideration two different scenarios:

1. All objectives have the same structure (e.g., putting an item in all knapsacks in the Knapsack problem, or an edge in the multi-objective TSP), and therefore, they share one defined feature set. However, the cost of a feature varies according to a particular objective. In order to define the cost of a feature in this case, the influence of the feature on each objective has to be considered and modelled into a single cost function. Such models include, for example, (weighted) aggregating approaches and other general functions such as min, max, or mean.
2. A distinct feature set needs to be defined for each objective, and a cost is associated with each feature to describe its influence on the corresponding objective. In this case, features from all feature sets should be considered at the penalization phase to pick one or more features to penalize.

The guidance strategy that GLS employs relies on penalizing some features exhibited by the recent local optimum. As described in section "Guided Local Search," the novelty of GLS is mainly in the way it selects features to penalize. The target is to penalize "bad features" when the local search settles in a local optimum. Two factors affect the utility of a feature, namely, its cost and the frequency of penalizing this feature in previous penalizations.

GPLS deals with a Pareto local optimum set instead of a local optimum. A straightforward penalization strategy is to evaluate the utility of all features exhibited by *any* nondominant solution in the *archive* and penalize features with maximum utility (Eq. 3). However, this simple strategy does not incorporate any information from the *archive* (i.e., the Pareto local optimum set). An example of important information that can be extracted from the *archive* is the number of nondominant solutions that exhibit a particular feature. This is another factor that can be incorporated into the utility function, such that the more Pareto local optima that exhibit a feature, the greater its utility of penalization. Recall that when a feature is penalized, only those Pareto local optima that exhibit the penalized feature will have the chance to escape. Therefore, increasing the utility of penalizing a feature that occurs in many Pareto local optima would enhance the chance of escaping a Pareto local optimum set by restarting from more solutions. It would also help to prevent the search from directing all its efforts towards any particular region of the PF, which therefore leads to a better spread over the PF. Bad features, in terms of their cost, are hoped to be removed either during the next calls of PLS or by future penalization.

The utility function, as stated in Eq. 3, is redefined to incorporate the number of solutions in the Pareto local optimum set that exhibits this feature (γ_i):

$$util_i(archive) = I_i(archive) \times \frac{c_i \times (\gamma_i / |archive|)}{1 + p_i} \tag{6}$$

where $archive$ is a Pareto local optimum set, $I_i(archive)$ indicates whether "at least" one solution in the *archive* exhibits feature i, c_i the feature's cost, p_i the

penalty, and $|archive|$ is the size of the Pareto local optimum set. The feature with the greatest $util$ value will be penalized. When a feature is penalized, its penalty value is always incremented by 1.

This utility function redefines the term "bad feature." If a feature is not exhibited in the Pareto local optimum set (indicated by I_i), then the utility of penalizing it is 0. The higher the cost of this feature (the greater c_i) and the more nondominant solutions exhibiting it (the greater γ_i), the greater the utility of penalizing it. Furthermore, the more times that it has been penalized (the greater p_i), the lower the utility of penalizing it again.

Having penalized a feature, all solutions in the $archive$ that exhibit this feature need to be marked as "non-visited," so as to be considered by the PLS method in the next iteration.

The lambda parameter λ is the only parameter to GLS which determines the scaling of the penalty. In multi-objective scenarios each objective ideally has its own lambda, which is calculated as a function of a local optimum with respect to the correspondent objective. Thus, GPLS requires a set of lambda parameters: $[\lambda_1, \cdots, \lambda_k]$, where λ_i is a parameter for the objective h_i. Recall that lambda can be dynamically computed after the first local optimum and before penalties are applied to features for the first time (Eq. 4).

GPLS proves its effectiveness to converge quite quickly, however, at the middle area of the Pareto front [7]. In [8], the speedy convergence property of GPLS is utilized, and the performance of GPLS is further enhanced by coupling it with an efficient initial solution set. Two GPLS-based frameworks are proposed, both of which require such an efficient initial solution set. The first framework applies the standard GPLS, after filling its archive with the initial set. The second framework is a parallel version of GPLS, where each independent GPLS run takes a solution from the initial set as a starting point. GPLS and its frameworks are successfully applied to the 0/1 multi-objective knapsack problem [7], the multi-objective TSP [6], and the empowerment-based workforce scheduling problem [6].

Other Attempts

Apart from GPLS, Alhindi et al. [4, 5] propose an idea of using GLS, as a heuristic local search procedure specific for single-objective optimization, in multi-objective evolutionary algorithms (MOEAs). In this work, GLS and multi-objective evolutionary algorithm based on decomposition (MOEA/D) [111] are combined to propose a highly efficient algorithm for solving MOPs. To this end, a combination of MOEA/D with GLS, called MOEA/D-GLS, is proposed. In MOEA/D-GLS, a MOP is decomposed into a number of single-objective subproblems. The subproblems are optimized in parallel by using neighborhood information and problem-specific knowledge. In the proposed work, GLS alternates between those subproblems to help them escape local Pareto optimal solutions. More specifically, for a subproblem

trapped in a local Pareto optimal solution, the GLS starts from its solution and constructs a transformation function (i.e., augmented function). Then, GLS optimizes the augmented function in order to identify a new better solution. The algorithm has been successfully applied to the multi-objective traveling salesman problems.

GLS Implementation on the Traveling Salesman Problem

For illustration, the implementation details of GLS on the TSP is discussed in this section. The TSP is chosen here as it is the most significant application of GLS. The full details about the application of GLS to the TSP is given in [103].

Problem Description

There are many variations of the traveling salesman problem (TSP). Here, we examine the classic symmetric TSP. The problem is defined by N cities and a symmetric distance matrix $D = [d_{ij}]$ which gives the distance between any two cities i and j. The goal is to find a tour (i.e., closed path), which visits each city exactly once and is of minimum length. A tour can be represented as a cyclic permutation π on the N cities if we interpret $\pi(i)$ to be the city visited after city i, $i = 1, \ldots, N$. The cost of a permutation is defined as:

$$g(\pi) = \sum_{i=1}^{N} d_{i\pi(i)} \tag{7}$$

and gives the cost function of the TSP.

Local Search

Solution Representation

The solution representation usually adopted for the TSP is that of a vector which contains the order of the cities in the tour. For example, the ith element of the vector will contain an identifier for the ith city to be visited. Since the solution of the TSP is a closed path, there is an edge implied from the last city in the vector to the first one in order to close the tour. The solution space of the problem is made of all possible permutations of the cities as represented by the vector.

Construction Method

A simple construction method is to generate a random tour. If the above solution representation is adopted, then all that is required is a simple procedure, which

generates a random permutation of the identifiers of the cities. More advanced TSP heuristics can be used if we require a higher-quality starting solution to be generated. This is useful in real-time/online applications where a good tour may be needed very early in the search process in case the user interrupts the algorithm. If there are no such concerns, then a random tour generator suffices since the GLS meta-heuristic tends to be relatively insensitive to the starting solution and capable of finding high-quality solutions even if it runs for a relatively short time.

Improvement Method

Most improvement methods for the TSP are based on the k-opt moves. Using k-opt moves, neighboring solutions can be obtained by deleting k edges from the current tour and reconnecting the resulting paths using k new edges. The k-opt moves are the basis of the three most famous local search heuristics for the TSP, namely, *2-opt* [27], *3-opt* [60], and *Lin-Kernighan (LK)* [61].

The reader can consider using the simple 2-opt method, which in addition to its simplicity is very effective when combined with GLS. With 2-opt, a neighboring solution is obtained from the current solution by deleting two edges, reversing one of the resulting paths and reconnecting the tour. In practical terms, this means reversing the order of the cities in a contiguous section of the vector or its remainder depending on which one is the shortest in length.

Computing incrementally the change in solution cost by a 2-opt move is relatively simple. Let us assume that edges e1 and e2 are removed and edges e3 and e4 are added with lengths d1, d2, d3, and d4, respectively. The change in cost is the following:

$$d3 + d4 - d1 - d2. \tag{8}$$

When we discuss the features used in the TSP, we will explain how this evaluation mechanism is revised to account for penalty changes in the augmented objective function.

Guided Local Search

For the TSP, a tour includes a number of edges and the solution cost (tour length) is given by the sum of the lengths of the edges in the tour (see Eq. (7)). As mentioned in section "Routing/Scheduling Problems," edges are ideal features for routing problems such as the TSP. First, a tour either includes an edge or not, and second, each edge incurs a cost in the objective function which is equal to the edge length, as given by the distance matrix $D = [d_{ij}]$ of the problem. A set of features can be defined by considering all possible undirected edges $e_{ij}(i = 1 \ldots N, j = i + 1 \ldots N, i \neq j)$ that may appear in a tour with feature costs given by the edge lengths d_{ij}. With each edge e_{ij} connecting cities i and j

is attached a penalty p_{ij} initially set to 0 which is increased by GLS during the search. When implementing the GLS algorithm for the TSP, the edge penalties can be arranged in a symmetric penalty matrix $P = [p_{ij}]$. As mentioned in section "Guided Local Search," penalties have to be combined with the problem's objective function to form the augmented objective function which is minimized by local search. We therefore need to consider the auxiliary distance matrix:

$$D' = D + \lambda \cdot P = [d_{ij} + \lambda \cdot p_{ij}]. \tag{9}$$

Local search must use D' instead of D in move evaluations. GLS modifies P and (through that) D' whenever the local search reaches a local minimum.

In order to implement this, we revise the incremental move evaluation formula (Eq. 8) to take into account the edge penalties and also parameter λ. If $p1$, $p2$, $p3$, and $p4$ are the penalties associated with edges $e1$, $e2$, $e3$, and $e4$, respectively, the revised version of (Eq. 8) is as follows:

$$(d3 + d4 - d1 - d2) + \lambda * (p3 + p4 - p1 - p2). \tag{10}$$

Similarly, we can implement GLS for higher-order k-opt moves.

The edges penalized in a local minimum are selected according to the utility function (Eq. 3), which for the TSP takes the form:

$$Util(tour, e_{ij}) = I_{e_{ij}}(tour) \cdot \frac{d_{ij}}{1 + p_{ij}}, \tag{11}$$

where

$$I_{e_{ij}}(tour) = \begin{cases} 1, & e_{ij} \in tour \\ 0, & e_{ij} \notin tour. \end{cases} \tag{12}$$

The only parameter of GLS that requires tuning is parameter λ. Alternatively, we can tune the parameter α parameter which is defined in section "Implementation Guideline" and is relatively instance independent. Experimenting with α on the TSP, we found that there is an inverse relation between α and local search effectiveness. Not so effective local search heuristics such as 2-opt require higher α values compared to more effective heuristics such as 3-opt and LK. This is probably because the amount of penalty needed to escape from local minima decreases as the effectiveness of the heuristic increases explaining why lower values for α (and consequently for λ which is a function of α) work better with 3-opt and LK. For 2-opt, the following range for α generates high-quality solutions for instances in the TSPLIB [79]:

$$1/8 \leq \alpha \leq 1/2. \tag{13}$$

The reader may refer to [103] for more details on the experimentation procedure and the full set of results.

Guided Fast Local Search

We can exploit the way local search works on the TSP to partition the neighborhood in sub-neighborhoods as required by guided fast local search. Each city in the problem may be seen as defining a sub-neighborhood, which contains all 2-opt edge exchanges removing one of the edges adjacent to the city. For a problem with N cities, the neighborhood is partitioned into N sub-neighborhoods, one for each city in the instance.

The sub-neighborhoods to be activated after a move is executed are those of the cities at the ends of the edges removed or added by the move.

Finally, the sub-neighborhoods activated after penalization are those defined by the cities at the ends of the edge(s) penalized. There is a good chance that these sub-neighborhoods will include moves that remove one or more of the penalized edges.

GLS/GPLS Implementation on a Workforce Scheduling Problem

The Workforce Scheduling Problem (WSP) is another application of GLS, which is chosen here as another illustrative example. It is chosen since both GLS and GPLS have been applied to two different versions of WSP. The implementation of GLS/GPLS components are provided here, and for full details the reader is referred to [6, 9, 96].

Problem Description

The WSP is basically the problem of allocating a set of technicians (resources): $R = \{r_1, r_2, \ldots, r_{|R|}\}$, to a set of tasks; $T = \{t_1, t_2, \ldots, t_{|T|}\}$. A task t is described by a 5-tuple:

$$< c_t, dur_t, reqSkill_t, [start_t, end_t], loc_t >$$

where c_t is a predefined priority which determines its importance to the company. The higher the value of c_t, the more important the task will be, and $c_t \in \Re$. dur_t is the expected duration a technician requires to finish this task. Each task requires a technician with a particular skill $reqSkill_t \in SkillSet$, where $SkillSet$ is the set of all skills: $SkillSet = \{skill_1, \ldots, skill_{|S|}\}$. A task t must be serviced within a predefined time window described by $[start_t, end_t]$. Tasks are geographically distributed, and the location of a task is denoted by loc_t.

Each technician $r \in R$ is described by the following triple:

$$< [start_r, end_r], skills_r, loc_r > .$$

Each technician has a limited shift hours where the beginning and end of the shift are expressed by $[br_r, er_r]$. $skills_r$ denotes the skill(s) a technician has, where $skills_r \subseteq SkillSet$. There is no single depot for technicians to start from, as they can start from home or from one of predefined depots. The location of a technician is denoted by loc_r.

There are two sets of decision variables in the WSP: the allocation variables $X = \{x_{rt} | r \in R; t \in T; x_{rt} \in \{0, 1\}\}$ and the service times $ServTime = \{st_t | t \in T\}$. A variable x_{rt} is set to 1 if the technician r is allocated to the task t, and 0 otherwise. A variable st_t denotes the start time of service for task t.

Having decided these variables, a set of routes $\pi = \{\pi_r | r \in R\}$ are defined. A route π_r is a sequence of tasks ($\subseteq T$) that are to be visited by technician r; $\pi_r = (\pi_{r1}, \cdots, \pi_{r\sigma_r}), 1 \leq \sigma_r \leq |T|$.

A main objective is to maximize the number of allocated tasks with respect to their priorities while satisfying all assignment and routing constraints.

The WSP can, then, be mathematically modelled as follows:

$$max \qquad \frac{\sum_{r \in R} \sum_{t \in T} c_t x_{rt}}{\sum_{t \in T} c_t} \tag{14}$$

subject to

$$\sum_{r \in R} x_{rt} \leqslant 1 \quad \forall t \in T \tag{15}$$

$$reqSkill_t \in skills_r \quad \forall x_{rt} = 1, t \in T, r \in R \tag{16}$$

$$start_t \leqslant st_t \quad \forall t \in T \tag{17}$$

$$st_t + dur_t \leqslant end_t \quad \forall t \in T \tag{18}$$

$$start_r \leqslant st_{\pi_{ri}} \quad \forall r \in R, i = \{1 \ldots \sigma_r\} \tag{19}$$

$$st_{\pi_{ri}} + dur_{\pi_{ri}} \leqslant end_r \quad \forall r \in R, i = \{1 \ldots \sigma_r\} \tag{20}$$

$$start_r + trvl_{loc_r loc_{\pi_{r1}}} \leqslant st_{\pi_{r1}} \forall r \in R \tag{21}$$

$$st_{t_i} + dur_{t_i} + trvl_{loc_{t_i} loc_{t_{i+1}}} \leqslant st_{t_{i+1}} \quad \forall t_i \in \pi_r, \pi_r \in \pi. \tag{22}$$

The objective function is represented by (14) which is normalized by dividing by the sum of all the costs associated with tasks. Constraint (15) imposes that each task is visited at most once. The skill constraint is expressed in (16). The time-window constraints of all tasks are assured by (17) and (18). (19) and (20) ensure that all tasks which are assigned to a technician must be within the technician's working time. Finally, constraints (21) and (22) ensure route validity by considering the traveling time between a technician's base location and the first task, as well as between subsequent tasks in technician's route.

Empowerment in Workforce Scheduling

Empowerment scheduling [6, 9] is a term introduced to refer to scheduling approaches that incorporate the empowerment concept in the scheduling system by involving technicians in the task-assignment decision. The hope of empowering human resources is to boost their contribution and commitment to the organization. In [6], an empowerment scheduling model is proposed for the workforce scheduling problem, named as the EmS-WSP, by enabling technicians to express their requests/preferences and submit plans for consideration in the allocation process. Naturally all plans can be expressed as a constraint relationship. These constraints will be considered to be satisfied in the scheduling process. Workforce scheduling problems are very complex, and thus, the promise of satisfying all the plans cannot be guaranteed. One direct way to handle employees' work plans is to treat them as soft constraints and associate a cost to each plan when it is not satisfied. In this case the task involves finding a schedule that satisfies the majority of constraints, rather than all the constraints. A key property of the empowerment scheduling model proposed in [9] is in the efficient strategy that dynamically determines the incurred cost of violating each plan; see [9] for more details.

Formally, every technician $r \in R$ is given an opportunity to provide a work plan (wp_r) every day. A plan is basically a constraint (ρ) by which a technician can describe the jobs he/she wants to undertake. For instance, a technician r might want to be allocated to jobs of a particular set of skills, or jobs in a particular region. Each plan is associated with a weight (ω); in our case this is equal to the EP value of r.

An indicator $y_r (\forall r \in R)$ is defined which is equal to 1 if the plan ρ_r is satisfied, and 0 otherwise.

The WSP is reformulated in the EmS-WSP to not only maximize the productivity in terms of the number of served jobs (Eq. 14), but also to satisfy the maximum number of working plans. The formulation of the additional objective is as follows:

$$wp_r = < \rho_r, \omega_r > \quad \forall r \in R, \quad 0 < \omega_r < 1 \tag{23}$$

$$max \qquad \frac{\sum_{r \in R} y_r \omega_r}{\sum_{r \in R} \omega_r}. \tag{24}$$

Local Search

Before going to the implementation details, it is worth mentioning that the two objectives in the EmS-WSP can be transformed to a single objective using an aggregation approach and then solved using a single-objective optimizer such as GLS. Otherwise, a multi-objective optimizer such as GPLS can be used to optimize the two objectives simultaneously. Since both GLS and GPLS are similar in the definition of their basic components, the following implementation details are for both algorithms.

Solution Representation

A candidate solution (i.e., a possible schedule) by a permutation of the jobs. Each permutation is mapped into a schedule using the deterministic algorithm described below:

Procedure **Evaluation** (input: one particular permutation of jobs)

1. For each job, order the qualified engineers in ascending order of the distances between their bases and the job (such orderings only need to be computed once and recorded for evaluating other permutations).
2. Process one job at a time, following their ordering in the input permutation. For each job x, try to allocate it to an engineer according to the ordered list of qualified engineers:
   (a) To check if engineer g can do job x, make x the first job of g; if that fails to satisfy any of the constraints, make it the second job of g, and so on.
   (b) If job x can fit into engineer g's current tour, then try to improve g's new tour (now with x in it): the improvement is done by a simple 2-opt algorithm (see section "GLS Implementation on the Traveling Salesman Problem"), modified in a such a way that only better tours which satisfy the relevant constraints will be accepted.
   (c) If job x cannot fit into engineer g's current tour, then consider the next engineer in the ordered list of qualified engineers for x; the job is unallocated if it cannot fit into any engineer's current tour.
3. The costs of the input permutation, which is the cost (as defined in Eq. 14 and 24) of the schedule thus created, are returned. These costs will be somehow aggregated in a single cost by GLS, or maintained simultaneously by GPLS.

Improvement Method

Given a permutation, the local search is performed in a simple way: the pairs of jobs are examined one at a time. Two jobs are swapped to generate a new permutation to be evaluated (using the evaluation procedure above) and compared to the current permutation. Note here that since the problem is also close to the vehicle routing problem (VRP), one may follow a totally different approach considering VRP move operators such as insertions, swaps, etc. In this case, the solution representation and construction methods need to be revised. The reader may refer to other works for more information on the application of GLS to the VRP (e.g., [14]) and also more advanced variants which are specific to this problem [11, 12].

Feature Definition

Since there are two objectives of different natures in the EmS-WSP, two sets of features need to be defined. As maximizing the total allocated tasks is an objective, each feature in the first set represents the inability to serving a task, so as to bias the local search to serve tasks of high importance. Thus, for each task t we define a feature $I_t(schedule)$ which is equal to 1 if t is unallocated in $schedule$, and 0 otherwise.

The cost of this feature is given by the task priority (c_t) which is equal to the cost incurred in the cost function (Eq. 14) when a task is unallocated.

The second objective concerns maximizing the total satisfied employees' plans, and therefore, each feature in the second feature set represents the inability to satisfy a work plan, so as to bias the (Pareto) local search to satisfy plans of high weight. Thus, for each technician r in the problem we define a feature $I_r(schedule) = y_r$, where y_r is equal to 1 if the work plan of r (ρ_r) is satisfied, and 0 otherwise. The cost of this feature is given by the working plan's weight (ω) which is equal to the cost incurred in the cost function (Eq. 24) when a plan is unsatisfied.

Overview of GLS Applications

GLS and its descendants have been applied to several nontrivial problems achieving state-of-the-art results.

Routing/Scheduling Problems

One of the most successful application of GLS and FLS is the *traveling salesman problem* (TSP). The Lin-Kernighan algorithm (LK) is a specialized algorithm for the TSP that has long been perceived as the champion of this problem [61, 64]. We tested GLS+FLS+2Opt against LK [103] on a set of benchmark problems from a public TSP library [79]. Given the same amount of time, GLS+FLS+2Opt found better results than LK on average. GLS+FLS+2Opt also outperformed simulated annealing [51], tabu search [53], and genetic algorithm [39] implementations for the TSP. One must be cautious when interpreting such empirical results as they could be affected by many factors, including implementation details. But given that the TSP is an extensively studied problem, it takes something special for an algorithm to outperform the champions under any reasonable measure ("find the best results within a given amount of time" must be a realistic requirement). It must be emphasized that LK is specialized for the TSP but GLS and FLS are much simpler general-purpose algorithms.

GLS extensions and hybrids have also been proposed for the TSP including a population-based GLS [91], the combination of GLS with memetic algorithms [47], and also with the dynamic-programming-based Dynasearch technique with encouraging preliminary results reported in [25].

Padron and Balaguer [72] have applied GLS to the related rural postman problem (RPP), Vansteenwegen et al. [99] applied GLS to the related team orienteering problem (TOP), and Mester et al. [66] applied the guided evolution strategy hybrid meta-heuristic to a genetic ordering problem (a unidimensional wandering salesperson problem [UWSP]).

In a vehicle routing problem, one is given a set of vehicles, each with its specific capacity and availability, and a set of customers to serve, each with specific weight and/or time demand on the vehicles. The vehicles are grouped at one or more depots.

Both the depots and the customers are geographically distributed. The task is to serve the customers using the vehicles, satisfying time, and capacity constraints. This is a practical problem which, like many practical problems, is NP-hard.

Kilby et al. applied GLS to vehicle routing problems and achieved outstanding results [52]. As a result, their work was incorporated in Dispatcher, a commercial package developed by IBM ILOG [14]. Over the years, the application of GLS and its hybrids to the VRP has been considerably extended to several variants of the problem. GLS has been applied to the vehicle routing problem with backhauls and time windows [113] and to the capacitated arc routing problem [20]. Guided tabu search has been applied to the VRP with time window [93, 94] and also extended to other variants of the VRP, namely, the VRP with two-dimensional loading constraints [109], the VRP with simultaneous pickup and delivery [110], and the VRP with replenishment facility [94]. GLS with VNS [55] as well as GLS with ES [65] hybrids has been proposed to solve large-scale VRPs. A new hybridization between GLS and GA has been devised to effectively tackle the transit network design problem in [78]. The deployment of fiber optics in the telecommunication industry has been successfully optimized using GLS in [26, 83].

More recently, we observed two directions with regards to GLS research on routing problems. One direction is towards creating advanced variants of GLS for tackling very-large-scale instances of routing problems. The other is towards utilizing open-source versions of the algorithm to address the needs of a variety of practical VRP-related applications.

One the first direction of tackling ever larger instances of the VRP, Arnold and Sorensen [12] introduced knowledge-guided local search (KGLS). KGLS is using some very powerful local search construction heuristics and move operators to explore the search space achieving high-quality local minima. This is followed by a "perturbation" phase applying up to 100 iterations of GLS. KGLS is selecting edges to penalize using a selection of different distance-related metrics which are alternating during different stages of the algorithm. Each perturbation phase is followed by another local search phase using the standard cost function without penalties and so forth.

KGLS is considered amongst the best algorithms for the VRP. It was applied in [11] against some of the largest instances of the problem ever addressed involving up to 30,000 visits, resembling real-world scenarios present in parcel distribution. Several of the AI-related GLS enhancements described earlier using LLMs have been applied to improve KGLS even further [62, 108].

On the second direction of using open-source versions of GLS to tackle practical routing problems, a landmark event was the release of Google's OR Tools [76]. Google's OR Tools is a publicly available software suite designed to tackle vehicle routing problems. This suite features one of the most proficient VRP solvers. It employs meta-heuristics like guided local search, tabu search, and simulated annealing to avoid local optima. To the words of the Google OR team referring to GLS, "this is generally the most efficient meta-heuristic for vehicle routing." The availability of an open-source version of GLS for the VRP provided by Google, in addition to the efficiency of the method as highlighted above, has encouraged

several research works using Google's GLS implementation as a benchmark or for addressing a diverse range of practical applications.

In [86], Silva et al. investigate the performance of GLS as implemented in Google OR tools to address dynamic delivery and pickup problems within constrained execution times of up to 10s. The application of GLS to solid waste collection in Saudi Arabia compared to SA and TS using the same underlying Google libraries is examined in [3]. Optimizing distribution routes for delivering medicines to pharmacies in Central Java using Google's GLS is described in [105]. Urban planning and transport network analysis for the city of New York using the same Google implementation is detailed in [107]. Published works probably represent only a small fraction of the actual uses of the algorithm in the real world since nowadays the wider developer community through open source can have access and put to use a highly efficient meta-heuristic algorithm for routing problems.

Assignment Problems

The generalized assignment problem is a generic scheduling problem in which the task is to assign agents to jobs. Each job can only be handled by one agent, and each agent has a finite resource capacity that limits the number of jobs that it can be assigned to. Assigning different agents to different jobs bear different utilities. On the other hand, different agents will consume different amounts of resources when doing the same job. In a set of benchmark problems, GGA found results as good as those produced by a state-of-the-art algorithm (which was also a GA algorithm) by Chu and Beasley [24], with improved robustness [59].

GLS hybrids have been proposed for the related QAP. Zhang et al. [112] proposed the GLS/EDA hybrid meta-heuristic. In addition, the hybrid of GLS with ACO (ACO_GLS) has been applied to a variation of the QAP [43]. This encourages Daoud et al. [28] to couple GLS with ACO, GA, and PSO into three frameworks which are successfully applied to the robotic assembly line balancing problem.

In the *radio link frequency assignment problem* (RLFAP), the task is to assign available frequencies to communication channels satisfying constraints that prevent interference [21]. In some RLFAPs, the goal is to minimize the number of frequencies used. Bouju et al. [21] is an early work that applied GENET to radio length frequency assignment. For the CALMA set of benchmark problems, which has been widely used, GLS+FLS reported the best results compared to all work published previously [101]. In the NATO Symposium on RLFAP in Denmark, 1998, GGA was shown to improve the robustness of GLS [58]. In the same symposium, new and significantly improved results by GLS were reported [102]. At the time, GLS and GGA held some of the best-known results in the CALMA set of benchmark problems.

We have experimented with GLS and FLS on a variety of other problems, including the maximum channel assignment problem, a bandwidth packing problem variant, graph coloring, and the car sequencing problem. Some of these works are largely undocumented due to lack of time during the original development phase of the algorithm.

GGA was also successfully applied to the processor configuration problem, with new best results than those found by other previously reported algorithms [57, 58].

GLS and FLS have been successfully applied to the 3-D bin packing problem and its variants [33, 34, 56] as mentioned earlier in this chapter and also to network planning problems [38, 106]. GLS has been applied to the natural language parsing problem [29], graph set T-coloring problem [23], query reformulation [69], and ligand docking problems via drug design [75]. Variations of GLS have been applied to graph coloring [18] and the multidimensional knapsack problem [46, 90]. The multi-objective 0/1 knapsack problem has been tackled using GPLS in [8].

Resource Allocation and Scheduling Problems

In the *workforce scheduling problem* (WSP) [13], the task is to assign technicians from various bases to serve the jobs, which may include customer requests and repairs, at various locations. Customer requirements and working hours restrict the service times at which certain jobs can be served by certain technicians. The objective is to minimize a function that takes into account the traveling cost, overtime cost, and unserved jobs. In the WSP, GLS+FLS holds the best-published results for the benchmark problem available to the authors [96]. GPLS has also been applied to a multi-objective WSP in [6]. Further applications of GLS to resource scheduling problems are described in [48, 71].

Constrained Optimization Problem

Given a set of propositions in conjunctive normal form, the satisfiability (SAT) problem is to determine whether the propositions can all be satisfied. The MAX-SAT problem is a SAT problem in which each clause is given a weight. The task is to minimize the total weight of the violated clauses. In other words, the weighted MAX-SAT problem is an optimization problem. Many researchers believe that many problems, including scheduling and planning, can be formulated as SAT and MAX-SAT problems; hence, these problems have received significant attention in recent years, e.g., see Gent et al. [40].

GLSSAT, an extension of GLS, was applied to both the SAT and weighted MAX-SAT problem [67]. On a set of SAT problems from DIMACS, GLSSAT produced more frequently better or comparable solutions than those produced by WalkSAT [81], a variation of GSAT [82], which was specifically designed for the SAT problem.

On a popular set of benchmark weighted MAX-SAT problems, GLSSAT produced better or comparable solutions, more frequently than state-of-the-art algorithms, such as DLM [84], WalkSAT [81], and GRASP [80]. In similar fashion, GLS has been utilized to very quickly produce feasible solutions to many hard MIP problem instances and proven to be highly effective on a range of problems from the MIPLIB 2017 benchmark set [63].

GLS in Commercial Packages

GLS and FLS have been incorporated into software packages, namely, iOpt, which is a software toolkit for heuristic search methods [104], and iSchedule [31], which is an extension of iOpt for planning and scheduling applications (e.g., for solving problems such as the VRP [32]). IBM ILOG Dispatcher, a commercial package developed by ILOG [14, 50], incorporates a version of GLS targeted at transport and logistics applications.

Conclusion

For many years, general heuristics for combinatorial optimization problems, with prominent examples such as simulated annealing and genetic algorithms, heavily relied on randomness to generate good approximate solutions to difficult NP-hard problems.

The introduction and acceptance of tabu search [41] by the Operations Research community initiated an important new era for heuristic methods where deterministic algorithms exploiting historical information started to appear and to be used in real-world applications.

Guided local search described in this chapter follows this trend. While tabu search is a class of algorithms (where a lot of freedom is given to the management of the tabu list), GLS is more prescriptive (the procedures are more concretely defined). GLS heavily exploits information (not only the search history) to distribute the search effort in the various regions of the search space. Important structural properties of solutions are captured by solution features. Solution features are assigned costs and local search is biased to spend its efforts according to these costs. Penalties on features are utilized for that purpose.

When local search settles in a local minimum, the penalties are increased for selected features present in the local minimum. By penalizing features appearing in local minima, GLS escapes the local minima visited (exploiting historical information) but also diversifies the choices, with regard to the various structural properties of solutions, as captured by the solution features. Features of high costs are penalized more often than features of low cost: the diversification process is directed and deterministic rather than undirected and random.

In general, several penalty cycles may be required before a move is executed out of a local minimum. This should not be viewed as an undesirable situation. It is caused by the uncertainty in the information as captured by the feature costs which forces the GLS to test its decisions against the landscape of the problem.

The penalization scheme of GLS is ideally combined with FLS which limits the neighborhood search to particular parts of the overall solution leading to the GFLS algorithm. GFLS significantly reduces the computation times required to explore the area around a local minimum to find the best escape route allowing many more penalty modification cycles to be performed in a given amount of running time.

Despite all the years of development, further research is possible to improve GLS and its related techniques further. The use of incentives implemented as negative penalties, which encourage the use of specific solution features, is one promising direction to be explored. Other interesting directions include probabilistic features matching specific solution patterns (perhaps clustered and identified by deep learning algorithms) with indicator functions returning real values in the [0, 1] interval, automated tuning of the λ or α parameters, definition of effective termination criteria, alternative utility functions for selecting the features to be penalized, and also studies about the convergence properties of GLS.

It is relatively easy to adapt GLS and GFLS to the different problems examined in this chapter. Although local search is problem dependent, the other structures of GLS and also GFLS are problem independent. Moreover, a mechanical, step-by-step procedure is usually followed when GLS or GFLS is applied to a new problem (i.e., implement a local search procedure, identify features, assign costs, define sub-neighborhoods, etc.). This makes GLS and GFLS easier to use by nonspecialist software engineers.

Abstract

Local search is a widely used method to solve combinatorial optimization problems. As many relevant combinatorial optimization problems are NP-hard, we often may not expect to find an algorithm that is guaranteed to return an optimal solution in a reasonable amount of time, i.e., in polynomial time. Therefore, one often resorts to heuristic methods that return good, suboptimal solutions in reasonable running times. Local search is a heuristic method that is popular for its ability to trade solution quality against computation time. By spending more time, we will generally get better solutions. Well-known examples of local search approaches are iterative improvement, simulated annealing, and tabu search.

The performance of local search, in terms of quality or running time, may be investigated empirically, probabilistically, and from a worst-case perspective. In this chapter we focus on the last option. That is, we give provable results on the worst-case performance of local search algorithms.

Besides combinatorial optimization problems, the theory discussed in this chapter also finds its application in game theory and computational complexity.

Keywords

Performance ratio · Time complexity · PLS · Iterative improvement

Introduction

Local search is a widely used method to solve combinatorial optimization problems. An instance of a combinatorial optimization problem P can be characterized by a pair (S, f), where S denotes a finite set of solutions and $f : S \to \mathbb{R}$ a cost function that assigns to each solution a real value that represents the quality of this solution. The problem is to find an optimal solution s_* in S, i.e., a solution for which $f(s_*) \leq f(s)$ for each $s \in S$ in case P is a minimization problem or a solution for which $f(s_*) \geq f(s)$ for each $s \in S$ in case P is a maximization problem.

As many combinatorial optimization problems are NP-hard, we often may not expect to find polynomial-time solution approaches that always return provably optimal solutions. In practice, one often has to settle for heuristic methods that return good, suboptimal solutions in reasonable running times. Local search is a heuristic method that is popular for its ability to trade solution quality against computation time. By spending more time, we will generally get better solutions. Well-known examples of local search approaches are iterative improvement, simulated annealing, and tabu search.

Loosely defined, a local search approach starts at an (often) arbitrarily chosen solution $s_{\text{init}} \in S$ and iteratively jumps to a (potentially) better solution in the neighborhood, until it ends at a locally optimal solution s_{end} for which—hopefully—$f(s_{\text{end}})$ is close to $f(s^*)$.

Using local search amounts to defining a neighborhood function $N: S \to P(S)$, where the power set $P(S)$ denotes the set of all subsets of solutions in S. For each solution $s \in S$, $N(s)$ gives the neighbors of s, i.e., the solutions one can jump to from S in one iteration of the local search approach.

Given S and N, the execution of a local search algorithm can be considered as a path in the directed neighborhood graph $G = (V, E)$, where each node $v \in V$ corresponds to a solution in S and $(v, w) \in E$ if and only if w corresponds to a neighbor of v. A local search algorithm specifies how s_{init} is chosen, how iteratively for the current solution s a neighboring solution from $N(s)$ is chosen as the next solution, and how eventually the algorithm will terminate. For example, iterative improvement starts with an initial solution and repeatedly selects for the given current solution s one of its neighbors $s' \in N(s)$ using some pivoting rule. If s' has a better quality than s, then s' is adopted as the new current solution. Otherwise, s is retained as the current solution. This procedure is repeated until the algorithm arrives at a local optimum, i.e., a solution that is better than any of its neighbors. This local optimum is then returned as the final solution. For a given local search approach, the transition graph is defined to be the subgraph of the neighborhood graph containing only the cost-improving edges.

The performance of a local search algorithm is determined by two aspects, namely, (1) the quality of the solutions it finally produces and (2) the time it takes to find these solutions (time complexity). The performance of a local search algorithm can be investigated in three ways:

- *empirical analysis*: investigate the performance by applying it to a representative set of problem instances.
- *probabilistic analysis*: assume a probability distribution over the set of all problem instances and use this to derive probabilistic results on solution quality and running time.
- *worst-case analysis*: investigate the performance by assuming worst-case assumptions.

Empirical and probabilistic analyses have the disadvantage that additional assumptions are required on how representative or how probable problem instances will be for a given application at hand and the information to base these assumptions upon may not be available. In this chapter we restrict ourselves to worst-case analysis.

Many of the examples that we give in this chapter relate to the traveling salesman problem (TSP). An instance of this well-known combinatorial optimization problem is defined by a set of n cities and an $n \times n$ distance matrix d, where $d_{ij} \in \mathbb{N}^+$ defines the distance from city i to city j. The problem is to find a tour visiting all n cities with minimum tour length. The TSP has three variants that will be considered in this chapter, namely, Symmetric TSP, Metric TSP, and Euclidean TSP. For the first variant, the distance matrix is required to be symmetric, i.e., $d_{ij} = d_{ji}$ for all i, j. For the second, the distance matrix should satisfy the triangle inequality,

i.e., $d_{ik} \leq d_{ij} + d_{jk}$ for all i, j, k. And a TSP instance is said to belong to the third variant if the distance matrix d is defined by the Euclidean distance.

This chapter can be considered as a condensed version of two chapters from the monograph *Theoretical Aspects of Local Search* [1]. For a more extensive treatment of the subject, the reader is referred to this work. This chapter is organized in two parts. The first part considers solution quality, while the second part considers time complexity.

Solution Quality

In this section we study the guaranteed solution quality for iterative improvement. This corresponds to determining the quality of local optima. Ideally, we want iterative improvement to be guaranteed to end up in an optimal solution. This means that the neighborhood function N is exact. In the subsection below, we give examples of this. However, in most applications of local search, we do not have the luxury of a practical exact neighborhood function. There, we have to be satisfied with suboptimal solutions. In these cases, it is interesting to know how far the quality of the suboptimal solution can be from that of an optimal one. To this end, we say that a neighborhood function has a performance bound U if all its local optima are guaranteed to have a cost at most U times the optimal cost in case of a minimization problem and a cost at least $1/U$ times the optimal cost in case of a maximization problem. If bound U is tight, then U is called a performance ratio. We devote a subsection to analyzing the performance ratio of the k-change neighborhood function for Euclidean TSP. In the last two subsections, we finally elaborate on the relation between the formal hardness of finding an R-approximate solution and the existence of an efficient neighborhood function with a performance bound of R.

Exact Neighborhood Functions

A neighborhood function is said to be exact if each locally optimal solution is also globally optimal. In this section we present some examples of exact neighborhood functions. First of all, consider sorting. Sorting a multiset of n numbers $a_1, a_2, \ldots, a_n$ corresponds to finding a permutation π of $\{1, 2, \ldots, n\}$ that minimizes the cost function $f(\pi) = \sum_{i=1}^{n} i \cdot a_{\pi(i)}$ if the numbers have to be put in non-increasing order and that maximizes this cost function if they have to be put in non-decreasing order. A well-known algorithm for sorting is bubble sort. This algorithm starts with an arbitrary permutation π and then swaps repeatedly two adjacent numbers that are not in the right order. Bubble sort finds an optimal solution because a sequence of numbers is sorted if and only if any two adjacent numbers in the sequence are sorted correctly. Obviously, swapping two adjacent numbers improves the cost

of a permutation if and only if they are not in the right order. This means that bubble sort corresponds to iterative improvement with the neighborhood function that constructs neighbors by swapping two adjacent numbers. Because bubble sort solves sorting, this neighborhood function is exact.

In the minimum spanning tree (MST) problem, we are asked to find a spanning tree with minimum weight for an edge-weighted graph. This problem can also be solved by applying iterative improvement with the exact neighborhood function proposed in the following theorem, which is taken from Papadimitriou and Steiglitz [2].

Theorem 1. *Consider for MST the neighborhood function that generates a neighbor of a spanning tree T in the following way. First of all, we add an arbitrary edge to T. This produces a single cycle. From this cycle we delete an arbitrary edge, which gives a new spanning tree. This neighborhood function is exact.*

Proof Suppose we have a spanning tree T that is a local optimum, but not a global optimum. To prove the theorem, we show that this yields a contradiction. Let T^* be an optimal spanning tree that has a maximum number of edges in common with T. Furthermore, let e be an edge with minimum weight from the set of edges that are in T^* but not in T. As any spanning tree has $n - 1$ edges, such an edge exists. The removal of e splits T^* into two subtrees T_1^* and T_2^*. We now construct a neighbor T' of T as follows. First, we add edge e to T. This results in a cycle c. Besides e, this cycle must contain at least one other edge e' connecting a node from T_1^* with a node from T_2^*. We now construct T' by removing e' from c.

Because T is a local optimum, we have that the cost of T' is at least the cost of T. Hence, $w(e) \geq w(e')$, where $w(e)$ and $w(e')$ give the weights of edges e and e'. However, this implies that connecting T_1^* and T_2^* by edge e' results in a spanning tree that is at least as good as T_* and that has at least one edge more in common with T. This yields a contradiction. Hence, we conclude that the proposed neighborhood function is exact. □

Exact Neighborhood Function for TSP: An NP-Completeness Proof

Theoretically, all problems admit an exact neighborhood function. If we choose as neighborhood of a solution s the complete solution set, i.e., $N(s) = S$ for all $s \in S$, then this neighborhood function is exact. However, this neighborhood is not very practical since verifying whether a solution is locally optimal corresponds to solving the decision problem underlying the optimization problem. Mostly, we want to use local search for NP-hard problems, in which case this problem is NP-complete. In order to be practically useful, it makes sense to aim for a neighborhood function with the property that a single iteration of iterative improvement can be implemented to run in polynomial time. This is captured by the following definition.

Definition 1. A neighborhood function is said to be *polynomially searchable* if in polynomial time we can decide whether a solution is locally optimal and, if not, construct a better neighboring solution. □

The problem is how do we know whether or not an exact polynomially searchable neighborhood function exists for a problem? One way of settling this issue is to use complexity theory to prove for a particular problem that an exact neighborhood function does not exist. We now present the result from Papadimitriou and Steiglitz [2, 3], who show how this can be done for Metric TSP.

An outline of the proof is as follows. It is well known that Hamiltonian cycle (HC) is NP-complete, where HC is the problem of deciding for a graph whether it contains a Hamiltonian cycle. We first prove that the problem does not become easier if in addition to the graph we are also given a Hamiltonian path. Remember that a Hamiltonian cycle is a Hamiltonian path in which we return to the starting node. Hence, we prove that the following problem is NP-complete.

Definition 2 (Restricted Hamiltonian Cycle (RHC)). Given are a graph G and a Hamiltonian path in G. Is there a Hamiltonian cycle in G? □

Using this result, we next show that Metric TSP suboptimality is also NP-complete, which was our goal. □

Definition 3 (Metric TSP Suboptimality). Given are an instance I of Metric TSP and a tour τ for I. Is τ suboptimal? □

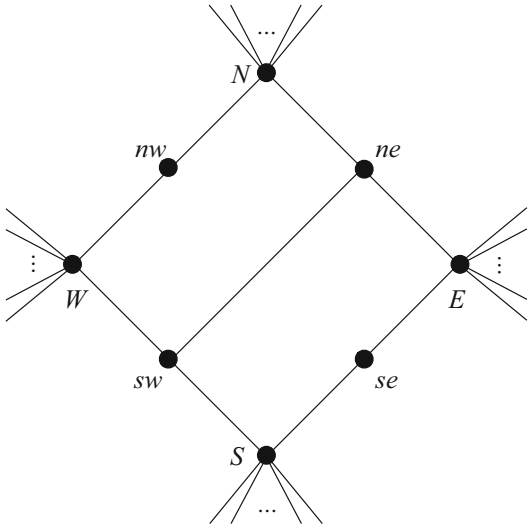
Lemma 1. *RHC is NP-complete.*

Proof Proving RHC $\in$ NP is trivial. Hence, to prove the lemma, it now suffices to show that RHC is polynomially reducible from HC. Let $G = (V, E)$ be an arbitrary graph defining a problem instance of HC. The construction of a corresponding instance of RHC is based on the special-purpose subgraph depicted in Fig. 1. This subgraph, which consists of eight nodes, is called a diamond.

In a diamond we identify four special nodes, called N (north), E (east), S (south), and W (west). We will use diamonds in such a way that if a graph G' contains a diamond D, then only these special nodes may be connected to other nodes in the graph. We now claim that if a graph G' contains a Hamiltonian cycle c, then for each diamond D in G' we have that its nodes are visited by c either in the way depicted in Fig. 2a or in the way depicted in Fig. 2b. The former case is referred to as north-south mode and the latter as east-west mode.

We now focus on proving this claim. Suppose that Hamiltonian cycle c enters diamond D in node N. We show that following any other path than the one depicted in Fig. 2a results in a contradiction. If node N is not succeeded by node *nw* (north-west) but by *ne*, then the only way for c to visit *nw* is via node W. However, this is not possible because, being in *nw*, we can neither go to N nor return to W as this would

Fig. 1 A diamond subgraph



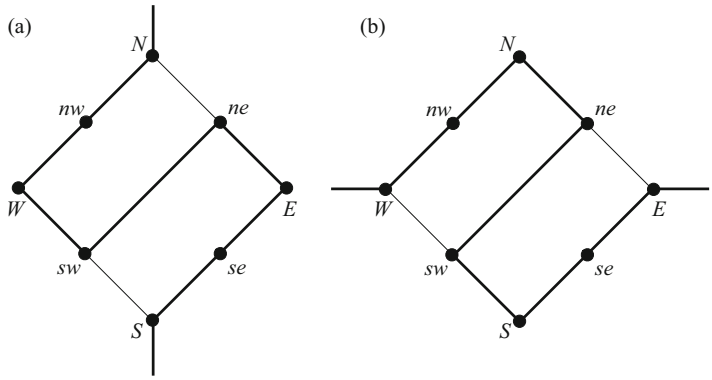


Fig. 2 (**a**) North-south mode. (**b**) East-west mode

imply visiting N or W twice. Hence, N is indeed succeeded by nw in c. Obviously, the only way to proceed from nw is to go to W. Once at node W, we cannot leave D because then the only way for c to visit sw and ne is by skipping se. From node sw we have to go to ne because if we chose S this would make it impossible to visit ne as well as se. From ne we can then only go to E, and to prevent skipping node se, we conclude the traversal of D by visiting se and S, successively. By a similar reasoning, it can be verified that if c enters a diamond D via the south, then D is also traversed as depicted in Fig. 2a, and if c enters D via the east or the west, then D is traversed as depicted in Fig. 2b. This proves our claim.

We now construct for our arbitrary graph $G = (V, E)$ specifying the arbitrary HC instance the following corresponding graph $G' = (V', E')$. Let $V = \{1, 2, \ldots, n\}$.

For each node $i \in V$, we introduce a diamond D_i with special nodes N_i, E_i, S_i, and W_i. Except for the last diamond D_n, we connect the south node of each diamond D_i with the north node of the next diamond D_{i+1}, i.e., we add the edges $\{S_i, N_{i+1}\}$ for all $1 \leq i < n$ to E'. Finally, we introduce for each edge $\{i, j\} \in E$ the two edges $\{W_i, E_j\}$ and $\{W_j, E_i\}$.

Obviously, the path that visits the diamonds in increasing order and traverses each diamond from north to south in the way depicted in Fig. 2a gives us a Hamiltonian path. Hence, to prove that we presented a valid polynomial-time reduction, it now suffices to show that G has a Hamiltonian cycle if and only if G' has one. We start with the "only if" part. Hence, suppose that G has a Hamiltonian cycle c. Then visiting the diamonds in G' in the order specified by c and the nodes inside a diamond in east-west mode yields a Hamiltonian cycle for G'. Next, assume that G' has a Hamiltonian cycle c. If c traverses one diamond in north-south mode, then it must traverse all diamonds in north-south mode as north and south nodes are not connected to east and west nodes. However, as only $n - 1$ north-south edges exist, no Hamiltonian cycle can exist that traverses each diamond in north-south mode. Hence, we can conclude that c must traverse each diamond in east-west mode. The order in which these diamonds are visited defines a Hamiltonian cycle for G. □

Theorem 2. *Metric TSP suboptimality is NP-complete.*

Proof Again, proving membership in NP is a trivial task. We now show that RHC is polynomially reducible to Metric TSP suboptimality. Let $G = (V, E)$ with Hamiltonian path $p = (v_1, v_2, \ldots, v_n)$ define an arbitrary problem instance I of RHC. If $\{v_1, v_n\} \in E$, then we can directly conclude that I is a yes-instance of RHC. Hence, without loss of generality, we assume that $\{v_1, v_n\} \notin E$. We transform problem instance I into the following problem instance of Metric TSP suboptimality. The set of cities is given by $C = V = \{1, 2, \ldots, n\}$, and the distance d_{ij} between cities i to j is defined by 1 if $\{i, j\} \in E$ and by 2 if $\{i, j\} \notin E$. Hamiltonian path p gives us a tour τ with cost $n + 1$ because $\{v_i, v_{i+1}\} \in E$ with $1 \leq i < n$ and $\{v_1, v_n\} \notin E$. Now, G has a Hamiltonian cycle if and only if tour τ is suboptimal. To see this, suppose that τ is suboptimal. A tour τ' then exists with length n. This tour defines a Hamiltonian cycle in G. Conversely, if G contains a Hamiltonian cycle, then this cycle determines a tour with length n, which implies that τ is suboptimal. This proves the theorem. □

Corollary 1. *Provided that $P \neq NP$, no polynomially searchable exact neighborhood function exists for Metric TSP.* □

Performance Ratios of Neighborhood Functions

In case a problem does not admit a polynomially searchable exact neighborhood function, we have to resort to a neighborhood function for which local optima can be suboptimal. To know how far we can be off from an optimal solution if we use

such a neighborhood function, we can try to derive bounds on the performance ratio of the neighborhood function. Observe that this performance ratio equals the performance ratio of iterative improvement where we select the initial solution randomly. If we select the initial solution more carefully, the performance ratio of iterative improvement may improve.

Consider Symmetric TSP. As the neighborhood size of k-change is polynomially bounded, a single iteration of k-Opt, which corresponds to a single step in the transition graph, can be implemented to run in polynomial time. Furthermore, finding a tour with length at most $2^{p(n)}$ times the optimal length is NP-hard for any fixed polynomial p [4]. Hence, if we were to prove that k-Opt is guaranteed to reach a locally optimal tour within a polynomial number of iterations, then we would obtain that, unless P = NP, k-Opt does not admit a performance ratio at most $2^{p(n)}$ for any fixed polynomial p. However, as we show in the next section, k-Opt may require an exponential number of iterations, which implies that the given reasoning is not applicable. The following theorem states that the lower bound of $2^{p(n)}$ on the performance ratio of k-Opt nevertheless holds. It even claims a stronger result: no function in n exists that gives an upper bound on the performance ratio of k-change. We note that this does not mean that it is impossible to bind the performance ratio. It can, for instance, be bounded trivially by the largest distance in the distance matrix d divided by the smallest distance in d.

Theorem 3. *For any fixed $k \geq 2$ and $n \geq 2\,k + 4$, the performance ratio of the k-change neighborhood function cannot be bounded by a constant for Symmetric TSP on n cities. This means that no function in n exists that gives a performance bound for k-change.*

Proof For any $k \geq 2$ and $\varepsilon > 0$, we define a problem instance of Symmetric TSP containing $n = 2\,k + 4$ cities. For this problem instance, we construct a locally optimal tour $\hat{\tau}$, which has a performance ratio of $1 + \frac{1}{n\varepsilon}$. It is easy to extend this problem instance and to modify the locally optimal tour, such that the problem instance contains any $n > 2\,k + 4$ cities, the tour $\hat{\tau}$ remains locally optimal, and the performance ratio of $\hat{\tau}$ is still $1 + \frac{1}{n\varepsilon}$. Since for $\varepsilon \to 0$ this performance ratio approaches ∞, this proves the theorem. □

We define the symmetric distance matrix d, such that all entries are given by $1 + \varepsilon$ except for the entries $d_{i,i+1}$ with $1 < i < n$, $d_{1,n}$, $d_{1,k+2+l}$ with $l = k \bmod 2$, and $d_{i,n-i+1}$ with $2 \leq i \leq k + 2$, which are all given by ε. In this definition we restrict ourselves without loss of generality to the entries d_{ij} with $i < j$.

Let $G = (V, E)$ be the graph obtained from the complete graph of n nodes by maintaining an edge $\{i, j\}$ if $d_{ij} = \varepsilon$ and by removing it if $d_{ij} = 1 + \varepsilon$; see Fig. 3. Obviously, a tour has length $n\varepsilon$ if it defines a Hamiltonian cycle in graph G and it has length at least $1 + n\varepsilon$ otherwise. Moreover, it can be proved that the tour $\tau^* = (1, n, n-1, 2, 3, n-2, n-3, \ldots)$ defines the only Hamiltonian cycle in G, where tours that only differ in their starting position or direction are considered to be equivalent. Hence, tour τ^* is the only optimal tour, and the length of any other tour τ is at least

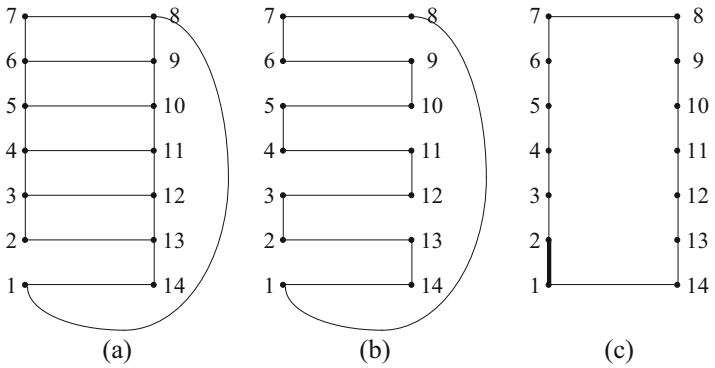

Fig. 3 For $k = 5$, the figure shows (**a**) graph G, (**b**) optimal tour τ^* of length $n\varepsilon$, and (**c**) locally optimal tour $\hat{\tau}$ of length $1 + n\varepsilon$

$1 + n\varepsilon$. From this it follows that if a tour $\hat{\tau}$ has length $1 + n\varepsilon$ and if it has $k + 1$ edges that are absent in τ^*, then $\hat{\tau}$ is a locally optimal tour with performance ratio $\frac{1+n\varepsilon}{n\varepsilon} = 1 + \frac{1}{n\varepsilon}$. It can be verified that such a tour is given by $\hat{\tau} = (1, 2, \ldots, n)$. This proves the theorem. □

In the remainder of this section, we focus on Metric TSP. Although solving this problem is as difficult as solving Symmetric TSP (they are both strongly NP-hard), it is easier to find an approximate solution for Metric TSP than for Symmetric TSP. Currently, Christofides' algorithm [5] is the polynomial-time algorithm with the best known worst-case performance. This constructive algorithm works as follows. First of all, it computes a minimum spanning tree T. Next, it converts this tree into an Eulerian graph, which is a graph in which each node has an even degree. This is done by deriving a perfect matching on the nodes with an odd degree. These edges are added to T. For an Eulerian graph, we can easily determine an Eulerian tour, which is a tour that traverses each edge exactly once. By introducing shortcuts, we can eliminate multiple visits to the same city in the tour. This results in a tour for which it can be proved that its length is at most $\frac{3}{2}$ times the optimal length.

For k-Opt Chandra, Karloff, and Tovey [6] have proved that, for infinitely many n, a lower bound on the performance ratio is given by $\frac{1}{4}\sqrt{n}$ for $k = 2$ and by $\frac{1}{4}n^{\frac{1}{2k}}$ for $k \geq 3$. Hence, from a worst-case perspective, the local search algorithm k-Opt cannot compete against Christofides' constructive algorithm. Nevertheless, k-Opt may still be preferred over Christofides' algorithm as in practice we may be more interested in a good average-case performance than in a good worst-case performance. Hence, it is still interesting to analyze the worst-case performance of k-Opt or, equivalently, k-change, not only to obtain a worst-case performance guarantee but also to enhance our understanding of the algorithm.

Chandra, Karloff, and Tovey [6] also proved that k-Opt has a performance bound, i.e., an upper bound on the performance ratio, of $4\sqrt{n}$ for any $k \geq 2$. By a tighter analysis, Levin and Yovel [7] improved this bound to $2\sqrt{2n}$. Below, we prove

this result. Note that this performance bound differs by a constant factor from the presented lower bound for $k = 2$ and by a factor that increases with n for any $k \geq 3$. In order to prove the bound, we need the following auxiliary result that states that a locally optimal tour cannot contain too many long edges as expressed as a fraction of the optimal tour length.

Lemma 2. *For an arbitrary problem instance of Metric TSP, let l^* be the optimal tour length and $\hat{\tau}$ a locally optimal tour with respect to the 2-change neighborhood function. For any i with $1 \leq i \leq n$, we have $|E_i| < i/2$, where set E_i contains the edges $\{j, j'\}$ from $\hat{\tau}$ with $d_{jj'} > \frac{2l^*}{\sqrt{i}}$.*

Proof We prove the lemma by contradiction. So, suppose we have $|E_i| \geq i/2$ for some i. Although the direction of $\hat{\tau}$ is irrelevant, we assume some orientation of the tour. As a result, the $r = |E_i|$ edges in E_i transform into r arcs (t_j, h_j) with $1 \leq j \leq r$. The cities t_j and h_j are called the tail and head of arc (t_j, h_j).

We first show that a tail t_u with $1 \leq u \leq r$ cannot be surrounded by too many other tails of arcs from E_i. Let V_u be the set of all tails of arcs from E_i that have a distance of at most $\frac{l^*}{\sqrt{i}}$ from t_u. Assume that $| V_u | \geq \sqrt{i}/2$. We prove that $| V_u | < \sqrt{i}/2$ by showing that this assumption yields a contradiction.

Let $t_j, t_{j'} \in V_u$. Because the triangle inequality holds and because, by definition, the distance from t_u to any of these two tails is at most $\frac{l^*}{\sqrt{i}}$, we obtain that the distance between t_j and $t_{j'}$ is at most $\frac{2l^*}{\sqrt{i}}$. This implies that the distance between the heads h_j and $h_{j'}$ is strictly larger than $\frac{2l^*}{\sqrt{i}}$. If this would not be the case, then replacing the edges $\{t_j, h_j\}$ and $\{t_{j'}, h_{j'}\}$ in $\hat{\tau}$ via a 2-change into $\{t_j, t_{j'}\}$ and $\{h_j, h_{j'}\}$ would result in a shorter tour because the length of each of the former two edges is strictly larger than $\frac{2l^*}{\sqrt{i}}$ by the definition of E_i. This would contradict the local optimality of $\hat{\tau}$.

Hence, $| V_u | \geq \sqrt{i}/2$ heads can be identified in E_i that all have a mutual distance of strictly more than $\frac{2l^*}{\sqrt{i}}$. This implies that the optimal tour on these heads is strictly more than l^*, which gives a contradiction because due to the triangle inequality it is not possible that an optimal tour over all cities is shorter than the optimal tour over a subset of all cities. This proves our claim $| V_u | < \sqrt{i}/2$. We use this result to derive a contradiction from the assumption $r \geq i/2$, which settles the proof of the lemma.

Consider the following labeling algorithm. Select an unlabeled tail t_u in E_i, and label all tails in E_i that have a distance of at most $\frac{l^*}{\sqrt{i}}$ from t_u (including t_u). Repeat this labeling step until all tails in E_i are labeled. As proved above, strictly fewer than $\sqrt{i}/2$ tails are labeled in each iteration. As $r \geq i/2$, this implies that the labeling procedure takes strictly more than $\sqrt{i}$ iterations. Obviously, the tails that are selected in these iterations all have a mutual distance strictly larger than $\frac{l^*}{\sqrt{i}}$. This implies that the optimal tour has length strictly larger than $\sqrt{i} \cdot \frac{l^*}{\sqrt{i}} = l^*$, which results in a contradiction. This proves the lemma. □

Using Lemma 2, we can now prove the claimed result.

Theorem 4. *The k-change neighborhood function has a performance bound of* $2\sqrt{2n}$ *for Metric TSP.*

Proof To prove the theorem, it suffices to show that a tour $\hat{\tau}$ has a performance ratio of at most $2\sqrt{2n}$ if it is a locally optimal tour with respect to the 2-change neighborhood function. Lemma 2 yields that the ith largest edge in $\hat{\tau}$ has a length of at most $\frac{\sqrt{2}l^*}{\sqrt{i}}$, where l^* is the optimal tour length. Hence, the length of $\hat{\tau}$ is at most

$$\sum_{i=1}^{n} \frac{\sqrt{2}l^*}{\sqrt{i}} = \sqrt{2}l^* \sum_{i=1}^{n} \frac{1}{\sqrt{i}}. \tag{1}$$

As $\frac{1}{\sqrt{x}}$ is a decreasing function in $x \in \mathbb{R}$, we have $\frac{1}{\sqrt{i}} \leq \int_{i-1}^{i} \frac{1}{\sqrt{x}}\,\mathrm{d}x$ for any positive integer i. Hence, the right-hand side of (1) is at most $\sqrt{2}l^* \int_0^n \frac{1}{\sqrt{x}}\mathrm{d}x$, which equals $2\sqrt{2n}l^*$. □

We note that, to get better performance guarantees, it sometimes helps to use an objective function that differs from the one defined in the optimization problem. An example of this is given by Angel et al. [8]. They refer to a result from [9] who show that the flip neighborhood function has a performance bound of $\frac{3}{2}$ for the non-weighted Max k-SAT problem. Khanna et al. [10] prove that this is the best you can achieve using any normal local search implementation. However, they also show that when using to a different objective function, the flip neighborhood function can achieve a performance ratio of $\frac{4}{3}$ for this problem.

Non-approximability Results

Above, we gave examples of performance ratio analyses for a particular neighborhood function. In this section, we show that we can also prove results on the performance ratio for a complete class of neighborhood functions for a problem.

Suppose that finding an R-approximate solution for Π is NP-hard for a given $R \geq 1$. Provided that P $\neq$ NP, this means that iterative improvement using neighborhood function N does not find a solution with performance ratio R in polynomial time. As it may take iterative improvement an exponential number of steps to reach a local optimum, this does not directly imply that N has a performance ratio larger than R. The following theorem from Yannakakis [11] states that the claim is nevertheless true. Observe that, by taking $R = 1$, the theorem yields that an NP-hard problem will not admit a polynomially searchable exact neighborhood function.

Theorem 5. *Let $\Pi \in$ NPO, and let N be a neighborhood function for Π that is polynomially searchable. If the problem of finding an R-approximate solution for Π is NP-hard for a given $R \geq 1$, then N does not have a performance bound of R, provided that NP $\neq$ co-NP.*

Proof We prove the result by contradiction. Suppose that approximating Π within a factor R is NP-hard and that N has a performance bound of R. We show that for any decision problem $\Pi_D \in$ NP the complementary problem Π_D^c obtained from Π_D by reversing the answers is also in NP. This yields a contradiction as it implies NP = co-NP.

To prove $\Pi_D^c \in$ NP, we need to show that each yes-instance of Π_D^c has a certificate that can be checked in polynomial time for validity, where the size of the certificate is polynomially bounded. As approximating Π within a factor R is NP-hard, a polynomial-time algorithm $\mathcal{A}$ exists that decides Π_D, where $\mathcal{A}$ may use an oracle that returns an R-approximate solution for any problem instance of Π. Hence, if for a problem instance I of Π_D we are given a sequence consisting of solutions that may be returned successively by the oracle during the execution of $\mathcal{A}$ on I, then we can determine in polynomial time whether I is a yes-instance or a no-instance of Π_D. This implies that as a certificate for yes-instances of Π_D^c we can use a sequence consisting of solutions that are locally optimal for the problem instances that are successively given to the oracle, i.e., the ith solution in the sequence is a local optimum for the ith problem instance given to the oracle. The certificate, which is of polynomial size, can be checked for validity in polynomial time by substituting each call of the oracle in $\mathcal{A}$ by a polynomial-time procedure that checks whether the corresponding solution in the certificate is a local optimum for the problem instance given to the oracle. By assumption this polynomial-time procedure exists. □

From the above theorem and the complexity result of Sahni and Gonzalez [4], it follows that if NP $\neq$ co-NP, then the performance ratio of the k-change neighborhood function cannot be bounded by $2^{p(n)}$ for some fixed polynomial p. Note that this result is weaker than the result of Theorem 3. Theorem 3 states that the performance ratio cannot even be bounded by 2^{2^n}, for instance, and that it also holds in the unlikely case that NP = co-NP.

From Neighborhood Function to Polynomial-Time Algorithm

Rewriting Theorem 5 gives that if a polynomially searchable neighborhood function N with performance bound R exists for some given combinatorial optimization problem $\Pi \in$ NPO, then the problem of finding an R-approximate solution for Π is not NP-hard, provided that NP $\neq$ co-NP. One question that arises is whether this result can be strengthened to the extent that the existence of such an N implies that the problem of finding an R-approximate solution for Π is easy, i.e.,

polynomially solvable. In this section we prove for a special type of combinatorial optimization problem that the answer is affirmative for $R = 1$ and that it is affirmative up to some arbitrary small error $\varepsilon > 0$ for $R > 1$. In other words, we show for a special type of combinatorial optimization problem how we can derive from a polynomially searchable exact neighborhood function a polynomial-time algorithm that solves the problem and how we can derive from a polynomially searchable neighborhood function with performance bound R a polynomial-time approximation algorithm with a performance bound of $R + \varepsilon$ for any precision $\varepsilon > 0$. Besides being polynomial in the input size, the $(R + \varepsilon)$-approximation algorithm is also polynomial in $\frac{1}{\varepsilon}$. Before proving these results, we introduce some terminology used in this section. The results are due to Schulz, Weismantel, and Ziegler [12] and Orlin, Punnen, and Schultz [13], respectively.

For many combinatorial optimization problems, it holds that a solution can be viewed as a subset of a ground set E and that the cost of a solution $s \subseteq E$ can be written as $\sum_{e \in s} c(e)$, where $c(e)$ is the cost of element $e \in E$. This is, for instance, the case for TSP: define E as the set of all pairs (i, j) of cities and $c(i, j)$ as the distance d_{ij} from city i to city j. We call such problems linear combinatorial optimization problems.

Definition 4. An *instance* of a linear combinatorial optimization problem is a pair (S, c), where each solution in the solution space $S \subseteq 2^E$ is a subset of a finite ground set $E = \{1, 2, \ldots, n\}$ and where $c : E \to \mathbb{Q}^+$ assigns a cost to each element $e \in E$. The cost of a solution $s \in S$ is defined by $f(s) = \sum_{e \in s} c(e)$. □

Definition 5. A *linear combinatorial optimization problem* Π is specified by a set of problem instances as defined in Definition 4, and the goal is to minimize for a problem instance the associated cost function f. Hence, for a problem instance (S, c), we have to find a solution s^* that satisfies $f(s^*) \leq f(s)$ for all $s \in S$. □

Definition 6. A linear combinatorial optimization problem Π is called *closed under scaling* whenever for each problem instance (S, c) of Π it holds that if we change function $c : E \to \mathbb{Q}^+$ to some other cost function $c' : E \to \mathbb{Q}^+$, then the problem instance remains in Π. □

In this section the focus is on linear combinatorial optimization problems Π that satisfy the following two properties.

- Π is closed under scaling.
- For each problem instance of Π, we can derive in polynomial time a feasible solution.

It can easily be verified that the linear combinatorial optimization problem TSP (the generic formulation) satisfies these two properties. However, this is not true, for instance, for Metric TSP because this problem is not closed under scaling.

If a problem is closed under scaling, then this need not necessarily mean that we can change the cost function of a problem instance in polynomial time. The reason for this is that an encoding scheme may be applied that does not give $c(e)$ explicitly for each $e \in E$. To avoid this problem, we focus on linear combinatorial optimization problems that are encoded by a cost-explicit encoding scheme, where a cost-explicit encoding scheme is defined as follows.

Definition 7. An encoding scheme of a linear combinatorial optimization problem is called *cost explicit* if the encoding $e_I \in \{0, 1\}^*$ of a problem instance $I = (S, c)$ with underlying ground set E is given by $e_I = e_I^{(1)} e_I^{(2)}$, where

- $e_I^{(1)}$ is an explicit encoding of the function $c : E \to \mathbb{Q}^+$, which means that it contains the encoding of $c(e)$ for each $e \in E$, and
- $e_I^{(2)}$ is an encoding, either implicit or explicit, of the solution space S.

Furthermore, $e_I^{(1)}$ only depends on S via its ground set E, and $e_I^{(2)}$ is independent of c. □

Exact Neighborhood Functions

Let Π be a linear combinatorial optimization problem from NPO that satisfies the two properties given above, and let a cost-explicit encoding scheme be used for Π. Furthermore, let N be an exact polynomially searchable neighborhood function for the problem. We will now present a polynomial-time algorithm, called $\mathcal{A}_{\text{opt}}(N)$, that solves Π.

Let $I = (S, c)$ be a problem instance of Π, where, without loss of generality, we assume that c is a function to the natural numbers instead of the rational numbers. $\mathcal{A}_{\text{opt}}(N)$ solves I in $K = \lceil \log_2(c_{\max} + 1) \rceil$ phases, where $c_{\max}$ is the maximum cost $c(e)$ of any element $e \in E$. In phase k an optimal solution is derived for the problem instance $I_k = (S, c_k)$ that is obtained from I by defining the cost $c_k(e)$ of an element $e \in E$ as the number represented by the k leading bits in the binary representation of $c(e)$. By adding leading zeros, the binary representation is made equally long for all $e \in E$, i.e., each binary representation consists of exactly K bits. We implement a phase by applying iterative improvement with the exact neighborhood function N. In the first phase, an arbitrary solution may be chosen as the starting solution, and in phase k with $k \geq 2$, the solution derived in phase $k - 1$ is chosen as the starting solution. Figure 4 gives the algorithm in pseudo-code, where f_k denotes the cost function related to problem instance I_k.

Theorem 6. *Let $\Pi \in$ NPO be a linear combinatorial optimization problem that is closed under scaling and for which we can derive a feasible solution in polynomial time. Furthermore, let N be a polynomially searchable exact neighborhood function for Π. Then the algorithm $\mathcal{A}_{\text{opt}}(N)$ given in Fig. 4 solves Π in polynomial time in the case that we use a cost-explicit encoding scheme for Π.*

algorithm $\mathcal{A}_{\mathrm{OPT}}(N)$

begin

$s :=$ some initial solution;

$K := \lceil \log_2(c_{\max} + 1) \rceil$;

for $k := 1$ **to** K **do**

begin

for all $e \in E$ **do** $c_k(e) := \lfloor c(e) \cdot 2^{k-K} \rfloor$;

repeat

generate an $s' \in N(s)$;

if $f_k(s') < f_k(s)$ **then** $s := s'$;

until $f_k(s') \geq f_k(s)$ for all $s' \in N(s)$;

end

end;

Fig. 4 Algorithm $\mathcal{A}_{\mathrm{opt}}(N)$ for a linear combinatorial optimization problem Π and an accompanying neighborhood function N. Π is closed under scaling, and (S, c) denotes an arbitrary problem instance of Π that is given as input to the algorithm. Cost function f_k relates to problem instance (S, c_k)

Proof By construction, the number of phases is bounded by $K = \lceil \log_2(c_{\max} + 1) \rceil$. Furthermore, because N is polynomially searchable, the individual iterations of the iterative improvement algorithm that makes up a single phase of $\mathcal{A}_{\mathrm{opt}}(N)$ can be implemented to run in polynomial time. Hence, to prove the theorem, we only have to show that in an arbitrary phase k the iterative improvement algorithm executed terminates within a polynomial number of iterations.

Let s_i be the solution derived in phase i of $\mathcal{A}_{\mathrm{opt}}(N)$, and let s_0 be the starting solution of the first phase. Hence, in phase k, iterative improvement starts with s_{k-1} and ends with s_k. Because the cost of the solution derived by iterative improvement decreases in each iteration, it suffices to prove that $f_k(s_{k-1}) - f_k(s_k)$ is polynomially bounded to show that in phase k iterative improvement terminates within a polynomial number of iterations. By defining $c^{(i)}(e)$ with $e \in E$ as the ith bit in the binary representation of $c(e)$, we obtain that for any solution s the cost $f_k(s)$ satisfies

$$f_k(s) = \begin{cases} \sum_{e \in s} c^{(1)}(e) & \text{if } k = 1 \\ 2 f_{k-1}(s) + \sum_{e \in s} c^{(k)}(e) & \text{if } k \geq 2. \end{cases}$$

Furthermore, we have $\sum_e \in {}_s c^{(k)}(e) \leq n$, where n denotes the number of elements in E. Using these two observations and the optimality of $s_k - {}_1$ with respect to cost function $f_k - {}_1$, we can derive for $k \geq 2$

$$f_k\,(s_{k-1}) - f_k\,(s_k) = 2\,(f_{k-1}\,(s_{k-1}) - f_{k-1}\,(s_k)) + \sum_{e \in s_{k-1}} c^{(k)}(e) - \sum_{e \in s_k} c^{(k)}(e) \leq n$$

and for $k = 1$

$$f_k\,(s_{k-1}) - f_k\,(s_k) = \sum_{e \in s_{k-1}} c^{(k)}(e) - \sum_{e \in s_k} c^{(k)}(e) \leq n.$$

This proves the theorem. □

Neighborhood Functions with Performance Bound

Theorem 6. Yields that if a polynomially searchable neighborhood function with performance bound $R = 1$ exists for a given linear combinatorial optimization problem Π that satisfies some properties, then the problem of finding an R-approximate solution for Π is polynomially solvable. We now show that for $R > 1$ this result holds up to some arbitrary small error $\varepsilon > 0$. More precisely, we proceed as follows.

Let Π be a linear combinatorial optimization problem from NPO that satisfies the same two properties as those given in Theorem 6 and for which we use a cost-explicit encoding scheme. Furthermore, let N be a polynomially searchable neighborhood function for Π with a performance bound of R. We now present an algorithm for which we will prove that for any precision $\varepsilon > 0$ it (*i*) has a running time that is polynomially bounded in both the input size and $\frac{1}{\varepsilon}$ and (*ii*) has a performance bound of $R + \varepsilon$.

Let $I = (S, c)$ be a problem instance of Π, and suppose that we perform iterative improvement on I, where we take an arbitrary $s \in S$ as a starting solution. By assumption, s can be derived in polynomial time. We turn iterative improvement into a polynomial-time algorithm in the following way: we replace the function c in I by c', such that in each iteration the cost of the solution derived by iterative improvement decreases by at least q and $f'(s)/q$ is polynomially bounded, where $f'(s)$ is the cost of solution s with respect to the new function $c' : E \to \mathbb{Q}^+$. The former property is achieved by defining for any $e \in E$

$$c'(e) = \left\lceil \frac{c(e)}{q} \right\rceil q.$$

The latter property is achieved by defining q as

$$q = \frac{f(s)\varepsilon}{2nR\,(R+\varepsilon)}$$

since we then have

$$\frac{f'(s)}{q} \leq \frac{f(s)+nq}{q} = 2nR\left(\frac{R}{\varepsilon}+1\right)+n,$$

which is polynomially bounded in $|I|$ and $\frac{1}{\varepsilon}$.

Using the polynomial-time algorithm described, we can now construct a polynomial-time $(R+\varepsilon)$-approximation algorithm $\mathcal{A}_\varepsilon(N)$ for Π. Algorithm $\mathcal{A}_\varepsilon(N)$ proceeds in phases. In each phase the algorithm described is executed, where the final solution of the previous phase is taken as a starting solution. If the algorithm arrives at a solution for which the cost is at most half the cost of the solution with which the phase started, then the algorithm is interrupted, and the next phase is initiated. If the algorithm terminates, i.e., if it arrives at a local optimum, then the overall algorithm $\mathcal{A}_\varepsilon(N)$ also terminates. In Fig. 5 algorithm $\mathcal{A}_\varepsilon(N)$ is given in pseudo-code.

Lemma 3. *Let $\Pi \in$ NPO be a linear combinatorial optimization problem that is closed under scaling and for which we can derive a feasible solution in polynomial time. Furthermore, let N be a polynomially searchable neighborhood function for Π. Then the algorithm $\mathcal{A}_\varepsilon(N)$ given in Fig. 5 runs in polynomial time in the case that we use a cost-explicit encoding scheme for Π.*

Proof The number of phases executed by $\mathcal{A}_\varepsilon(N)$ is bounded by $\log(nc_{\max})$, where $c_{\max}$ is the maximum cost $c(e)$ of any element $e \in E$. As a cost-explicit encoding scheme is assumed, this implies that the number of executed phases is polynomially bounded. Combined with the above-derived polynomial running time of each individual phase, this proves the polynomial-time running time of $\mathcal{A}_\varepsilon(N)$. □

The next lemma focuses on the quality of the solutions returned by $\mathcal{A}_\varepsilon(N)$.

Lemma 4. *Let Π be a linear combinatorial optimization problem that is closed under scaling, and let N be a neighborhood function for Π with performance bound R. Then the algorithm $\mathcal{A}_\varepsilon(N)$ given in Fig. 5 is an $(R+\varepsilon)$-approximation algorithm.*

Proof Let s_{init}, q, c', and f' denote the corresponding values at the moment $\mathcal{A}_\varepsilon(N)$ terminates, let s be the solution returned by the algorithm, and let s^* be an optimal solution to the problem instance $I = (S, c)$, which is the problem instance that is given as input to the algorithm.

algorithm $\mathcal{A}_\varepsilon(N)$

begin

$s :=$ some initial solution;

$stop :=$ FALSE;

while $\neg stop$ **do**

begin

$s_{\text{init}} := s$;

$q := f(s_{\text{init}})\varepsilon/(2nR(R+\varepsilon))$;

for all $e \in E$ **do** $c'(e) := \left\lceil \frac{c(e)}{q} \right\rceil q$;

repeat

if $f'(s') \geq f'(s)$ for all $s' \in N(s)$ **then** $stop :=$ TRUE;

else

begin

generate an $s' \in N(s)$;

if $f'(s') < f'(s)$ **then** $s := s'$;

end

until $stop =$ TRUE or $f(s) \leq f(s_{\text{init}})/2$;

end

end;

Fig. 5 Algorithm $\mathcal{A}_\varepsilon(N)$ for a linear combinatorial optimization problem Π that is closed under scaling, an accompanying neighborhood function N, and an arbitrary precision $\varepsilon > 0$. (S, c) denotes an arbitrary problem instance of Π that is given as input to the algorithm. Cost function f relates to problem instance (S, c), while cost function f' relates to problem instance (S, c')

According to the definition of function c', we have $f(s) \leq f'(s)$. Furthermore, as s is locally optimal for problem instance $I' = (S, c')$ (but not necessarily for I) and as the neighborhood function has a performance bound of R, by assumption, we have $f'(s) \leq R \cdot f'(s^*)$. Using this, we can derive

$$f(s) \leq R \cdot f'\left(s^*\right) = R \sum_{e \in s^*} \left\lceil \frac{c(e)}{q} \right\rceil q \leq R \sum_{e \in s^*} (c(e) + q) \leq R \cdot f\left(s^*\right) + Rnq. \tag{2}$$

Moreover, $f(s_{\text{init}})/2 < f(s)$ holds because otherwise the last phase of the algorithm would have been interrupted just before setting the variable *stop* to true. From this and the definition of q, it now follows that $q < f(s)\frac{\varepsilon}{nR(R+\varepsilon)}$. Combined with (2) this gives $f(s) \leq R \cdot f(s^*) + f(s)\frac{\varepsilon}{R+\varepsilon}$, which can be rewritten as $f(s) \leq (R + \varepsilon) f(s^*)$. □

Theorem 7. *Let $\Pi \in$ NPO be a linear combinatorial optimization problem that is closed under scaling and for which we can derive a feasible solution in polynomial time. Furthermore, let N be a polynomially searchable neighborhood function for Π with performance bound R. Then the algorithm $\mathcal{A}_\varepsilon(N)$ given in Fig. 5 is a polynomial-time $(R + \varepsilon)$-approximation algorithm in the case that we use a cost-explicit encoding scheme for Π.*

Proof The theorem follows directly from Lemmas 3 and 4. □

Time Complexity

Since optimal algorithms for NP-hard problems have exponential running time, we presented local search as an approach that trades off quality against performance. More precisely, it tries to reduce execution time by not solving the real optimization problem, but an associated local search problem, as defined below.

Definition 8. An *instance* of a local search problem is a triple (S, f, N), where (S, f) is an instance of a combinatorial optimization problem and $N: S \to 2^S$ is a neighborhood function on S. □

Definition 9. A *local search problem* Π_{LS} is specified by a set of problem instances, and it is either a minimization or a maximization problem. The problem is to find for a given instance (S, f, N) a locally optimal solution $\hat{s} \in S$. For a minimization problem, this means that $f\left(\hat{s}\right) \leq f(s)$ for all $s \in N(s)$, and for a maximization problem, it means that $f\left(\hat{s}\right) \geq f(s)$ for all $s \in N(s)$. □

For the time complexity of a local search algorithm, we can both be interested in the average case time complexity or in a guaranteed, i.e., worst-case time complexity. In this section we focus on the latter. First we study the computational complexity of local search problems. This means that we try to find an answer to the question of how hard the problem is that a local search algorithm tries to solve. This section is based on the paper of Yannakakis [11], who gives an

excellent presentation of the complexity theory for local search problems introduced by Johnson, Papadimitriou, and Yannakakis [14]. Second, we look at the time complexity of the basic local search algorithm: iterative improvement.

Computational Complexity of Local Search Problems

To distinguish easy *decision* problems from hard ones, the theory of NP-completeness has been developed. In a nutshell, the idea of this theory is as follows. A class NP of decision problems is defined that contains the decision variants of many apparently hard and interesting combinatorial optimization problems. To relate the complexity of two problems in NP, polynomial-time reductions are introduced. If a problem Π is polynomially reducible to problem Π', then Π' is at least as hard as Π, which means that a polynomial-time algorithm for Π' can only exist if it exists for Π. The problems in NP to which all problems in this class are polynomially reducible are called NP-complete. These problems are the hardest problems in NP since they only allow an efficient polynomial-time algorithm if such an algorithm exists for all problems in NP. This is very unlikely as no polynomial-time algorithm has been found for an NP-complete problem despite the enormous amount of effort that has been spent by many experts on finding one.

A similar strategy is used to identify hard local search problems for which it is very unlikely that they can be solved by a polynomial-time algorithm. First of all, we define a complexity class, called PLS, which contains local search problems that are specified by a combinatorial optimization problem from NPO and a "reasonable" corresponding neighborhood function. Next, we present a reduction to express that a local search problem is at least as hard as another given local search problem. Using this reduction, we can identify the hardest problems in PLS. Because no polynomial-time algorithm is known for any of these PLS-complete problems, as they are called, it is commonly believed that no such algorithm exists for these problems.

We now further elaborate on this theory. Let Π be a combinatorial optimization problem from NPO, and let N be a neighborhood function for it. A successful application of local search for this problem depends on whether it is easy to generate an initial solution and to check whether a solution is locally optimal and, if not, to derive a better neighbor. In terms of iterative improvement, this means that both the initialization and each single iteration of the algorithm can be implemented to run in polynomial time. The number of iterations, however, may be exponential. The class PLS contains all local search problems in which the properties described are satisfied.

Definition 10. Let Π_{LS} be a local search problem, and let Π be the underlying combinatorial optimization problem. Local search problem Π_{LS} is in the class *PLS (Polynomial-time Local Search)* if $\Pi \in$ NPO and if two polynomial-time algorithms A and B exist that satisfy the following properties.

- For a problem instance (S, f, N) of Π_{LS}, algorithm A returns a solution $s \in S$.
- For a problem instance (S, f, N) of Π_{LS} and a solution $s \in S$, algorithm B decides whether s is a local optimum and, if this is not the case, it returns a neighboring solution with better cost.

□

The following definition specifies a PLS-reduction by which we can relate the complexity of two local search problems. From the definition it follows directly that if local search problem Π_{LS} is PLS-reducible to local search problem Π'_{LS}, then the existence of a polynomial-time algorithm for Π'_{LS} implies the existence of such an algorithm for Π_{LS}. In other words, Π'_{LS} is at least as hard as Π_{LS}. Furthermore, it can be verified that PLS-reductions are transitive, which means that if Π_{LS} is PLS-reducible to Π'_{LS} and Π'_{LS} is PLS-reducible to Π''_{LS}, then Π_{LS} is also PLS-reducible to Π''_{LS}.

Definition 11. Local search problem Π_{LS} is *PLS-reducible* to local search problem Π'_{LS}, denoted by $\Pi_{\text{LS}} \propto \Pi'_{\text{LS}}$, if two polynomial-time algorithms φ_1 and φ_2 exist that satisfy the following properties; see also Fig. 6.

- Algorithm φ_1 transforms a problem instance I of Π_{LS} into a problem instance $\varphi_1(I)$ ofΠ'_{LS}.
- Algorithm φ_2 maps a problem instance $I = (S, f, N)$ of Π_{LS} and a solution $s' \in S'$ with $\varphi_1(I) = (S', f', N')$ to a solution $s \in S$.
- For a problem instance I of Π_{LS}, we have that if $s' \in S'$ is a local optimum for $\varphi_1(I) = (S', f', N')$, then $\varphi_2(I, s')$ is a local optimum for I.

The pair (φ_1, φ_2) is called a *PLS-reduction*. □

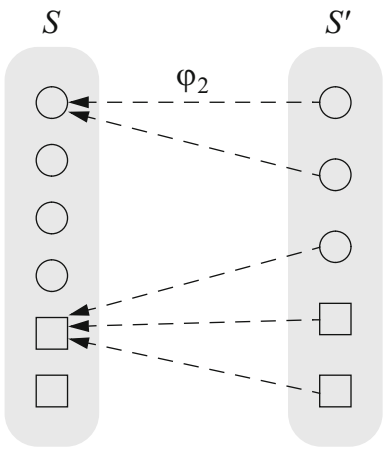

Fig. 6 Example of algorithm φ_2 for mapping solutions from S' to solutions from S. The squares indicate the local optima

We note that the definition of φ_2 can be weakened. For φ_2 it suffices that instead of all solutions in S', only the local optima are mapped to a solution in S. However, if we have $\Pi_{LS} \in$ PLS, then we can easily transform such a φ_2 into an algorithm that satisfies Definition 11 by mapping all solutions that are not in the domain of the restricted φ_2 to the solution returned by the polynomial-time algorithm A defined in Definition 10. Analogously to NP-completeness, we define the notion of PLS-completeness to indicate the hardest problems in PLS.

Definition 12. A local search problem in PLS is *PLS-complete* if each problem $\Pi_{LS} \in$ PLS is PLS-reducible to it. □

Let NPCO contain all NP-hard problems from NPO. When determining the complexity of solving some combinatorial optimization problem from NPO to optimality, one generally aims to decide whether the problem is in PO or in NPCO. It is therefore interesting to relate the class PLS and the subclass of PLS-complete problems to the classes PO, NPO, and NPCO. This is the focus of the remainder of this section.

First we show that PLS $\subseteq$ NPO. Let Π_{LS} be an arbitrary local search problem in PLS. Problem Π_{LS} can be formulated as a minimization problem $\Pi \in$ NPO by defining an instance $(S, f') \in \Pi$ for any instance $(S, f, N) \in \Pi_{LS}$, such that cost function $f': S \rightarrow \{0, 1\}$ satisfies $f'(s) = 0$ if s is locally optimal and $f'(s) = 1$ otherwise. The existence of algorithm B as defined in Definition 10 for Π_{LS} implies that f' is computable in polynomial time. From this it follows that Π is indeed a problem from NPO. Moreover, Π_{LS} and Π are clearly equivalent. As a result, we get PLS $\subseteq$ NPO.

We now show that PO $\subseteq$ PLS. Let $\Pi \in$ PO and let $\mathcal{A}$ be an optimal polynomial-time algorithm for Π. Without loss of generality, we assume that Π is a minimization problem. Then we define minimization problem $\Pi' \in$ PO such that any instance $I = (S, f)$ of Π corresponds to an instance (S, f') of Π', where $f'(s) = 0$ if solution s is optimal with respect to cost function f and $f'(s) = 1$ otherwise. If we define a neighborhood function for Π' in such a way that each solution has only one neighbor, namely, the solution returned by $\mathcal{A}$, then we obtain a local search problem that is equivalent to Π. Furthermore, the problem is in PLS. Algorithm A in Definition 10 can be defined as $\mathcal{A}$, and algorithm B in this definition can be realized by first comparing the cost of the solution given by $\mathcal{A}$ with the cost of a given solution s and by then returning the optimal solution derived by $\mathcal{A}$ if the latter cost is larger. Hence, we now obtain the following result.

Theorem 8. *The complexity classes PO, PLS, and NPO satisfy*

$$PO \subseteq PLS \subseteq NPO.$$

□

From the relation PLS $\subseteq$NPO, it follows that a PLS-complete problem is not harder than any NP-hard problem in NPO, as will now be shown. Suppose that a polynomial-time algorithm exists for an NP-hard problem in NPCO. This means that all problems in NPO are polynomially solvable, including those in PLS. To substantiate the intractability of PLS-complete problems, a more interesting question is whether PLS-complete problems are also at least as hard as the problems in NPCO. If the answer were to be affirmative, then the existence of a polynomial-time algorithm for a PLS-complete problem would be as unlikely as the existence of such an algorithm for a problem in NPCO. However, this is not the case because the following theorem states that if NP $\neq$ co-NP, then a PLS-complete problem is not NP-hard. Hence, in the unlikely case that PLS-complete problems turn out to be polynomially solvable, this still does not imply that the problems in NPCO are also solvable in polynomial time. Figure 7 depicts the relations between the different complexity classes.

Theorem 9. *If NP $\neq$ co-NP, then none of the problems in PLS are NP-hard.*

Proof The result can be proved in a similar way as Theorem 5. Note that Theorem 5 easily follows from this theorem. Suppose that a problem $\Pi_{\mathrm{LS}} \in$ PLS is NP-hard. We show that this contradicts NP $\neq$ co-NP by showing that it implies that, for any decision problem Π_D in NP, the complementary problem Π_D^c obtained by reversing the answers in Π_D is also in NP.

As Π_{LS} is NP-hard, a polynomial-time algorithm $\mathcal{A}$ exists that decides Π_D, where $\mathcal{A}$ may use an oracle that, for any problem instance of Π_{LS}, returns a local optimum. Hence, if for a problem instance I of Π_D we are given a sequence consisting of local optima that may be returned successively by the oracle during the execution of $\mathcal{A}$ on I, then we can determine in polynomial time whether I is a yes-instance or a no-instance of Π_D. As a result, we can use this sequence of locally optimal solutions as a certificate for yes-instances of Π_D^c. Furthermore, the certificate, which is of polynomial size, can be checked in polynomial time for validity by substituting each call of the oracle in $\mathcal{A}$ by a polynomial-time procedure that checks whether the corresponding solution in the certificate is a solution to the problem instance of Π_{LS} given to the oracle. The existence of polynomial-time

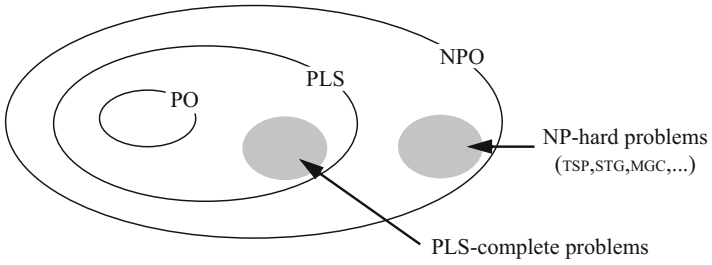

Fig. 7 Positioning of the classes PO, PLS, and NPO in the case that P $\neq$ NP, NP $\neq$ co-NP, and PO $\neq$ PLS

algorithm B in Definition 10 shows that this polynomial-time procedure exists. This proves $\Pi_D^c \in$ NP, which completes the proof of the theorem. □

Proving PLS-Completeness

As for the theory of NP-completeness, the theory of PLS-completeness only becomes useful once we have a first problem for which we can prove that it is among the hardest of the class PLS. After that, we can prove PLS-completeness of a problem by simply proving that a known PLS-complete problem is PLS-reducible to it. The first problem for which PLS-completeness has been proved is circuit/flip as defined below.

Suppose we want to apply local search to the problem of finding an integer s with $0 \leq s < 2^n$ for which a given function $f: \{0, 1, \ldots, 2^n - 1\} \to \{0, 1, \ldots, 2^m - 1\}$ is minimized. We can use the neighborhood function in which $s' \in \{0, 1, \ldots, 2^n - 1\}$ is a neighbor of s if s' can be obtained from s by flipping exactly one of the n bits in the binary representation of s. The corresponding local search problem, formulated in terms of Boolean circuits, is the first problem that has been proved to be PLS-complete.

Boolean circuits are theoretical counterparts of the digital circuits from which computers are made. They compute Boolean functions $f: \{0, 1\}^n \to \{0, 1\}^m$, and, conversely, each Boolean function is computed by a circuit.

Definition 13. A *Boolean circuit* is a directed acyclic graph $D = (V, A)$. The node set V consists of n input nodes and $|V| - n$ gates. The input nodes have indegree zero and are labeled by the binary variables $x_1, x_2, \ldots, x_n$. The labels of the gates are taken from the set $\{\wedge, \vee, \neg\}$ of Boolean functions. The gates with outdegree zero are called the output nodes, and they are additionally labeled by the binary variables $y_1, y_2, \ldots, y_m$. Boolean circuit D computes a Boolean function $f: \{0, 1\}^n \to \{0, 1\}^m$ by deriving for given values of the input variables $x_1, x_2, \ldots, x_n$ corresponding values for the output variables $y_1, y_2, \ldots, y_m$ in the following way.

Let l be the label of a gate g. If l is given by $\neg$, then the value of g is one minus the value of the node from which the only incoming edge of g is incident. Next, suppose that $l \in \{\wedge, \vee\}$. Then g has exactly two incoming edges. Let o_1, o_2 be the values of the nodes from which these two edges are incident. If g is labeled $\wedge$, then it is assigned the value 1 if $o_1 = o_2 = 1$, and it is assigned the value 0, otherwise. If g is labeled $\vee$, then it is assigned the value 0 if $o_1 = o_2 = 0$, and it is assigned the value 1 otherwise. The *size* of Boolean circuit $D = (V, A)$ is given by the number of nodes in V. □

By interpreting the input and output vectors as two numbers written in binary notation, i.e., by interpreting the input as $\sum_{i=1}^{n} 2^{i-1} x_i$ and the output as $\sum_{i=1}^{m} 2^{i-1} y_i$, a Boolean circuit can compute an integer function. Hence, the local search problem mentioned above can be formalized by the following definition. We note that the

Hamming distance of two strings s and s' of equal size, denoted by $H(s, s')$, is given by the number of positions in which s and s' differ.

Definition 14 (Circuit/flip). Given is a Boolean circuit D with n input nodes x_1, x_2, ..., x_n and m output nodes y_1, y_2, ..., y_m. The neighborhood function, called flip, is based on the solution space $\{0, 1\}^n$ containing all possible input vectors (x_1, x_2, ..., x_n) of the circuit. A solution s is a neighbor of solution s' if s and s' have a Hamming distance $H(s, s')$ of one. Find a solution $\hat{s}$ that is locally optimal with respect to the cost function

$$f\left(\hat{s}\right) = \sum_{i=1}^{m} 2^{i-1} y_i,$$

which gives the integer interpretation of the output of Boolean circuit D on input $\hat{s}$. In min-circuit/flip, it is our goal to minimize the cost function, while in max-circuit/flip it is our goal to maximize the cost function. □

Theorem 10. *Min-circuit/flip and max-circuit/flip are both PLS-complete.* □

Although very interesting, the proof of the above theorem is rather complex and therefore left out of this chapter. For details, we refer to Yannakakis [11], Johnson, Papadimitriou, and Yannakakis [14] or Michiels, Aarts, and Korst [1]. To focus on how the theory can be used, we now give an example of how it can be used to show that the uniform graph partitioning problem with the Kernighan-Lin neighborhood function is PLS-complete.

Definition 15 (Uniform Graph Partitioning (UGP)). Given is an edge-weighted graph $G = (V, E)$ with $|V| = 2n$ and a weight $w(e) \in \mathbb{N}$ for each edge $e \in E$. Find a partition of V into two subsets V_1 and V_2 with $|V_1| = |V_2| = n$, such that the sum of the weights of the edges that have one endpoint in V_1 and one endpoint in V_2 is minimal, i.e., such that

$$c\left(V_1, V_2\right) = \sum_{e \in E \cap (V_1 \times V_2)} w(e)$$

is minimal. □

An obvious neighborhood function for UGP is the swap neighborhood function in which the neighbors of a partition (V_1, V_2) are obtained by interchanging a node from V_1 with a node from V_2. Variable-depth search gives an effective approach for making the swap neighborhood function more powerful. The main idea is that we allow multiple swaps to be performed simultaneously. We call the resulting neighborhood function Kernighan-Lin, after its two inventors. For each i with $1 \leq i \leq n$, the Kernighan-Lin neighborhood of a partition (V_1, V_2) contains exactly one partition that is obtained from (V_1, V_2) by exchanging i nodes from V_1 with i nodes from V_2.

The n Kernighan-Lin neighbors of a partition (V_1, V_2), written as $\left(V_1^{(i)}, V_2^{(i)}\right)$ for $1 \leq i \leq n$, can be determined in n steps as follows. In Step i we derive partition $\left(V_1^{(i)}, V_2^{(i)}\right)$ by performing the best possible swap on (V_1, V_2) if $i = 1$ and on the partition $\left(V_1^{(i-1)}, V_2^{(i-1)}\right)$ derived in the previous step if $2 \leq i \leq n$. We are not allowed to select a node that has already been selected before for a swap. By the best possible swap, we mean the swap of the nodes from $V_1^{(i-1)}$ and $V_2^{(i-1)}$ that produces the maximum decrease in cost or, if such a swap does not exist, a minimum increase in cost. In the case of a tie, a tie-breaking rule is used to choose a unique pair of nodes that is swapped. The neighborhood consists of n partitions because, after n swaps, all nodes of the graph have been selected for an exchange and, by definition, each node may only be selected once. In other words, the neighbors are obtained by performing iterative improvement using the best-improvement pivoting rule and the swap neighborhood function. However, unlike the standard iterative improvement algorithm, we have the additional constraint that each node may only be selected once for a swap and that we accept a best cost-increasing neighbor if we are in a local optimum.

We prove that UGP with the Kernighan-Lin neighborhood function is PLS-complete by a reduction from another local search problem. Before defining this problem, we introduce some terminology. Let U be a set of binary variables. A truth assignment for U assigns to each variable in U either the value 0 (false) or 1 (true). A variable $u \in U$ is called a positive literal, and its negation $\overline{u} = 1 - u$ is called a negative literal. A clause is a set of literals and/or constants, where a constant has the value either 0 or 1.

Definition 16 (Positive Not-All-Equal Max-3Sat (POS NAE MAX-3SAT)). Given is a set U of binary variables, a set C of clauses over U, and a positive integer weight $w(c)$ for each clause $c \in C$. A clause does not contain negative literals, and the number of positive literals plus the number of constants in each clause is at most three. A clause is satisfied by some truth assignment if and only if it contains at least one literal/constant with value 1 and at least one literal/constant with value 0. The problem is to find a truth assignment that maximizes the sum of the weights of clauses that are satisfied. □

A possible neighborhood function for POS NAE MAX-3SAT is the flip neighborhood function in which truth assignment t' is a neighbor of truth assignment t if t' can be obtained from t by changing (flipping) the value of one variable. In much the same way as the Kernighan-Lin neighborhood function for UGP is obtained by applying variable-depth search to the swap neighborhood function, the Kernighan-Lin neighborhood function for POS NAE MAX-3SAT is obtained by applying variable-depth search to the flip neighborhood function. This means that a truth assignment t' is a neighbor of truth assignment t with respect to the Kernighan-Lin neighborhood function if it can be derived from t by performing a sequence of flips, where in each step the most profitable (least unprofitable) flip is chosen from the flips that change the value of a variable that has not been flipped before

in this sequence. An arbitrary rule may be used for breaking ties. We now state the following result without proof. For a proof, we again refer to Yannakakis [11], Johnson, Papadimitriou, and Yannakakis [14] or Michiels, Aarts, and Korst [1].

Theorem 11. *POS NAE MAX-3SAT with the Kernighan-Lin neighborhood function is PLS-complete.* □

Knowing that POS NAE MAX-3SAT/Kernighan-Lin is PLS-complete, we are now able to prove that UGP/Kernighan-Lin is PLS-complete.

Theorem 12. *UGP with the Kernighan-Lin neighborhood function is PLS-complete.*

Proof Let the cut of a partition (V_1, V_2) be defined as the set of edges that have one endpoint in V_1 and one in V_2.

UGP is equivalent to its maximization variant in which we are asked to partition the nodes of a graph into two sets V_1, V_2 of equal size, such that the weight $c(V_1, V_2)$ of the resulting cut is maximized instead of minimized. This can be seen as follows. Let $G = (V, E)$ be a weighted graph with maximum weight $W = \max_e \in_E w(e)$, and let K be the complete graph on the same node set V, in which the weight of an edge e is given by $W - w(e)$ if $e \in E$ and by W otherwise. The cost of a partition (V_1, V_2) in one variant of the problem is then equivalent to n^2W minus the cost of this partition in the other variant. This implies that both problems are indeed equivalent.

When we inspect the given relation between the two variants, it follows easily that the corresponding local search problems under the Kernighan-Lin neighborhood function are also equivalent. As a result, we can prove the theorem by giving a PLS-reduction (φ_1, φ_2) from POS NAE MAX-3SAT/Kernighan-Lin to the maximization version of UGP with the Kernighan-Lin neighborhood function, where we use Theorem 11, which states that the former problem is PLS-complete.

Definition PLS-reduction. Let I be an arbitrary problem instance of POS NAE MAX-3SAT/Kernighan-Lin, and let $x_1, x_2, \ldots, x_m$ be the binary variables of I. The problem instance $\varphi_1(I)$ is defined by the following graph $G = (V, E)$. Node set V contains two nodes x_i and x_i' for each variable x_i in I. The nodes x_i and x_i' represent the value of the variable x_i and its negation, respectively. To V we also add the nodes y and z, which represent the constant 1, and the nodes y' and z', which represent the constant 0. This concludes the definition of V.

The edge set E is partitioned into the two subsets E_1 and E_2. Set E_1 contains all edges that connect an unprimed node x_i with its primed variant. Furthermore, it contains an edge from each of the two 1-nodes y and z to each of the two 0-nodes y' and z'. All these $m + 4$ edges are assigned the same large weight of $W + 1$, where W is defined as the total weight of all clauses in I. The following two conditions are necessary and sufficient to guarantee that a cut contains all edges from E_1.

- Nodes y and z that represent the constant 1 are both assigned to the same subset, and nodes y' and z' that represent the constant 0 are both assigned to the other subset.
- The nodes x_i and x_i' are assigned to different subsets for all $1 \leq i \leq m$.

If these two conditions are satisfied by a partition, we say that the partition is feasible; see Fig. 8 for an example. We can assume the following one-to-one correspondence between a feasible partition and a truth assignment without violating the interpretation of the nodes x_i and x_i' as being the value of variable x_i and its negation. A variable x_i or its negation is assigned the value 1 if and only if the corresponding node is contained in the same subset as the variables y, z that represent the constant 1. This means that if a variable or its negation is assigned the value 0, then the corresponding node is contained in the same subset as the two variables y' and z' that represent the constant 0. We define P_t as the feasible partition corresponding to truth assignment t and R as the set of all feasible partitions, i.e., $R = \{P_t \mid t \text{ truth assignment}\}$.

To be able to derive the cost of a truth assignment t from the feasible partition P_t, we add additional edges to E via E_2. For each clause $c = \{a, b\}$, we add the edge $\{a, b\}$ to E_2 with the same weight as clause c, where for the constants 1 and 0 we use the nodes y and y', respectively. If such an edge contributes its weight to the cost of a feasible partition P_t, then a and b are assigned to different subsets, which imply that the clause $\{a, b\}$ is satisfied by truth assignment t.

For a clause $c = \{a, b, c\}$ of weight w, we include the three edges $\{a, b\}$, $\{b, c\}$, and $\{a, c\}$ in E_2, each with weight $w/2$. It can be verified that the cut of a potentially infeasible partition contains either two out of the three edges or none of the three edges. Moreover, for a feasible partition P_t, the former case implies that clause c is satisfied by t, and the latter case implies that c is not satisfied by t. As a result, the edges contribute w to the cost of a feasible partition P_t if c is satisfied by t and they do not contribute otherwise. We note that if a pair of nodes a, b occurs in several

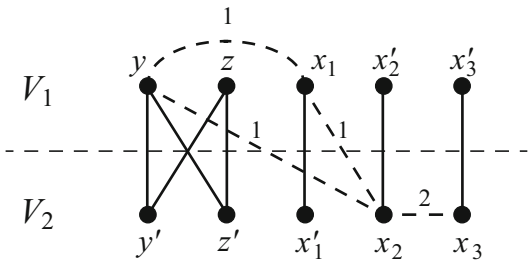

Fig. 8 Feasible partition $P_t = (V_1, V_2)$ for the graph $\varphi_1(I)$, where I is the problem instance of POS NAE MAX-3SAT/Kernighan-Lin consisting of the two clauses $\{x_1, x_2, 1\}$ and $\{x_2, x_3\}$. Both clauses have a weight of two. The undashed edges are from E_1 and the dashed edges are from E_2. Each edge from E_1 has weight $W + 1 = 5$, and the weights of the edges from E_2 are denoted in the figure. Feasible partition P_t corresponds to truth assignment t with $x_1 = 1$ and $x_2 = x_3 = 0$. This truth assignment satisfies the clause $\{x_1, x_2, 1\}$ but not the clause $\{x_2, x_3\}$

clauses, we assign to edge $\{a, b\}$ the weight obtained by summing up the weights that arise from all these clauses. This concludes the definition of G and therefore of problem instance $\varphi_1(I)$. To complete the definition of our PLS-reduction, we define algorithm φ_2 in such a way that it returns for a potentially infeasible partition P the truth assignment that assigns to a variable x_i the value 1 if and only if it is contained in the same subset as variable y. Note that this algorithm complies with the given relation between a truth assignment t and the feasible partition P_t.

Proof strategy. As the total weight W of the edges from E_2 that can be in the cut of a partition is strictly smaller than the weight $W + 1$ of a single edge in E_1 and as the cut of a feasible partition contains all edges from E_1, we can make the following observation.

Observation. The minimum cost over all feasible partitions is strictly larger than the maximum cost over all infeasible partitions.

This implies that, for any feasible partition P_t, the transition graph $T_{\varphi_1(I)}$ of $\varphi_1(I)$ only contains outgoing arcs to other feasible solutions. Consequently, to prove that (φ_1, φ_2) correctly defines a PLS-reduction, it suffices to prove that the transition graph satisfies the following two conditions.

- *Condition 1.* $T_{\varphi_1(I)}$ contains an arc $(P_t, P_{t'})$ if and only if T_I contains the arc (t, t'). See Fig. 9.
- *Condition 2.* For any partition $P \notin R$, transition graph $T_{\varphi_1(I)}$ contains a path to a feasible partition.

In the proof we assume that, to determine the Kernighan-Lin neighborhood of a partition, an arbitrary rule is used for breaking ties in the case that several pairs of nodes qualify for being selected for a swap. Given this rule, we may choose the tie-breaking rule used to determine the Kernighan-Lin neighborhood of a truth assignment as we like because the PLS-completeness result for POS NAE MAX-3SAT/Kernighan-Lin holds regardless of this rule.

Proof of Condition 1 As the cost of a feasible partition P_t is given by $|E_1|(W + 1)$ plus the cost of truth assignment t, the first condition holds if we can prove that

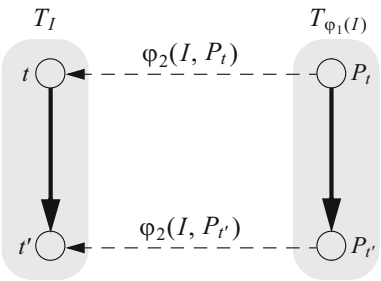

Fig. 9 Correspondence between arc in transition graph T_I and arc in transition graph $T_{\varphi_1(I)}$

for any truth assignment t, partition P_t and t have the same neighborhood. More precisely, it suffices to show that $P_{t'}$ is a neighbor of P_t for $t' \neq t$ if and only if t' is a neighbor of t. Until all pairs of nodes x_i, x_i' have been swapped and thus blocked, we only swap pairs x_i, x_i' of nodes when deriving the neighbors of P_t. This is true since swapping such a pair in a feasible partition results again in a high-quality, feasible partition, while swapping any other pair of nodes results in a low-quality, infeasible partition. After all pairs of nodes x_i, x_i' have been swapped, the nodes y, z and y', z' are swapped in two steps, where the intermediate partition is infeasible. This brings us back to partition P_t.

Swapping x_i and x_i' has the same effect on the cost of a feasible partition as flipping the value of variable x_i on the cost of the corresponding truth assignment. As a result, we obtain that, if the same rule is used for breaking ties in the derivation of the Kernighan-Lin neighborhood of t as is used in the derivation of the Kernighan-Lin neighborhood of P_t, then the feasible neighbors of P_t, excluding P_t, correspond to the truth assignments in the neighborhood of t. This proves the first claimed condition given above.

Proof of Condition 2 To prove the second condition, suppose that it does not hold, which means that an infeasible partition $\hat{P}$ exists that is locally optimal. We show that this gives rise to a contradiction. As $\hat{P} = (V_1, V_2)$ is infeasible, either V_1 contains a pair u, u' of corresponding nodes or the two 1-nodes y, z are split. First of all, consider the former case. Obviously, V_2 also contains a pair v, v' of corresponding nodes as $|V_1| = |V_2|$. Swapping u and v leads to a weight gain of at least $W + 1$ via the edges from E_1, and it leads to a weight reduction of at most W via the edges from E_2. This contradicts the assumption that $\hat{P}$ is locally optimal. Next, assume that the two 1-nodes are split but that V_1 does not contain a pair u, u' of corresponding nodes. The two 0-nodes then also have to be in different subsets. Swapping a 0-node from one subset with a 1-node in the other subset yields a cost improvement of $2(W + 1)$. Again, this contradicts the local optimality of $\hat{P}$. □

It follows from the definition of PLS that an improving solution can be found in polynomial time if it exists. This is true for k-Opt, where an improving tour can be found in $\mathcal{O}\left(n^k\right)$ time. However, this is only practical for very small k. An interesting question is whether we can do better. This is studied by Marx [15] and Guo et al. [16]. They prove for a number of TSP neighborhood functions that the answer to this question is negative. However, the complexity may be exponential in k.

Time Complexity of Iterative Improvement

While the focus of the previous section was on the computational complexity of local search problems, we now study the time complexity of the iterative improvement algorithm when it is used to solve such a problem. A local search problem can be formulated as finding a node in a transition graph with outdegree zero. Iterative improvement is the obvious algorithm for tackling this problem. It

traverses a transition graph, which is directed and acyclic, until it reaches a node without outgoing arcs. The precise path that the algorithm follows is determined by the pivoting rule. This rule specifies the neighboring solution that is selected if a solution has more than one neighbor with better cost. In terms of the transition graph, the pivoting rule prescribes which arc is to be selected in a given node if it has multiple outgoing arcs. Ideally, we would like to use a pivoting rule that takes the shortest path to a local optimum. However, computing this rule may be NP-hard, as, for instance, is the case for TSP with the 2-change neighborhood function [17].

As most of the neighborhood functions used in practice induce relatively small neighborhoods, which is reflected in our definition of the class PLS, it is generally easy to derive efficient implementations of commonly used (heuristic) pivoting rules as first improvement and best improvement. Hence, with regard to the time complexity of iterative improvement, we are particularly interested in the number of iterations required by iterative improvement. Obviously, the maximum number of iterations required by iterative improvement is bounded from above by the longest path that occurs in the transition graph. This upper bound holds regardless of the pivoting rule used and the solution with which the algorithm starts. Whether or not this bound is tight depends on the pivoting rule applied and on the algorithm we use for generating the initial solution. With regard to the starting solution of iterative improvement, we generally do not want to make any assumptions. A reason for this is that because the quality of a starting solution generally has a major effect on the quality of the final solution, we want to have the opportunity to tune the algorithm that derives a starting solution to the application we are considering. Another reason is that, in order to make multiple runs of iterative improvement successful, we like to initialize each run with a solution that is quite different from the starting solutions used in the other runs.

Suppose that we apply iterative improvement to solve a problem Π_{LS} in PLS and let c be the cost of the solution with which we initialize the algorithm. Because the cost function is assumed to be integral and because in each iteration of iterative improvement the cost of the solution improves, the number of iterations the algorithm needs for reaching a local optimum is bounded by $|c - f^*|$, where f^* is the cost of an optimal solution. From this, it follows that if in the combinatorial optimization problem underlying Π_{LS} the cost of a solution is polynomially bounded in the input size, then iterative improvement can be implemented to run in polynomial time for Π_{LS}.

Although not satisfying this strong constraint, the cost functions of many combinatorial optimization problems satisfy the weaker property that the cost of a solution is polynomially bounded in the input size and the magnitude of the largest number that occurs in the problem instance. In these cases iterative improvement has a pseudo-polynomial running time. Examples include the already discussed problems TSP and UGP. For TSP the cost of a solution is, for instance, bounded by n times the longest distance in the distance matrix. In the combinatorial optimization problem underlying circuit/flip, the cost function does not even satisfy this weaker property.

In the next two subsections, we describe two different strategies for analyzing the time complexity of iterative improvement. In the first subsection, we give an

example of the strategy where we analyze a specific implementation of iterative improvement. That is, the analysis assumes a certain pivoting rule. In the next subsection, we take a more generic strategy where we further exploit the theory of PLS-completeness to derive negative results that hold regardless of the pivoting rule used.

Ad Hoc Strategies

In the literature, a number of results have appeared on the maximum number of iterations that are required by an implementation of iterative improvement. Proving a negative result, i.e., that the number of iterations can be exponential, is easiest if we assume the pivoting rule that selects an improving neighbor randomly. In that case, we only need to show that there exists a path in the transition graph that has exponential length. An example of this is given in the result below from Luecker [18]. We note, however, that the result has been improved by Englert, Röglin and Vöcking [19] who prove that also for Euclidean TSP, the 2-change neighborhood function may result in an exponential number of iterations.

Theorem 13. *For Metric TSP with the 2-change neighborhood function, iterative improvement may require an exponential number of iterations to reach a local optimum if the pivoting rule is used that selects an improving move randomly.*

Proof Consider a problem instance I of Symmetric TSP instead of Metric TSP. By adding to each entry d_{ij} of the distance matrix d the maximum distance $d_{\max}$ occurring in d, we obtain a distance matrix that satisfies the triangle inequality. This modification does not affect a run of iterative improvement as for any tour it results in a length increase of exactly $n \cdot d_{\max}$. Hence, to prove the theorem, it suffices to show that it holds for Symmetric TSP.

We now proceed as follows. For any even n, we construct a problem instance I of Symmetric TSP consisting of n cities. For this problem we then derive a sequence of exponentially many tours that can be visited successively by the iterative improvement algorithm. Note that because iterative improvement runs in pseudo-polynomial time for Symmetric TSP, the distance matrix of I will have to contain distances of exponential length.

Because we are considering Symmetric TSP, we have $d_{ij} = d_{ji}$. Therefore, it suffices to define the distance d_{ij} for the case where $i \geq 2$ and either $j > i$ or $j = 1$. The definition of the distance matrix d is visualized in Fig. 10. Formally, for even $i \geq 2$, the distance d_{ij} is given by 2^{2i+3} if j is odd and either $j = 1$ or $j > i$, and d_{ij} is given by $d_{ij} = 2^{2i+4}$ if j is even and $j > i$. For odd $i \geq 2$, we apply the same case distinction: d_{ij} is given by 2^{2i} if j is odd and either $j = 1$ or $j > i$, and it is given by 2^{2i+3} if j is even and $j > i$.

We prove that iterative improvement can take an exponential number of iterations to transform the tour $(1, 2, \ldots, n)$ into the tour $(1, n-1, n-2, \ldots, 2, n)$ for the problem instance described. We prove this result by showing by induction on q that

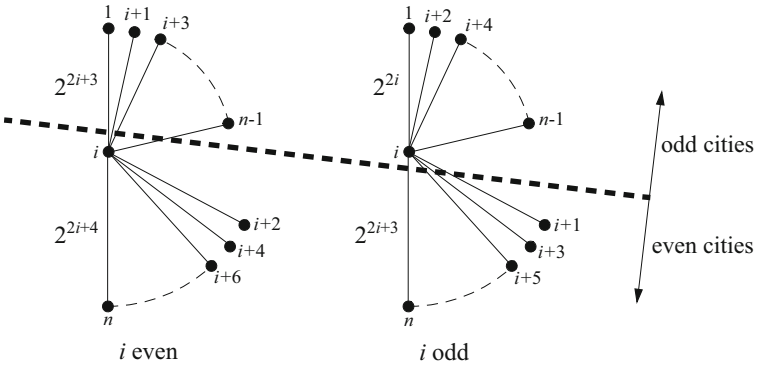

Fig. 10 Definition of the distance matrix d in the problem instance of Symmetric TSP introduced in the proof of Theorem 13, where $i \geq 2$ is an arbitrary city that is either even (left) or odd (right)

the following assertion holds. Let tour τ contain a subtour $x, 2, 3, \ldots, 2q+1, y$ for a $q \leq \frac{n-2}{2}$, where x and y are cities, possibly 1 and $2q+2$, such that for all $2 \leq i \leq 2q+1$ we have $d_{x,i} = d_{1,i}$ and $d_{i,y} = d_{i,2q+2}$. Then a sequence of at least 2^{q-1} improving 2-changes exists that transforms tour τ into τ_q, where tour τ_q is equivalent to τ, except that the subtour $x, 2, 3, \ldots, 2q+1, y$ is replaced by the subtour $x, 2q+1, 2q, \ldots, 2, y$, in which the order of the $2q$ middle cities has been reversed.

We first prove the basis case $q = 1$. Tour $\tau_q = \tau_1$ that contains $x, 3, 2, y$ is obtained from tour τ that contains $x, 2, 3, y$ by the single 2-change that replaces the edges $\{x, 2\}$ and $\{3, y\}$ by $\{x, 3\}$ and $\{2, y\}$. As $2^{q-1} = 1$, the basis case now follows if τ_1 is shorter than τ. This is true because for the cost improvement $\Delta(\tau, \tau_1)$ of τ_1 in comparison with τ, we can derive

$$\begin{aligned}\Delta(\tau, \tau_1) &= d_{1,2} + d_{3,4} - d_{1,3} - d_{2,4} \\ &= 2^7 + 2^9 - 2^6 - 2^8 \\ &> 0.\end{aligned}$$

Next, consider the case $q \geq 2$. We show how τ can be transformed into τ_q in at least 2^{q-1} improving 2-changes, where we distinguish five phases in the transformation. The final tour in phase i is denoted by $\tau^{(i)}$. Hence, $\tau^{(5)} = \tau_q$.

In the first phase, $\tau^{(1)} = \tau_{q-1}$ is derived from τ. By the induction hypothesis, this can be done in 2^{q-2} improving 2-changes. In Phase 2 we next change the order of the cities $2q$ and $2q+1$ in subtour $x, 2q-1, 2q-2, \ldots, 2, 2q, 2q+1, y$ of $\tau^{(1)}$ by performing a 2-change on the edges $\{2, 2q\}$ and $\{2q+1, y\}$. This results in a tour $\tau^{(2)}$ with shorter length than $\tau^{(1)}$ since

$$\begin{aligned}\Delta\left(\tau^{(1)}, \tau^{(2)}\right) &= d_{2,2q} + d_{2q+1,2q+2} - d_{2,2q+1} - d_{2q,2q+2} \\ &= 2^8 + 2^{4q+5} - 2^7 - 2^{4q+4} \\ &> 0.\end{aligned}$$

In Phase 3 the first and last edges $\{x, 2q-1\}$ and $\{2q, y\}$ occurring in subtour x, $2q-1, 2q-2 \ldots, 2, 2q+1, 2q, y$ of $\tau^{(2)}$ are replaced by the two edges $\{x, 2q\}$ and $\{2q-1, y\}$. This yields a cost improvement of

$$\begin{aligned}\Delta\left(\tau^{(2)}, \tau^{(3)}\right) &= d_{1,2q-1} + d_{2q,2q+2} - d_{1,2q} - d_{2q-1,2q+2} \\ &= 2^{4q-2} + 2^{4q+4} - 2^{4q+3} - 2^{4q+1} \\ &> 0.\end{aligned}$$

The resulting tour $\tau^{(3)}$ contains x, $2q$, $2q+1$, 2, 3, $\ldots$, $2q-1$, y. By the definition of the distance matrix, we have $d_{2q+1,i} = d_{1,i}$ and $d_{i,2q+2} = d_{i,2q}$ for all $2 \leq i \leq 2q$. As a result, we can apply the induction hypothesis to the subtour x', 2, 3, $\ldots$, $2q-1$, y' of $\tau^{(3)}$ with $x' = 2q+1$ and $y' = y$. This yields that $\tau^{(3)}$ can be transformed into $\tau^{(4)}$ by at least 2^{q-2} improving 2-changes, where $\tau^{(4)}$ is given by $\tau^{(3)}$ with the order of the cities 2, 3, $\ldots$, $2q-1$ reversed, i.e., $\tau^{(4)}$ contains x, $2q$, $2q+1$, $2q-1$, $2q-2$, $\ldots$, 2, y. In the final phase, we reverse the order of the cities $2q$ and $2q+1$ by performing a 2-change on $\{x, 2q\}$ and $\{2q+1, 2q-1\}$. This again results in an improvement of the tour as we have

$$\begin{aligned}\Delta\left(\tau^{(4)}, \tau^{(5)}\right) &= d_{1,2q} + d_{2q-1,2q+1} - d_{1,2q+1} - d_{2q-1,2q} \\ &= 2^{4q+3} + 2^{4q-2} - 2^{4q+2} - 2^{4q+1} \\ &> 0.\end{aligned}$$

In conclusion, we have transformed τ into $\tau^{(5)} = \tau_q$ by only performing improving 2-changes. The total number of 2-changes is at least 2^{q-2} in Phase 1, one in Phases 2 and 3, at least 2^{q-2} in Phase 4, and one in Phase 5. This makes a total of more than 2^{q-1} improving 2-changes. This proves the induction hypothesis and consequently it proves the theorem. □

The above result does not match the subquadratic number of iterations that one observes in practice [20]. To better understand the average case behavior, Chandra, Karloff, and Tovey [6] analyzed the expected length of the longest path in the transition graph in case the n cities are placed uniformly at random in the unit square. They proved an expected length of $\mathcal{O}\left(n^{10}\log(n)\right)$.

General Strategy

Suppose that, either empirically or via an analysis as given in the above subsection, we find out that iterative improvement takes an exponential number of steps. A question that arises is whether this bad worst-case behavior can be avoided by choosing a less naive pivoting rule or whether it is unavoidable due to the structure of the transition graph. This means that we are interested in the question of whether iterative improvement would still run in worst-case exponential time if for the pivoting rule we were to have an oracle at our disposal that gives us a neighbor that leads to a nearest local optimum. This problem, called the transition graph complexity problem, is formalized as follows.

Definition 17. Let T be a transition graph and let $\hat{V}$ be the nodes with outdegree zero (they represent the local optima). The potential of a node v is the minimum distance in T between v and a node in $\hat{V}$. The potential of T is the maximum potential over all its nodes.

Definition 18. For a given local search problem Π_{LS}, the *transition graph complexity problem* corresponds to deciding whether Π_{LS} can induce transition graphs with an exponentially large potential. □

In this section we study the transition graph complexity problem for PLS-complete problems. For PLS-complete problems, we already know that, unless PO = PLS, they cannot be solved in polynomial time. Solving the transition graph complexity problem gives us additional information on whether the unavoidable exponential running time is caused by the structure of the transition graph or is only caused by the intractability of computing an optimal pivoting rule.

The reason we introduced local search problems is that they are the problems that are actually solved by iterative improvement. Solving a local search problem is generally not a goal in itself. Therefore, considerably less attention has been paid by scientists to solving these problems efficiently than to finding efficient algorithms for NP-hard combinatorial optimization problems and NP-complete decision problems. As a result, we have stronger evidence for the inequality $\text{P} \neq \text{NP}$, which is equivalent to $\text{PO} \neq \text{NPO}$, than for $\text{PO} \neq \text{PLS}$. This brings us to the second relevant implication of knowing that the potential of a transition graph can be exponentially large for a given PLS-complete problem. It proves an exponential worst-case running time for iterative improvement even in the case that PO = PLS. We nevertheless emphasize that it is commonly believed that $\text{PO} \neq \text{PLS}$ holds.

To solve the transition graph complexity problem, we proceed as follows. We defined PLS-reductions such that if $\Pi_{\text{LS}} \propto \Pi'_{\text{LS}}$ holds and if Π_{LS} cannot be solved in polynomial time, then Π'_{LS} cannot be solved in polynomial time either. Below we refine the definition of a PLS-reduction such that, in addition to this behavior, we have that if $\Pi_{\text{LS}} \propto \Pi'_{\text{LS}}$ holds and if a transition graph for Π_{LS} can have an exponentially large potential, then a transition graph of Π'_{LS} can also have an exponentially large potential. This more powerful PLS-reduction is called a tight PLS-reduction. We show that the class PLS contains a local search problem for which the transition graph can have an exponentially large potential. Furthermore, most known PLS-reductions, including the ones for circuit/flip and Theorem 11, are tight [1, 11, 14]. We now elaborate a bit more on the details.

Let (φ_1, φ_2) define a PLS-reduction between two local search problems Π_{LS} and Π'_{LS}, and let $I = (S, f, N)$ be an arbitrary problem instance of Π_{LS} with image $\varphi_1(I) = (S', f', N')$. By definition, algorithm φ_2 maps any solution in S' to a solution in S, such that a local optimum in S' is also a local optimum in S. Figure 11a depicts possible transition graphs T_I and $T_{\varphi_1(I)}$ of I and $\varphi_1(I)$, respectively, and a possible choice for φ_2. For (φ_1, φ_2) to be a tight PLS-reduction, a subset R of S' has to

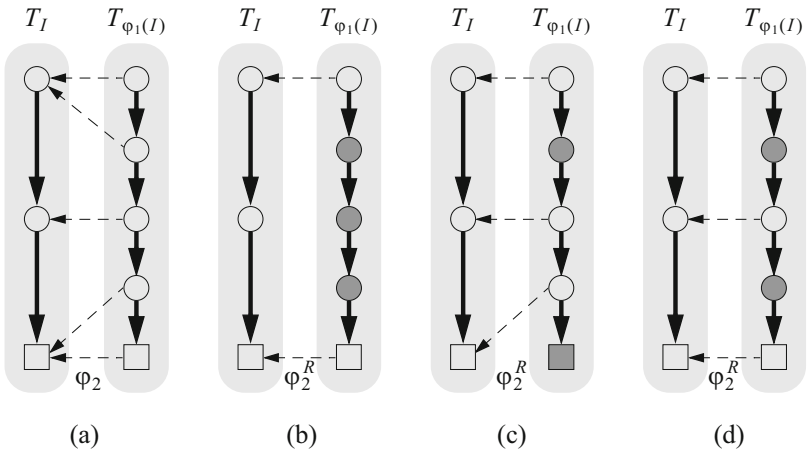

Fig. 11 (**a**) Transition graphs T_I of $I = (S, f, N)$ and $T_{\varphi_1(I)}$ of $\varphi_1(I) = (S', f', N')$ and algorithm φ_2 for some local search problem instance I and PLS-reduction (φ_1, φ_2). A dashed arc originates from an $s' \in S'$ and points to $s = \varphi_2(I, s')$. (**b**)–(**c**) Invalid choices of R, where R is given by S' minus the shaded solutions in transition graph $T_{\varphi_1(I)}$. φ_2^R denotes algorithm φ_2 for I with the solution set S' of $\varphi_1(I)$ restricted to R. (**d**) Valid choice of R

exist that satisfies the following three conditions. In the first place, φ_2 has to be surjective for I when restricting the solution set S' of $\varphi_1(I)$ to R. This means that for each solution $s \in S$, a solution $s' \in R$ must exist that is mapped to s by algorithm φ_2. Furthermore, solution s' must be computable in polynomial time. Note that for (φ_1, φ_2) to be a standard PLS-reduction it is not necessary that φ_2 is surjective for a given problem instance, as follows from Fig. 6. The second condition on R is that it contains all local optima of $\varphi_1(I)$. Figure 11b, c give examples of R that do not satisfy the first and second condition, respectively, and Fig. 11d gives an example of R that satisfies both conditions. The third and last condition that has to be satisfied is that if in $T_{\varphi_1(I)}$ a solution $s'_2 \in R$ can be reached from a solution $s'_1 \in R$ without visiting any other solution from R, then the distance between the corresponding solutions in S is not too large, i.e., it is polynomially bounded.

Definition 19. Local search problem Π_{LS} is *tightly PLS-reducible* to local search problem Π'_{LS}, denoted by $\Pi_{\mathrm{LS}} \propto_{\mathrm{tight}} \Pi'_{\mathrm{LS}}$, if a PLS-reduction (φ_1, φ_2) exists, such that for a polynomial p the following holds. For any problem instance $I = (S, f, N)$ of Π_{LS} with image instance $\varphi_1(I) = (S', f', N')$ of Π'_{LS}, we can choose a subset $R \subseteq S'$ that satisfies the following properties.

- For any $s \in S$ we can construct in polynomial time a solution $s' \in R$ with $\varphi_2(I, s') = s$.
- R contains all local optima in S'.

- If transition graph $T_{\varphi_1(I)}$ of $\varphi_1(I)$ contains a direct path from $s'_1 \in R$ to $s'_2 \in R$, then the distance from $s_1 = \varphi_2\left(I, s'_1\right)$ to $s_2 = \varphi_2\left(I, s'_2\right)$ in transition graph T_I of I is bounded from above by $p(|I|)$, where a path in $T_{\varphi_1(I)}$ is said to be direct if, except for the first and last solution, it only contains solutions outside R.

The pair (φ_1, φ_2) is called a *tight PLS-reduction*. □

Definition 20. A local search problem in PLS is *tightly PLS-complete* if each problem $\Pi_{\text{LS}} \in \text{PLS}$ is tightly PLS-reducible to it. □

This definition of a tight PLS-reduction preserves the property that a transition graph induced by a problem can be exponential, as shown in the following. By the last condition in Definition 19, we have that if the distance between any two solutions $s'_1 \in R$ and $s'_2 \in R$ in $T_{\varphi_1(I)}$ is $d_{s'_1,s'_2}$, then $d_{s'_1,s'_2} \cdot p\,(|I|)$ gives an upper bound on the distance between the corresponding solutions $s_1 = \varphi_2\left(I, s'_1\right)$ and $s_2 = \varphi_2\left(I, s'_2\right)$ in T_I. As R contains all local optima, this implies that if $s' \in R$ is within k steps of a local optimum $\hat{s}'$ in $T_{\varphi_1(I)}$, then solution $s = \varphi_2(I, s')$ is within $k \cdot p(|I|)$ steps of $\hat{s} = \varphi_2\left(I, \hat{s}'\right)$, which by the definition of a PLS-reduction is a local optimum in S. Hence, by the second condition in Definition 19, the potential of T_I is at most $p(|I|)$ larger than the potential of $T_{\varphi_1(I)}$. Because the input size of $\varphi_1(I)$ is bounded from above by a polynomial in the input size of I, this implies that if T_I has an exponentially large potential, then $T_{\varphi_1(I)}$ must have one as well. We thus arrive at the following result.

Lemma 5. *If (φ_1, φ_2) defines a tight PLS-reduction from local search problem Π_{LS} to local search problem Π'_{LS} and if the potential of Π_{LS} cannot be bounded by a polynomial, then neither can the potential of Π'_{LS}.* □

By Lemma 5, it now suffices to indicate one local search problem in PLS for which the transition graph can have an exponentially large potential to conclude that this result holds for any tightly PLS-complete problem.

Lemma 6. *PLS contains a local search problem for which the potential of the transition graph cannot be bounded by a polynomial.*

Proof Consider the trivial combinatorial optimization problem that, given an integer n, asks for the smallest integer i between 1 and n. This means that we want to minimize the cost function $f(i) = i$ with $1 \leq i \leq n$. For this problem, we consider the solution space consisting of the integers $1, 2, \ldots, n$, and we assume a neighborhood function in which integer 1 has no neighbors and integer $i \geq 2$ has only one neighbor, namely, $i - 1$. This yields a local search problem that is obviously in PLS. Furthermore, the transition graph is given by a single directed path that successively visits the solutions $n, n - 1, \ldots, 1$. The potential of this graph equals the distance from n to 1, which is $n - 1$. This is exponentially large as the input size is only $\log n$. □

Theorem 14. *For a tightly PLS -complete problem, iterative improvement requires an exponential number of iterations in the worst case to reach a local optimum, regardless of the pivoting rule used.* □

It can be verified from the definition that the PLS-reduction given in Theorem 12 is tight. Furthermore, as shown in [1, 11, 14], the problem POS NAE MAX-3SAT/Kernighan-Lin from which the reduction is made is tightly PLS-complete. This brings us at the following result.

Theorem 15. *The local search problem UGP/Kernighan-Lin is tightly PLS-complete.* □

Suppose that for a combinatorial optimization problem Π we have two neighborhood functions N and N', where N' is a generalization of N, i.e., $N(s) \subseteq N'(s)$ for any solution s. For TSP, the 2-change and 3-change neighborhood functions are examples of N and N', respectively. Then the local search problem Π_{LS} specified by Π and N is PLS-complete if this is the case for the local search problem Π'_{LS} specified by Π and N'. More generally, this means that to prove PLS-completeness results for one combinatorial optimization problem and multiple neighborhood functions it suffices to prove that the weakest neighborhood function induces a PLS-complete problem. However, if we want to know whether the induced local search problems are *tightly* PLS-complete, we can no longer restrict ourselves to the weakest neighborhood function. It may be the case that Π_{LS} is tightly PLS-complete, while this is not the case for Π'_{LS}. The reason for this is that the generalization can add arcs to the transition graph, which may decrease its potential to a polynomially bounded value.

We refer you to Michiels, Aarts, and Korst [1] and to Monien, Dumrauf, and Tscheuschner [21] for a set of local search problems that have been proven to be (tightly) PLS-complete.

Relevance of PLS Beyond Local Search

Although introduced to enhance the understanding of applying local search algorithms to combinatorial optimization problems, the class PLS has also found its way to other disciplines. First of all, the theory of PLS-completeness is used in game theory to prove the hardness of computing pure Nash equilibria. An overview of such results until 2010 is given in [21]. Furthermore, PLS is an interesting class of problem in between P and NP-hard. We motivate this using the argumentation given by the excellent paper of Papadimitriou [22]. Many search problems have proven either to be NP-complete or to belong to P. The complexity of NP-hard problems typically results from the difficulty of deriving whether a solution exists. As a result of this, most of the problems that have not been categorized as being either NP-complete or in P belong to the class of total search problems. For problems in this class, a solution is known to exist. The most well-known example of this

is factoring. It is known that any integer number can be factored into primes, but finding the factorization is considered to be difficult. This problem has not proven to be NP-complete, but as for NP-complete problems, many have tried to solve it in polynomial time but without success. Therefore, it is commonly assumed that this problem is also hard to solve. The security of the widely used cryptographic cipher RSA even relies on this assumption.

Different classes of total search problems are used to capture the possible different reasons why a total search problem can be hard to solve. PLS is such a class. Others are Polynomial Parity Argument (PPA), Polynomial Pigeonhole Principle (PPP), and Polynomial Parity Argument for Directed graphs (PPAD). Interesting papers in this area are [22–24].

Conclusion

Local search owes its popularity mainly to its good average-case performance. Its worst-case performance is typically less good compared to alternative solution approaches, like constructive algorithms. Nevertheless, studying the worst-case performance is still valuable since it both provides performance guarantees and enhances our understanding of the algorithm. In this chapter we discussed several worst-case local search results that have been scattered over the literature. We presented results on the worst-case performance ratio of local search implementations and on the time complexity of reaching a locally optimal solution. The latter results also find their applications outside the scope of local search for combinatorial optimization problems, viz., game theory and general computational complexity theory.

Abstract

Variable neighborhood descent (VND) is a local search-based heuristic which performs a deterministic exploration of a fixed set of neighborhood structures. Its success is based on the simple fact that different neighborhood structures usually have different local minimum. Thus, the local optima trap problem may be eventually solved by deterministic change of neighborhoods. VND can be used as a local search routine, and, therefore, it could be used within other metaheuristics. In this chapter we discuss typical problems that arise when designing VND: what neighborhood structures could be used, what would be their order, what rule of their change during the search would be used, etc. Comparative analysis of usual sequential VND variants is performed considering the traveling salesman problem.

VND · Local search · Neighborhood · Sequential VND · Nested VND · Mixed VND

Introduction

Optimization is a key discipline in fields such as Computer Science, Artificial Intelligence, and Operations Research. Outside these scientific communities, the meaning of optimization becomes quite vague going to mean simply "do it as better as you can." In the context of this chapter, the concept of optimization is conceived as the process of trying to find the best possible solution to an optimization problem, usually in a limited time horizon.

In the simplest case, an optimization problem may be defined by a 2-tuple (X, f), where X represents the set of feasible solutions and f is an objective function that assigns a real number to each solution $x \in X$, which represents its quality or fitness. Then, the main objective of an optimization problem is to find a solution $x^\star \in X$ with the best objective function value among all solutions in the search space. Therefore, in a minimization problem, $x^\star \in X$ is a minimum point if $f(x^\star) \leq f(x)$, $\forall x \in X$. Notice that minimization of f is equivalent to maximization of $-f$.

In optimization problems there is usually either finite but a huge number or infinity number of solutions and a clear criterion for the comparison among them. Some well-known examples of optimization problems are the traveling salesman problem (TSP), the vehicle routing problem (VRP), the quadratic assignment problems (QAP), and scheduling problems, among others [3, 37]. The difficulty of solving these problems has been studied since the late 1970s [12]. These studies concluded that there is a subset of problems where it is possible to design an algorithm, which presents a polynomial computational complexity, i.e., the execution time of these algorithms polynomially grows with the problem size. Such problems belong to the class $\mathcal{P}$ and they are considered "easy to solve."

Examples of these problems are the shortest path problem (Dijkstra algorithm), the minimum spanning tree (Prim or Kruskal algorithms), and flows in networks (Ford-Fulkerson algorithm). However, computing optimal solutions is intractable for many optimization problems of industrial and scientific importance (i.e., there is no known algorithm with polynomial complexity to solve it optimally). This type of problems belongs to a class known as $\mathcal{NP}$ and they are considered "hard to solve."

In practice, we are usually satisfied with "good" solutions, which are obtained by heuristic algorithms. In particular, metaheuristics (MHs) represent a family of approximate [42] optimization techniques that gained a lot of popularity in the past two decades, becoming the most promising and successful techniques for solving hard problems. Unlike exact optimization algorithms, metaheuristics do not guarantee the optimality of the obtained solutions. Additionally, metaheuristics do not define how close the obtained solutions are from the optimal ones, in contrast with approximation algorithms. MHs provide "acceptable" solutions in a reasonable computing time for solving hard and complex problems in science and engineering.

The term metaheuristic was coined in 1986 [13] as a way of defining *a master process that guides and modifies other subordinate heuristics to explore solutions beyond simple local optimality*. MHs are among the most prominent and successful techniques to solve a large amount of complex and computationally hard combinatorial and numerical optimization problems arising in human activities, such as economics, industry, and engineering. MHs can be seen as general algorithmic frameworks that require relatively few modifications to be adapted to tackle a specific problem. They constitute a very diverse family of optimization algorithms including methods such as simulated annealing (SA), tabu search (TS), genetic algorithms (GA), ant colony optimization (ACO), and variable neighborhood search (VNS).

Metaheuristics are high-level strategies for exploring the search space using different methods. The search strategies are highly dependent on the philosophy of the metaheuristic itself. In particular, *trajectory-based metaheuristics* can be seen as intelligent extensions of traditional local search methods. The goal of this kind of MHs is to escape from a local optimum in order to proceed in the exploration of the search space and move on to find other hopefully better local optimum. Examples of these MHs are tabu search [13], simulated annealing [23], and variable neighborhood search [15], among others. *Population-based metaheuristics* deal with a set of solutions instead of dealing with only one solution. These techniques proved a natural and intrinsic way for the exploration of the search space. The final performance of these methods strongly depends on how the population is managed. Examples of population-based metaheuristics are genetic algorithms [19], scatter search [14], or memetic algorithms [33], among others. Some authors consider a third kind of metaheuristics called *constructive-based metaheuristics*, where the main effort is put in the intelligent construction of the solution. In other words, instead of starting the search from a random solution, these methods try to construct a high-quality initial solution. Examples of constructive-based metaheuristics are GRASP [10], ant colony optimization [5], and iterated greedy [41], among others.

The number of new proposed metaheuristics has amazingly increased in the last 25 years. Nowadays, the portfolio of MHs contains more than 50 variants, only considering the most stabilized ones (MHs successfully applied to a relatively large set of optimization problems). However, at the end, when designing a metaheuristic for an optimization problem, we face with two contradictory criteria: intensification (exploitation) and diversification (exploration). In fact, the performance of a metaheuristic basically relies on how it balances both criteria. The intensification of an algorithm describes its ability to thoroughly explore the promising regions in the hope to find better solutions. On the other hand, diversification describes the ability of the metaheuristic to explore non-visited regions of the search space in order to assure the evenly exploration of the search space and to avoid the confinement to the procedure to a reduced number of regions. Therefore, when tackling an optimization problem, it is necessary to search for the equilibrium between both criteria.

Variable neighborhood search (VNS) is a metaheuristic which was proposed in [32] as a general framework to solve hard optimization problems. This methodology is based on performing systematic changes of neighborhoods during the search space exploration. VNS has evolved in recent years, resulting in a large variety of strategies. Some of the most relevant variants are reduced VNS (RVNS), variable neighborhood descent (VND), basic VNS (BVNS), skewed VNS (SVNS), general VNS (GVNS), variable formulation search (VFS), and variable neighborhood decomposition search (VNDS), among others (see [18] for a recent survey on VNS). We refer the reader to [7, 8, 34, 35, 39] to some recent and successful applications of VNS to hard optimization problems.

This chapter is focused on variable neighborhood descent (VND), the deterministic variant of VNS. VND deserves separate attention since it is usually used in context of other metaheuristics as a local search routine. Once the set of neighborhood structures is selected, to be used in a deterministic manner, the VND is designed in three possible ways: (i) sequential VND, where neighborhoods are placed in the list with a given order and always explored in that order; (ii) nested or composite VND, where neighborhood operators are composed, i.e., $N_1(N_2(N_3(\ldots(x))))$ (neighborhood one of neighborhood two of neighborhood three, etc. of x); and (iii) mixed nested VND, where the two previous strategies are combined.

This chapter starts with some possible classification of neighborhood structures that are usually used in solving continuous and discrete optimization problems. Then, the pseudo-codes of sequential, composite, and mixed nested variants of VND are presented. Finally, variants of sequential VND are compared on the well-known traveling salesman problem.

Neighborhoods

The representation (encoding) of a solution in an optimization problem plays a relevant topic in the design of an algorithm. In fact, as it is well documented, this representation determines the difficulty of solving a problem [12] and also the complexity of some routines within algorithm. In addition, this encoding strongly

influences the way in which the neighborhoods of a given solution are defined. Therefore, it is not possible to separate the neighborhood of a solution from its corresponding representation in the computer memory.

Let us assume, without loss of generality, that each solution $x \in X$ is represented by a vector $x = (x_1, \ldots, x_n)$, being n the size of the problem. Depending on the values of each x_i, we can distinguish among different types of problems:

- Continuous $\rightarrow x_i \in \mathbb{R}$
- Binary $\rightarrow x_i \in \{0, 1\}$
- Integer $\rightarrow x_i \in \mathbb{N}$
- Permutations $\rightarrow x_i \in \mathbb{N}$, $1 \leq x_i \leq n$ and $x_i \neq x_j$ if $i \neq j$

We could also identify a fifth class of problems which encompasses mixed variables. In this section, we describe the most common neighborhoods defined in the related literature as well as some basic properties.

Neighborhoods for Continuous Optimization Problems

The continuous constrained nonlinear global optimization problem (GOP) in general form is given as follows:

$$(GOP) \quad \begin{cases} \min & f(x) \\ \text{s.t.} & g_i(x) \leq 0 \quad \forall i \in \{1, 2, \ldots, m\} \\ & h_i(x) = 0 \quad \forall i \in \{1, 2, \ldots, r\} \\ & a_j \leq x_j \leq b_j \ \forall j \in \{1, 2, \ldots, n\} \end{cases}$$

where $x \in \mathbb{R}^n$, $f : \mathbb{R}^n \rightarrow \mathbb{R}$, $g_i : \mathbb{R}^n \rightarrow \mathbb{R}$, $i = 1, 2, \ldots, m$, and $h_i : \mathbb{R}^n \rightarrow \mathbb{R}$, $i = 1, 2, \ldots, r$, are possibly nonlinear continuous functions, and $a, b \in \mathbb{R}^n$ are the variable bounds.

GOP naturally arises in many applications, e.g., in advanced engineering design, data analysis, financial planning, risk management, scientific modeling, etc. Most cases of practical interest are characterized by multiple local optima, and, therefore, in order to find the globally optimal solution, a global scope search effort is needed.

If the feasible set X is convex and objective function f is convex, then GOP is relatively easy to solve, i.e., the Karush-Kuhn-Tucker conditions may be applied. However, if X is not a convex set or f is not a convex function, we could have many local minima, and thus, the problem may not be solved by using classical techniques.

For solving GOP, neighborhood structures $\mathcal{N}_k(x)$ are usually induced from the ℓ_p metric:

$$\rho(x, y) = \left(\sum_{i=1}^{n} |x_i - y_i|^p \right)^{1/p} \quad (1 \leq p < \infty) \tag{1}$$

or

$$\rho(x, y) = \max_{1 \leq i \leq n} |x_i - y_i| \quad (p \to \infty). \tag{2}$$

The neighborhood $\mathcal{N}_k(x)$ denotes the set of solutions in the k–th neighborhood of x, and using the metric ρ, it is defined as

$$\mathcal{N}_k(x) = \{y \in X \mid \rho(x, y) \leq \rho_k\}, \tag{3}$$

or

$$\mathcal{N}_k(x) = \{y \in X \mid \rho_{k-1} \leq \rho(x, y) \leq \rho_k\}, \tag{4}$$

where ρ_k, known as the radius of $\mathcal{N}_k(x)$, is monotonically increasing with k.

Note that in some papers neighborhood structures in $\mathbb{R}^n$ are not induced from the ℓ_p metric (see, e.g., [1]).

Neighborhoods for Binary Problems

There are a large family of optimization problems, whose solution is usually represented as a binary array, where the presence or absence of an element is described by means of a binary variable. The Knapsack Problem [28], the Max-Cut Problem [29], and the Maximum Diversity Problem [6] are examples of these problems. For solving binary problems, neighborhood structures $\mathcal{N}_k(x)$ are usually induced from the Hamming metric:

$$d_H(x, y) = \sum_{i=1}^{n} |x_i - y_i| \tag{5}$$

More precisely, the k–th neighborhood of a solution x, i.e., $\mathcal{N}_k(x)$, relatively to Hamming metric, is defined as

$$\mathcal{N}_k^{Bin}(x) = \{y \in X \mid d_H(x, y) = k\}, \tag{6}$$

We will use the Max-Cut Problem to illustrate the most relevant characteristics of binary problems. Consider a graph $G = (V, E)$ with vertex set V and edge set E. Let w_{ij} be the weight associated with edge $(i, j) \in E$. A $cut(W, W')$ is a partition of V into two sets W, $W' = V \setminus W$, and its value is given by the expression:

$$cut(W, W') = \sum_{i \in W \wedge j \in W'} w_{ij}$$

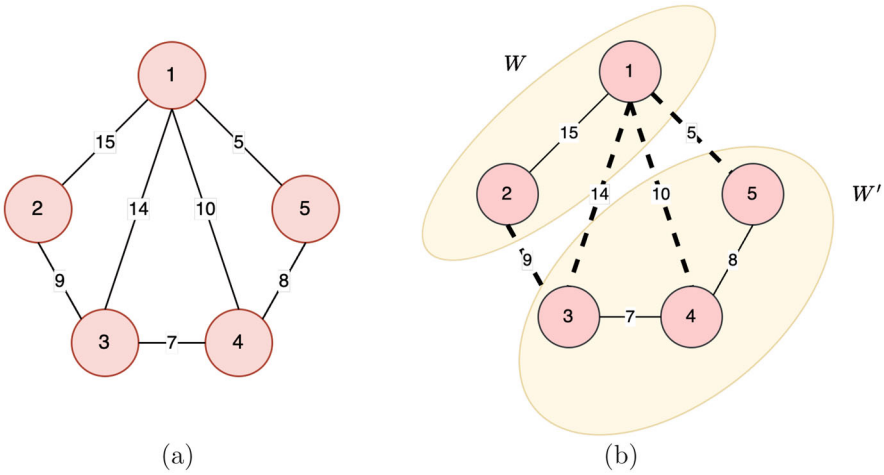

Fig. 1 Example of graph with five vertices and seven edges and a possible solution for the MCP. (**a**) Example of a graph. (**b**) Solution $x = \{1, 1, 0, 0, 0\}$

The Max-Cut Problem (MCP) consists of finding a cut in G with maximum value. Karp [22] showed that MCP is an $\mathcal{NP}$-hard problem. Figure 1a shows an example graph with five vertices and seven edges where the number close to each edge represents the corresponding weight. Figure 1b shows a possible solution, $x = (W, W')$, where $W = \{1, 2\}$ and $W' = \{3, 4, 5\}$. The value of this solution is $cut(W, W') = 9 + 14 + 10 + 5 = 38$, computed as the sum of the edges whose endpoints are in different sets (dashed edges). This solution can be represented as a binary vector $x = \{1, 1, 0, 0, 0\}$ where $x_i = 1$ indicates that the corresponding vertex is in W while $x_i = 0$ means that the vertex is in W'.

For a given solution x of a MCP, we define $\mathcal{N}^{Bin}_{drop}(x)$ neighborhood using the $drop(x, i)$ move operator. This operator is responsible of changing the value of a variable x_i from 1 to 0, producing a new solution x'. The associated neighborhood, $\mathcal{N}^{Bin}_{drop}(x)$, has size n (in the worst case) and is a subset of $\mathcal{N}^{Bin}_{1}(x)$. Formally, $\mathcal{N}^{Bin}_{drop}(x)$ is defined as

$$\mathcal{N}^{Bin}_{drop}(x) = \{x' \leftarrow drop(x, i) : x_i = 1 \wedge 1 \leq i \leq n\}$$

Figure 2a shows an example of this type of move. In particular, $drop(x, 2)$ considers the solution x (depicted in Fig. 1b), removes the vertex 2 from W, and includes it in W', producing a new solution $x^{drop} = \{1, 0, 0, 0, 0\}$. The Hamming distance between x and x' is 1 since there is only one vertex located in a different group.

Symmetrically, we define the $add(x, i)$ as the move operator responsible of changing the value of a variable x_i from 0 to 1, producing a new solution x^{add}. Considering the MCP, this move operator removes a vertex from W' and includes it

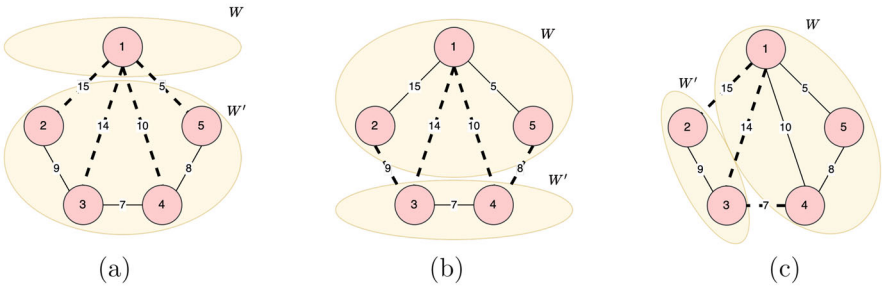

Fig. 2 Solutions generated when performing the different moves to the one depicted in Fig. 1b. (**a**) $x' \leftarrow drop(x, 2)$. (**b**) $x'' \leftarrow add(x, 5)$. (**c**) $x''' \leftarrow swap(x, 1, 3)$

in W. This move is represented as $x'' \leftarrow add(x, i)$ and the neighborhood, $\mathcal{N}^{Bin}_{add}(x)$, with size n in the worst case, is

$$\mathcal{N}^{Bin}_{add}(x) = \{x'' \leftarrow add(x, i) : x_i = 0 \wedge 1 \leq i \leq n\}$$

Figure 2b shows the move $add(x, 1)$. It considers again the solution x (depicted in Fig. 1b), removes the vertex 1 from W' including it in W. The Hamming distance between the new produced solution, $x'' = \{1, 1, 0, 0, 1\}$, and x is again 1.

Finally, we define $\mathcal{N}^{Bin}_{swap}(x)$ neighborhood as a subset of $\mathcal{N}^{Bin}_{2}(x)$ defined by *swap* move. *Swap* move is defined as an operation that changes the value of one variable x_i from 1 to 0 and simultaneously a different variable x_j change the value from 0 to 1. This move interchanges a vertex from W to W' and, simultaneously a different vertex from W' to W. This move is represented as $x''' \leftarrow swap(x, i, j)$ and the neighborhood, $\mathcal{N}^{Bin}_{swap}(x)$ (with size n^2 in the worst case), is

$$\mathcal{N}^{Bin}_{swap}(x) = \{x''' \leftarrow swap(x, i, j) : x_i \neq x_j \wedge 1 \leq i, j \leq n\}$$

Figure 2c shows the move $swap(x, 1, 3)$. It considers again the solution x (depicted in Fig. 1b) and interchanges the vertices 1 and 3 between W and W', respectively. The Hamming distance between the new produced solution, $x''' = \{0, 1, 1, 0, 0\}$, and x is in this case 2.

Neighborhoods for Integer Problems

There are some optimization problems where the solution x is represented as a vector of n variables, $x = (x_1, x_2, \ldots, x_n)$, such that $l \leq x_j \leq u$ for all j, assuming that all variables are integer and bounded within the interval $[l, u]$. For example, the solutions to the Set Covering Problem [9], the Capacitated Task Allocation Problem [24], or the Maximally Diverse Grouping Problems [11] can be represented

as a vector of integer values. For solving these problems, neighborhood structures $\mathcal{N}_k^{Int}(x)$ are usually induced from the metric defined as

$$\rho_{int}(x, y) = \sum_{i=1}^{n} |x_i - y_i| \tag{7}$$

or

$$\rho_{int}(x, y) = \max_{1 \le i \le n} |x_i - y_i| \tag{8}$$

The neighborhood $\mathcal{N}_k^{Int}(x)$ denotes the set of solutions in the k–th neighborhood of x, and it is defined as

$$\mathcal{N}_k^{Int}(x) = \{y \in X \mid \rho_{int}(x, y) \le k\}, \tag{9}$$

or

$$\mathcal{N}_k^{Int}(x) = \{y \in X \mid k - 1 \le \rho_{int}(x, y) \le k\}, \tag{10}$$

We use the Maximally Diverse Grouping Problem to illustrate neighborhoods for integer problems. It consists of grouping a set of M elements into G mutually disjoint groups in such a way that the diversity among the elements in each group is maximized. The diversity among the elements in a group is calculated as the sum of the individual distances between each pair of elements, where the notion of distance depends on the specific application context. The objective of the problem is to maximize the overall diversity, that is, the sum of the diversity of all groups. Figure 3 shows an example of a graph with ten vertices where we must select three groups of elements. For the sake of clarity, we only represent the distances among selected elements. In addition, we use different colors to differentiate the vertices on each group. In particular, group 1 (red) is $G_1 = \{1, 4, 9\}$ whose distances among edges are represented with dashed lines; group 2 (yellow) is $G_2 = \{3, 5, 8\}$ represented with dotted lines; and group 3 (blue) is $G_3 = \{2, 6, 7, 10\}$ represented with solid lines. Therefore, this solution can be represented as a vector $x = \{1, 3, 2, 1, 2, 3, 3, 2, 1, 3\}$ (i.e., each vertex i is located in group x_i).

With this representation, we define the following moves.

Exchange of values (Swap move): given a solution x, the exchange of the values of the variables x_i and x_j is denoted by $swap(x, i, j)$ and generates a new solution x' such that $x'_k = x_k, \forall k \neq i, j$ and $x'_i = x_j, x'_j = x_i$. Note that resulting solution x' belongs to the neighborhood:

$$\mathcal{N}_0^{Int}(x) = \{y \in X \mid \max_{1 \le i \le n} |x_i - y_i| = 0\}.$$

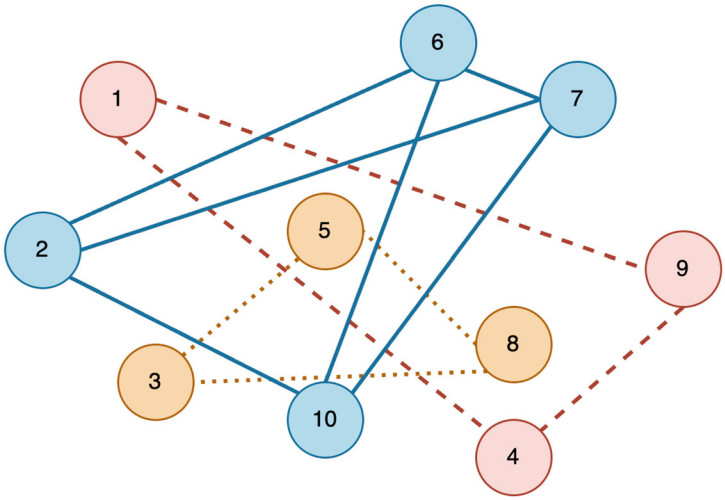

Fig. 3 Example of the Maximally Diverse Grouping Problem

Replacement of a single value (Replacement move): given a solution x, the replacement move denoted by $replace(x, j, i)$ creates a solution x' for which $x'_k = x_k, \forall k \neq j$ and $x'_j = i$. The move is such that $x_j \neq i$. In this case the resulting solution x' belongs to the neighborhood:

$$\mathcal{N}_m^{Int}(x) = \{y \in X \mid \sum_{1 \leq i \leq n} |x_i - y_i| \leq m\},$$

where $m = |x_j - i|$.

Given the solution $x = \{1, 3, 2, 1, 2, 3, 3, 2, 1, 3\}$, the move $swap(x, 6, 5)$ interchanges the corresponding group of vertices 6 and 5, producing the solution $x' = \{1, 3, 2, 1, 3, 2, 3, 2, 1, 3\}$ (see Fig. 4a). Similarly, the move $replace(x, 2, 1)$ includes the vertex 2 in group 1 (removing it from its original group). The final solution in this case is $x'' = \{1, 1, 2, 1, 2, 3, 3, 2, 1, 3\}$ (see Fig. 4b).

Neighborhoods for Permutation Problems

In permutation-based representations, a solution is typically expressed as a labeling (permutation), where each element receives a unique label from 1 to n, being n the size of the problem. The traveling salesman problem [38], the linear ordering problem [30], and the cutwidth minimization problem [36] are examples of this kind of problems. For solving these problems, neighborhood structures $\mathcal{N}_k^{Int}(x)$ may be induced using several metrics (see, e.g., [4] for possible metric). However, neighborhoods are usually induced from the Cayley distance:

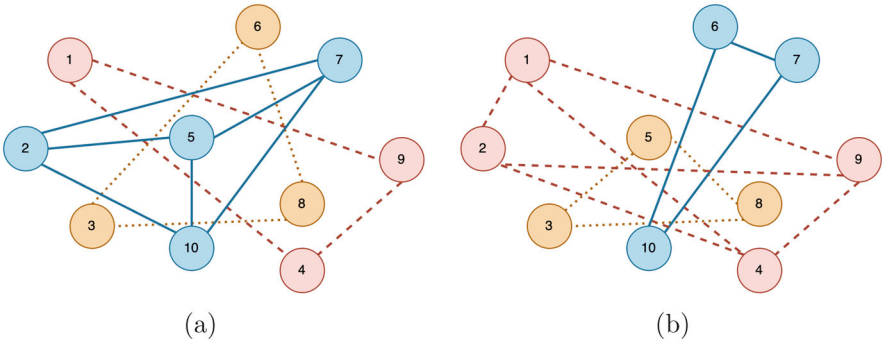

Fig. 4 Example of moves applied to a solution for the Maximally Diverse Grouping Problem. (**a**) $x' \leftarrow swap(x, 6, 5)$. (**b**) $x'' \leftarrow replace(x, 2, 1)$

$$\rho_{perm}(x, y) := \text{the minimum number of transpositions needed to obtain } y \text{ from } x \tag{11}$$

So, the neighborhood $\mathcal{N}_k^{Perm}(x)$ denotes the set of solutions in the k–th neighborhood of x and it is defined as

$$\mathcal{N}_k^{Perm}(x) = \{y \in X \mid \rho_{perm}(x, y) = k\}, \tag{12}$$

We use the cutwidth minimization problem (CMP) to illustrate some neighborhoods for permutation-based problem. It can be easily described in mathematical terms. Given a graph $G = (V, E)$ with $n = |V|$ and $m = |E|$, a labeling or linear arrangement x of G assigns the integers $\{1, 2, \ldots, n\}$ to the vertices in V, where each vertex receives a different label. The cutwidth of a vertex v with respect to x, $CW_x(v)$, is the number of edges $(u, w) \in E$ satisfying $x(u) \leq x(v) < x(w)$. In mathematical terms

$$CW_x(v) = |\{(u, w) \in E : x(u) \leq x(v) < x(w)\}|$$

The cutwidth of G with respect to x is defined as the maximum value of all $CW_x(v)$ for $v \in V$. More formally

$$CW_x(G) = \max_{v \in V} CW_x(v)$$

The optimum cutwidth of G is then defined as the minimum $CW_x(G)$ over all possible layouts of G. This optimization problem is $\mathcal{NP}$-hard even for graphs with a maximum degree of three [27]. Figure 5a shows an example of an undirected graph with six vertices and seven edges. Figure 5b shows a labeling, x, of the graph in Fig. 5a, setting the vertices in a line with the order of the labeling, as commonly represented in the CMP. We represent x with the ordering (6, 1, 3, 2, 4, 5) meaning that vertex 6 is located in the first position (label 1), vertex 1 is located in the second

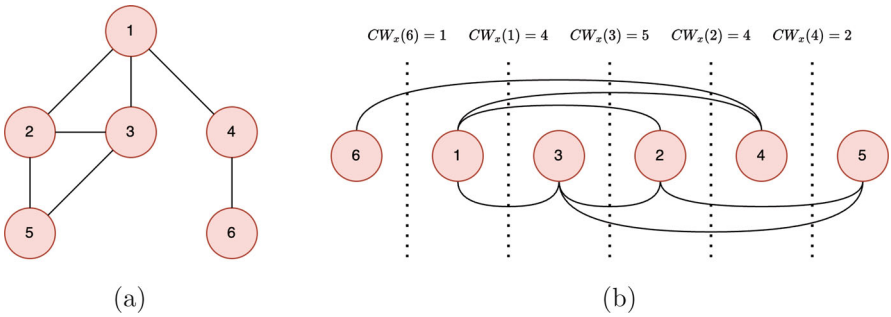

Fig. 5 Graph with six vertices and seven edges, and an example solution for the CWP. (**a**) Example graph. (**b**) Cutwidth of G for a labeling x

position (label 2), and so on. In Fig. 5b, the cutwidth of each vertex is represented as a dashed line with its corresponding value. For example, the cutwidth of vertex 6 is $CW_x(6) = 1$, because the edge $(6, 4)$ has and endpoint in 6 labeled with 1 and the other endpoint in a vertex labeled with a value larger than 1. In a similar way, we can compute the cutwidth of vertex 1, $CW_x(1) = 4$, by counting the appropriate number of edges: $(6, 4)$, $(1, 4)$, $(1, 2)$, and $(1, 3)$. Then, since the cutwidth of the graph G, $CW_x(G)$, is the maximum of the cutwidth of all vertices in V; in this particular example, we obtain $CW_x(G) = CW_x(3) = 5$.

The associated neighborhoods for this optimization problem are typically based on two different move operators. The first one is referred to as *exchange*. Given a solution $x = (v_1, \ldots, v_i, \ldots, v_j, \ldots, v_n)$, we define $exchange(x, i, j)$ as exchanging in x the vertex in position i (i.e., vertex v_i) with the vertex in position j (i.e., vertex v_j), producing a new solution $x' = (v_1, \ldots, v_{i-1}, v_j, v_{i+1}, \ldots, v_{j-1}, v_i, v_{j+1}, \ldots, v_n)$. So, *exchange* move represents a transposition. For the sake of simplicity, we denote $x' = exchange(x, i, j)$. The associated neighborhood $\mathcal{N}^{Perm}_{exchange}$, obtained applying all possible *exchange* moves, has size $n(n-1)/2$, and it is formally defined as

$$\mathcal{N}^{Perm}_{exchange}(x) = \{x' \leftarrow exchange(x, i, j) : i \neq j \wedge 1 \leq i, j \leq n\}$$

This neighborhood is actually $\mathcal{N}^{Perm}_1$ neighborhood.

The second move operator for CMP is known as *insert*. Specifically, given a solution x, we define $insert(x, j, v_i)$ as the move consisting of deleting v_i from its current position i and inserting it in position j. This operation results in the new solution x', as follows:

- If $i \geq j$, then $x = (\ldots, v_{j-1}, v_j, v_{j+1}, \ldots, v_{i-1}, v_i, v_{i+1}, \ldots)$ and the vertex v_i is inserted just before the vertex v_j, obtaining $x' = (\ldots, v_{j-1}, v_i, v_j, v_{j+1}, \ldots, v_{i-1}, v_{i+1}, \ldots)$.

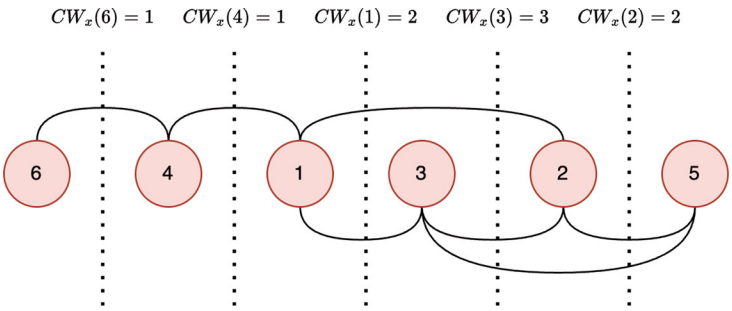

Fig. 6 Resulting solution after $insert(x, 2, 4)$ over solution depicted in Fig. 5b

- If $i < j$, then $x = (\ldots, v_{i-1}, v_i, v_{i+1}, \ldots, v_{j-1}, v_j, v_{j+1}, \ldots)$ and the vertex v_i is inserted just after the vertex v_j, obtaining $x' = (\ldots, v_{i-1}, v_{i+1}, \ldots, v_{j-1}, v_j, v_i, v_{j+1}, \ldots)$.

Thus, a move $insert(x, j, v_i)$ generates a solution belonging to the neighborhood $\mathcal{N}^{Perm}_{|j-i|}(x)$. The associated neighborhood $\mathcal{N}^{Perm}_{insert}$, obtained applying all possible *insert* moves, has size $n(n-1)/2$, and it is formally defined as

$$\mathcal{N}^{Perm}_{insert}(x) = \{x' \leftarrow insert(x, j, v_i) : i \neq j \wedge 1 \leq i, j \leq n\}$$

The following example illustrates how the *insert* is implemented. Let $x = (6, 1, 3, 2, 4, 5)$ be a solution of the cutwidth problem. Suppose that we perform $insert(x, 2, 4)$, obtaining solution $x' = (6, 4, 1, 3, 2, 5)$. Figure 6 graphically shows the solutions before and after the move.

As it can be seen in the resulting solution, the node 4 is now located at position 2, scrolling to the right the nodes located between the new and the original position. In this case, the maximum cutwidth value is obtained at node 3, with $CW_x(3) = 3$, thus reducing the objective function value in 2 units.

Local Search Methods

Local search methods are likely the oldest and simplest heuristic methods. Starting from a given feasible solution, these procedures explore a determined neighborhood in each iteration, replacing the current solution if a neighbor improves the objective function. The search ends when all neighbor solutions are worse (i.e., larger objective function value in a minimization problem) meaning that a local optimum is found.

There exist two typical strategies to explore the corresponding neighborhood: **best improvement** and **first improvement**. In the former (also known as **steepest descent**), the associated neighborhood is completely explored by a fully deterministic procedure, performing the best associated move. Therefore, no matter how the

neighborhood is scanned, since all neighborhood solutions are visited. Algorithm 1 shows the typical pseudo-code of this local search method for a minimization problem. The algorithm starts by initializing the control variable *improve* (step 1). Then, the best improvement strategy performs iterations until it finds a local optimum with respect to neighborhood $N(x)$ (steps 2–9). Given a solution x, the best neighbor solution x' is determined in step 4. This instruction explores the complete set of $|N(x)|$ solutions belonging to neighborhood $N(x)$. In steps 5–8 it is decided whether to perform a new iteration (by updating x to x') or not (abandoning the search).

Algorithm 1: Best-Improvement(x)

```
1: improve ← true
2: while (improve) do
3:     improve ← false
4:     x' ← arg min_{x∈N(x)} f(x)
5:     if f(x') < f(x) then
6:         x ← x'
7:         improve ← true
8:     end if
9: end while
10: return x
```

The first improvement strategy tries to avoid the time complexity of exploring the whole neighborhood by performing the first improving move encountered during the exploration of the corresponding neighborhood. In this kind of exploration, the order in which the neighbors are inspected can have a significant influence of the efficiency of the search. Instead of using a fixed ordering for scanning the neighbors, random orders are usually suggested, since the first scanning strategy always drives to the same local optimum, while the second one favors diversity, eventually reaching different local optima.

The pseudo-code of this strategy is equivalent to the one presented in Algorithm 1. The only difference is in step 4 where, instead of selecting the best neighbor, it is selected the first neighbor which improves the incumbent solution (in terms of objective function value). Additionally, if we follow a predefined order (e.g., a lexicographic order), the first positions in that order (e.g., $1, 2, \ldots$, in the lexicographic order) are favored, producing a kind of bias in the search.

Figure 7 shows the performance of two iterations of both strategies starting from the same solution, where the numbers over the arrows indicate the order of exploration of the solutions. Specifically, considering the MCP described in section "Neighborhoods for Binary Problems," the initial solution is $x_1 = [1, 1, 0, 0, 0]$, representing $W = [1, 2]$ and $W' = [3, 4, 5]$, with an objective function value of 38. The neighborhood selected to be explored is $\mathcal{N}_{add}^{Bin}(x_1)$, where each neighbor is generated by adding a new vertex to W (removing it from W'). In the first iteration, the best improvement strategy (Fig. 7a) generates all possible neighbor solutions for x_1 (i.e., x_2, x_3, x_4). The exploring order, as stated before, is irrelevant, since it is going to explore the whole neighborhood. Then, the method selects

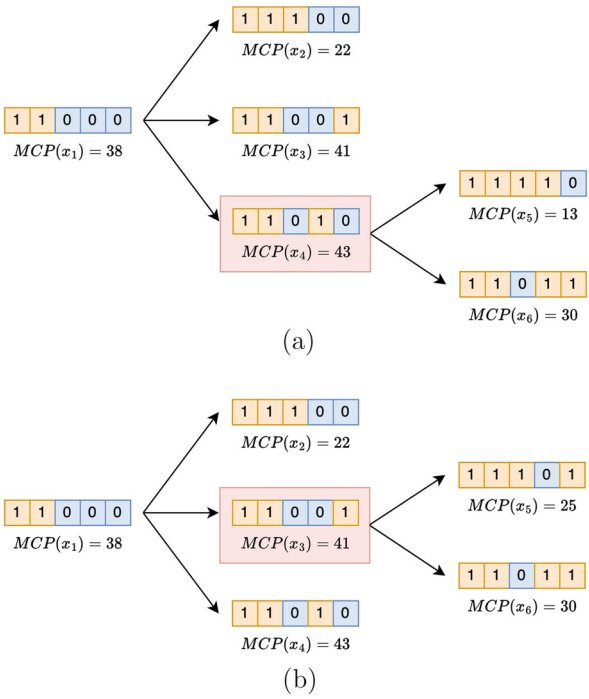

Fig. 7 Comparison of best and first improvement strategies when starting from the same solution for the MCP. (**a**) Best improvement. (**b**) First improvement

the best neighbor solution, which is x_4 in Fig. 7a, with a higher (better) objective function value of 43. Finally, in the next iteration, the method explores the entire x_4 neighborhood, stopping after the exploration, since there is no better neighbor solution.

Regarding the first improvement method (Fig. 7b), the exploration order (which is relevant in this case) is a lexicographical order, starting with solution x_2. As the objective function value of x_2 is lower (worse) than x_1, the method explores another neighbor, which is x_3. The objective function value for x_3, 41, is better than for x_1, 38, so in this case, the first improvement strategy stops the iteration, starting the next one from this new best solution x_3. Notice that although solution x_4 is better than x_3, it is not explored in this strategy, since the order selected has led the method to find a better solution before reaching x_4. Finally, in the next iteration, the method starts from x_4 and then explores, in this order, x_5 and x_6, stopping the search since there is no improvement in any neighbor.

In the context of large neighborhoods, there is a compromise between the number of iterations required to find a local optimum and the associated computing time. In general, iterations performed in the first improvement strategy are more efficient than those in the best improvement one, since the former only evaluates part of the neighborhood, while the latter explores it completely. On the other hand, the improvement obtained in the first improvement strategy is typically smaller than the one achieved by the best improvement strategy, requiring in general more iterations to obtain the local optimum. Additionally, the best improvement strategy

is usually more adequate to perform efficient catching and updating mechanisms, which allows the search to efficiently explore the neighborhood [20].

In [17], an empirical study on traveling salesman problem was conducted in order to compare the first and the best improvement strategy within 2-opt neighborhood structure. It appeared that the quality of the final solution depends on the quality of the initial solution: (i) if random initial solution is chosen, the better and faster is the first improvement strategy; (ii) the opposite holds if the greedy solution is taken as initial one.

VND Variants

The variable neighborhood search (VNS) is a metaheuristic proposed in [32] as a general framework to solve hard problems. It is based on a simple idea: systematical changes of neighborhood structures within the search procedure. Let $\mathcal{N} = \{\mathcal{N}_1, \ldots, \mathcal{N}_{k_{max}}\}$ be set of operators such that each operator $\mathcal{N}_k$, $1 \leq k \leq k_{max}$ maps a given solution x to a neighborhood structure $\mathcal{N}_k(x)$.

Note that the order of operators taken from the set $\mathcal{N}$ also defines the order of neighborhood structures of a given solution x examined. When solving an optimization problem by using different neighborhood structures, VNS methodology proposes to explore them in three different ways: (i) at random, (ii) deterministically, or (iii) mixed (combining both deterministic and random exploration).

Variable neighborhood descent (VND) is a variant of VNS that explores a predefined set of neighborhoods. In general, VND explores small neighborhoods until a local optimum is encountered. At that point the search process switches to a different (typically larger) neighborhood that might allow further progress. This approach is based on the fact that a local optimum is defined with respect to a neighborhood relation, such that if a candidate solution x is locally optimal in a neighborhood $\mathcal{N}_i(x)$, it is not necessarily a local optimum for another neighborhood $\mathcal{N}_j(x)$. Thus, VND explores the solution space using several neighborhood structures either in a (i) sequential, (ii) a nested (or composite), or (iii) mixed nested way [21,43].

Sequential Variable Neighborhood Descent

Most typical VND variants traverse the list of neighborhood structures in a sequential way. Let suppose that we have an ordered list of k_{max} neighborhoods, the current solution is x and new candidate solution x' is found in the neighborhood $k \leq k_{max}$. The main question that arises is by exploring which neighborhood structure we resume the search. The answer to this question is provided by the neighborhood change step. We may distinguish the neighborhood change steps that maintain a static list of neighborhoods and those with a dynamic list of neighborhoods. In the case of neighborhood change steps with the static order, the order of examining neighborhoods is predefined in advance, while in the case of a dynamic order, the order may evolve depending on the success/failure within some neighborhood structure.

All sequential VND procedures follow the steps given in Algorithm 2 and start from a given solution x. In each VND iteration, a local search procedure through a given neighborhood structure is applied (step 8), followed by a neighborhood change function (step 9). The neighborhood change function defines the neighborhood structure that will be examined in the next iteration. Each VND variant stops when there is no improvement with respect to any of the considered neighborhood structures. Thus, the solution obtained by any sequential VND is a local optimum with respect to all neighborhood structures.

Algorithm 2: SeqVND (x,$k_{\max}$,$\mathcal{N}$)

```
1: x ← x''
2: Stop ← False
3: while not Stop do
4:     x ← x''
5:     Stop ← True
6:     k ← 1
7:     while k ≤ k_max do
8:         x' ← arg min_{y∈N_k(x)} f(y)
9:         NeighborhoodChange(x, x', k)
10:        if f(x') < f(x'') then
11:            x'' ← x'
12:            Stop ← False
13:        end if
14:    end while
15: end while
16: return x''
```

VND with the static order of neighborhoods (Static VND) Within the variants with the static order of neighborhoods, the basic VND, the pipe, the cyclic VND, and the union VND emerge as the most representative search procedures. These variants differ in how they implement the neighborhood change procedures. Specifically, if an improvement has been detected in some neighborhood, how the search (after updating the incumbent solution) is continued:

- **Basic VND (B-VND)** – returns to the first neighborhood from the list.
- **Pipe VND (P-VND)** – continues the search in the same neighborhood.
- **Cyclic VND (C-VND)** – resumes the search in the next neighborhood from the list.
- **Union VND (U-VND)** (sometimes called multiple neighborhood search [44], where the single neighborhood is obtained as the union of all predefined neighborhoods) – continues the search in the same large neighborhood. U-VND is recently proposed in [2, 26, 44] and used within tabu search.

VND with dynamic order (Dynamic VND) Among VNDs with the dynamic order, the most typical ones are random VND and adaptive VND:

- **Random VND**. The random VND procedure as new neighborhood to be explored suggests one chosen at random from the list of available neighborhoods. This happens regardless we have the change of the incumbent solution or not.
- **Adaptive VND**. The simple adaptive VND changes neighborhoods according to "merits" of neighborhoods. At simplest, the merit needs to reflect the success/-capability of certain neighborhood to improve incumbent solution. Hence, the merit evolves during the search and accordingly the order of neighborhoods may change. One possibility is to have all the time neighborhoods that are ordered according to their merit and then favor that those with higher merit are explored at first. The merits may be maintained by using some adaptive mechanism or machine learning technique.

Empirical Study on Static VNDs

We show the performance of the aforementioned static VND variants, considering the example introduced in [31]. In particular, it shows an empirical study on different static VND variants used to solve traveling salesman problem. For testing purposes, 15,200 random test instances were generated in the way described in [17]. Within VND variants, three classical TSP neighborhood structures are considered: 2-opt (Fig. 8), Insertion-1 (Fig. 9), and Insertion-2 (Fig. 10).

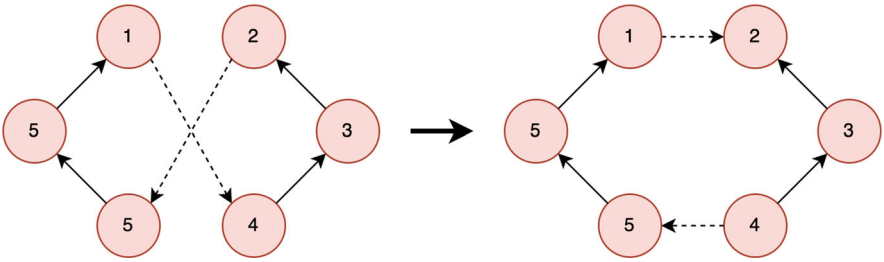

Fig. 8 Example of a 2-opt move involving vertices 1, 2, 4, and 5

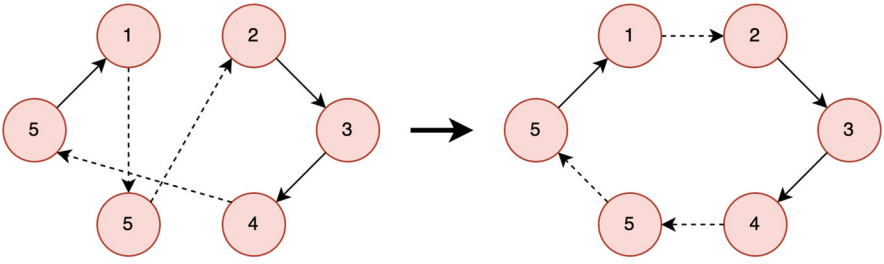

Fig. 9 Example of an Insertion-1 move where vertex 5 is inserted between vertices 1 and 2, and removed from its corresponding former position

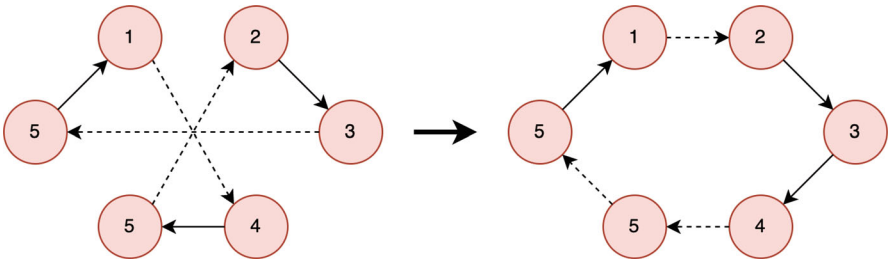

Fig. 10 Example of an Insertion-2 move where vertices 4 and 5 are inserted between vertices 1 and 2, removing them from its corresponding former position

Table 1 Comparison of VND variants

VND	Avg.	Time (s)
Basic VND	1198.24	0.16
Pipe VND	1198.52	0.12
Cyclic VND	1198.76	0.46
Union VND	1197.65	1.06

On each instance from this data set, each VND variant, except U-VND, is tested under 24 different settings. Each setting corresponds to choosing the following: (i) one out of two common ways for getting an initial solution, at *random* (solution generated as a random permutation of nodes) or *greedy*; (ii) one out of six possible neighborhood orders; and (iii) the *best* or the *first improvement search strategy*. This gives $2 \times 6 \times 2 = 24$ different search methods that use 2-opt, Insertion-1, and Insertion-2 neighborhoods.

On the other hand, U-VND is tested under only two different settings as U-VND that uses the best improvement search strategy and the greedy initial solution and U-VND that uses the best improvement search strategy and the random initial solution. Note that if the first improvement search strategy is used within U-VND, then U-VND is equivalent to basic VND.

Table 1 summarizes results considering the entire set of 15,200 instances as a test case. Namely, the average solution values (Column *Avg.*) and average CPU times (Column *Time (s)*) over all test instances in the data set, attained by VND variants under the best settings, are reported.

From the results presented in Table 1, the following conclusions may be drawn: (i) U-VND is slightly better than the other VNDs, regarding the best average values attained, but much slower than the others. This is explained by the fact that U-VND in each iteration performs exploration of large part of the solution space before deciding to re-center the search. Obviously, such principle is suitable for reaching good final solution, but requires a large CPU time; (ii) comparing VNDs that re-center the search in the inner loop (i.e., B-VND, P-VND, and C-VND), it follows that B-VND is able to provide the best solution values. Regarding average CPU times consumed by B-VND, P-VND and C-VND to find the best reported average solution value, their ranking is as follows: the fastest is P-VND, B-VND is ranked

as the second, while C-VND is the slowest one. However, since, B-VND consumed negligible more CPU time to find the best reported average solution value comparing to CPU time that P-VND consumed to do so, we may conclude that B-VND is the most appropriate sequential VND version.

Nested Variable Neighborhood Descent

A nested (composite) variable neighborhood descent procedure [21] explores a large neighborhood structure obtained as a composition of several neighborhoods. More precisely, let $\mathcal{N} = \{\mathcal{N}_1, \ldots \mathcal{N}_{k_{max}}\}$ again be set of move operators such that each one $\mathcal{N}_k$, $1 \leq k \leq k_{max}$ maps a given solution x to a predefined neighborhood structure $\mathcal{N}_k(x)$. Then, the neighborhood explored within a nested variable neighborhood procedure is defined with operator $\mathcal{N}_{nested} = \mathcal{N}_1 \circ \mathcal{N}_2 \circ \cdots \circ \mathcal{N}_{k_{max}}$. More precisely, the composite neighborhood of solution x is formed by first applying the move operator $\mathcal{N}_1$, obtaining $\mathcal{N}_1(x)$. Then, it is applied the move operator $\mathcal{N}_2$ to all solutions in $\mathcal{N}_1(x)$, forming the set $\mathcal{N}_1(\mathcal{N}_2(x))$, and so on. Obviously, the cardinality of a neighborhood structure $\mathcal{N}_{nested}x) = \mathcal{N}_1(\mathcal{N}_2(\ldots(\mathcal{N}_{k_{max}}(x))))$ of some solution x is less than or equal to the product of cardinalities of nested (composed) neighborhoods. More formally

$$|N(x)| \leq \prod_{k=1}^{k_{max}} |N_k(x)|$$

Such cardinality obviously increases chances to find an improvement in the neighborhood. The nested VND is illustrated in Algorithm 3. The neighborhood $\mathcal{N}(x)$ may be explored by using either the first or the best improvement search strategy. However, since its cardinality is usually very large, the first improvement is used more often [21,43].

Algorithm 3: *NestedVND*$(x, k_{\max}, \mathcal{N})$

1: $\mathcal{N}_{nested} = \mathcal{N}_1 \circ \mathcal{N}_2 \circ \cdots \circ \mathcal{N}_{k_{\max}}$
2: **repeat**
3: $x' \leftarrow x$
4: $x \leftarrow \arg\min_{y \in \mathcal{N}_{nested}(x')} f(y)$
5: **until** $f(x') \leq f(x)$
6: **return** x'

We use the Uncapacitated r-Allocation p-Hub Median Problem (r-p-HMP) to illustrate how this VND strategy works. Specifically, the r-p-HMP may be stated as follows. Given n nodes, this problem considers for each pair of nodes i and j, the distance d_{ij} and the amount of flow $t_{ij} \geq 0$ that needs to be transferred from i to j. It is generally assumed that the transportation between non-hub nodes i, j is

only possible via hub nodes h_i, h_j, to which nodes i, j are assigned, respectively. Transferring t_{ij} units of flow through path $i \rightarrow h_i \rightarrow h_j \rightarrow j$ induces a cost $c_{ij}(h_i, h_j)$, which is computed as

$$c_{ij}(h_i, h_j) = t_{ij}(\gamma d_{ih_i} + \alpha d_{h_i h_j} + \delta d_{h_j j}).$$

Parameters γ, α, and δ represent unit rates for collection (origin–hub), transfer (hub–hub), and distribution (hub–destination), respectively. Note that the hub nodes h_i and h_j may be equal.

We represent a solution of r-p-HMP by a set H containing p hubs and a matrix A, where each row i contains r hubs assigned to node i (i.e., i-throw coincides with the set H_i). Thus, our solution is represented as $x = (H, A)$. The initial solution is obtained using the greedy heuristic described in [40]. We consider two neighborhood structures of a given solution $x = (H, A)$. The first neighborhood structure, denoted by $\mathcal{N}_H$, is obtained by replacing one hub node from H by another non-hub node from $N \setminus H$ (see Fig. 11). More formally,

$$\mathcal{N}_H(x) = \{x' \mid x' = (H', A'), |H \cap H'| = p - 1\}.$$

The second neighborhood, denoted by $\mathcal{N}_A$, is obtained by replacing one hub assigned to some node with another hub, while the set H remains unchanged (see Fig. 12):

$$\mathcal{N}_A(x) = \{x' | x' = (H, A'), |A \setminus A'| = 1\}.$$

Unfortunately, evaluating the objective function value of a solution from $\mathcal{N}_H$ requires to solve an allocation problem, which is $\mathcal{NP}$-hard by itself [25]. Therefore, solving exactly the associated allocation problem will be quite time-consuming. In

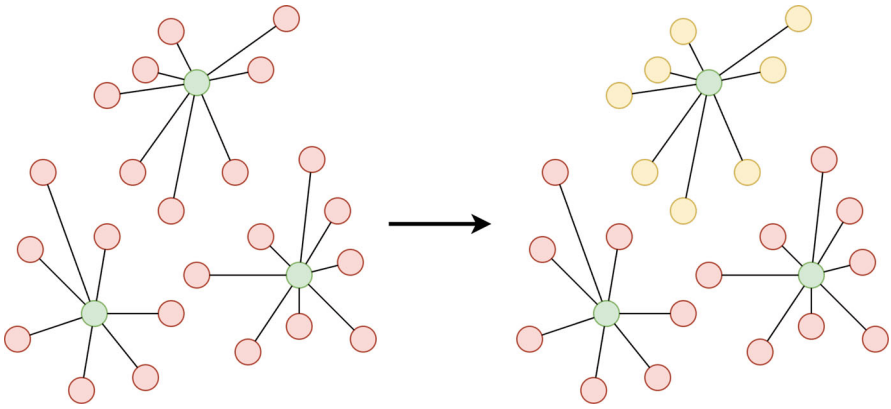

Fig. 11 Interchange neighborhood $\mathcal{N}_H$. Yellow dots are the possible new hub location for the one represented in green

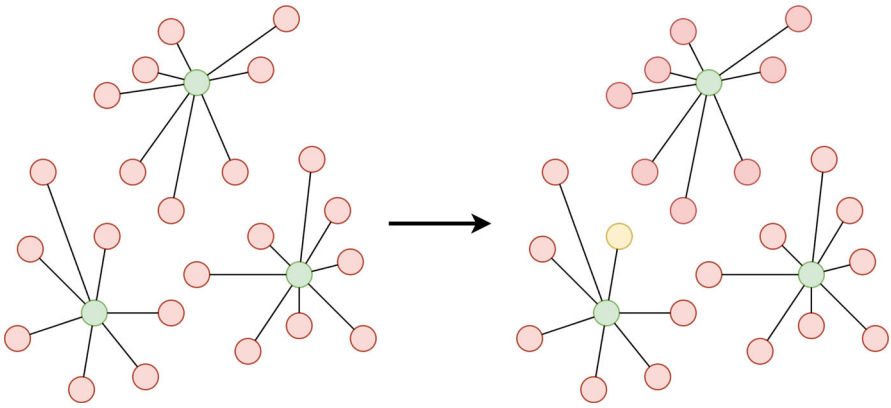

Fig. 12 Allocate neighborhood $\mathcal{N}_A$. Yellow dot represents the non-hub node which is reallocated to the another hub

order to deal with this drawback, we find near-optimal allocation A' of some solution $x'' \in \mathcal{N}_H$ as follows. For each node, we firstly determine node-to-hub allocation using the greedy procedure (see Algorithm 4).

Algorithm 4: *GreedyAllocation*(H, A)

for $i \in \mathcal{N}$ **do**
  for $j \in 1 \dots p$ **do**
    $value(j) = d_{ih_j} \sum_{k \in N} t_{ik} + \sum_{k \in N} t_{ik} d_{h_j k}$
  end for
  $Sort(value)$
  for $j \in 1 \dots r$ **do**
    $A[i][j] = h_{\pi(j)}$
  end for
end for

The solution $x'' = (H'', A'')$ obtained in this way is then improved by exploring the second neighborhood $\mathcal{N}_A(x'')$. In that way, the so-called nested variable neighborhood descent (Nest-VND) is defined (see Algorithm 5).

Algorithm 5: *NestedVND*(x)

for $x'' = (H'', A'') \in \mathcal{N}_H(x)$ **do**
  $GreedyAllocation(H'', A'')$
  $x' \leftarrow \arg\min_{y \in \mathcal{N}_A(x'')} f(y)$
  if $f(x') < f(x)$ **then**
    $x \leftarrow x'$
  end if
end for
return x

Table 2 Comparison of GRASP and GVNS on AP instances

	GRASP		GVNS_RP		
n	Avg.	Time (s)	Avg.	Time (s)	% Improve
60	122,348.90	4.59	121,829.27	3.73	0.42
65	123,001.53	6.66	122,689.74	5.87	0.25
70	123,931.76	10.51	123,604.38	5.75	0.26
75	124,776.42	11.11	124,650.73	5.93	0.10
80	125,148.22	14.40	124,844.76	9.36	0.24
85	125,566.58	19.48	125,378.23	13.10	0.15
90	124,934.99	22.95	124,734.55	12.32	0.16
95	125,121.18	24.27	124,926.55	25.45	0.16
100	125,805.04	4.81	125,588.19	10.39	0.17
150	126,728.85	21.42	126,307.10	24.70	0.33
200	129,144.44	58.86	128,788.66	98.67	0.28
Avg.	125,137.08	18.10	124,849.29	19.57	0.23

In [43], the above nested VNDs were used as a local search within a general variable neighborhood search (GVNS)-based heuristic. The performance of this heuristic, named `GVNS_RP`, was compared with the GRASP heuristic proposed in [40]. In Table 2, we provide a summarized result of comparison of `GVNS_RP` and GRASP on instances from AP data set (see [43]). The average value of best found solutions and average CPU times needed for finding these solutions over all instances with the same number of nodes are reported. The column headings are defined as follows. In the first column of Table 2, we report the number of nodes in the considered instances, whereas in the columns "Avg.," we provide the average of best solution values found by GRASP and `GVNS_RP`, respectively. In columns "Time (s)," the average time needed to reach best found solutions for instances with n nodes is given, while in Column "% Improve," we report the percentage improvement obtained by `GVNS_RP` compared with the current best known values. From the reported results, it follows that within each set of instances with the same number of nodes, there is at least one instance where the best known solution is improved by `GVNS_RP`. Moreover, the average improvement on AP data set achieved by GVNS variants is around 0.25%.

Mixed Variable Neighborhood Descent

Mixed variable neighborhood descent [21] combines ideas of sequential and nested variable neighborhood descent. Namely, it uses a set of move-operators $\mathcal{N} = \{\mathcal{N}_1, \ldots \mathcal{N}_b\}$ to define a nested neighborhood, and, after that, on each element in this nested neighborhood, it applies a sequential variable neighborhood descent variant defined by a set of move-operators $\mathcal{N}' = \{\mathcal{N}_{b+1}, \ldots \mathcal{N}_{k_{\max}}\}$. The cardinality of the set explored in one iteration of a mixed VND is bounded by

$$|\mathcal{N}_{mixed}(x)| \leq \prod_{\ell=1}^{b} |\mathcal{N}_\ell(x)| \times \sum_{\ell=b+1}^{k_{\max}} |\mathcal{N}_\ell(x)|, x \in S.$$

In Algorithm 6 we show the pseudo-code of a mixed VND. Note that if the set $\mathcal{N}$ is the empty set (i.e., $b = 0$), we get pure sequential VND. If $b = k_{\max}$, we get pure nested VND. Since nested VND intensifies the search in a deterministic way, boost parameter b may be seen as a way of balancing intensification and diversification in deterministic local search with several neighborhoods.

Algorithm 6: *MixedVND*$(x, b, k_{\max}, \mathcal{N}, \mathcal{N}')$

$\mathcal{N} \leftarrow \mathcal{N}_1 \circ \mathcal{N}_2 \circ \cdots \circ \mathcal{N}_b$
$x' \leftarrow x$
repeat
  stop $\leftarrow$ `True`
  $x \leftarrow x'$
  for $y \in \mathcal{N}(x)$ **do**
    $x'' \leftarrow SeqVND(y, k_{\max} - b, \mathcal{N}')$
    if $f(x'') < f(x')$ **then**
      stop $\leftarrow$ `False`
      $x' \leftarrow x''$
    end if
  end for
until *stop* = `True`
return x'

In [21], two mixed VND heuristics along with one basic sequential VND heuristic were proposed for solving the uncapacitated single allocation p-hub median problem (USApHMP). Neighborhood structures examined within these VND variants are cluster based. A cluster represents one hub with all locations assigned to it. In particular, the following neighborhood structures are distinguished:

- *Allocate*: change membership of a non-hub node by reallocating it to the another hub without changing the location of hubs.
- *Alternate*: change the location of the hub in one cluster.
- *Locate*: select one cluster C with hub h and a location node that is not in this cluster. The selected node becomes a hub, and all locations from the cluster C are assigned to the closest hub (including the new one).

The proposed basic sequential VND heuristic, named `Seq-VND`, examines neighborhood structures *Allocate*, *Alternate*, and *Locate* in that order. On the other hand, the first mixed VND heuristic, named `Mix-VND1`, takes several random points from *Locate* neighborhood and starting from each of them carries out search applying a basic sequential VND heuristic `Seq-VND1`. The used `Seq-VND1` explores *Allocate* and *Alternate* neighborhoods in that order. The second mixed VND heuristic, named `Mix-VND2`, performs more thoroughly exploration of the solution space than `Mix-VND1` applying `Seq-VND1` on each point from *Locate*

neighborhood. These three VND variants together with three local searches in the three defined neighborhood structures (Allocate, Alternate, and Locate) are experimentally compared on AP instance with $n = 100$ and $p = 15$ (see [21]). One thousand initial points are generated at random in the solution space, and a local search is conducted from each one in each type of neighborhood. The distance-to-target diagram [16] presented at Fig. 13 shows the distribution of local minima. Each point (x, y) plots the distance x and percentage deviation y of the local minimum from the best known solution. The results are summarized in Table 3.

Comparing the results in Table 3, we observe that (i) the search in first (*Allocate*) and second (*Alternate*) local neighborhoods are faster than the others, but they have the worse quality; (ii) `Seq-VND` gives better results than the third local search (*Locate*), and is considerable faster; (iii) all three multistart VND local searches

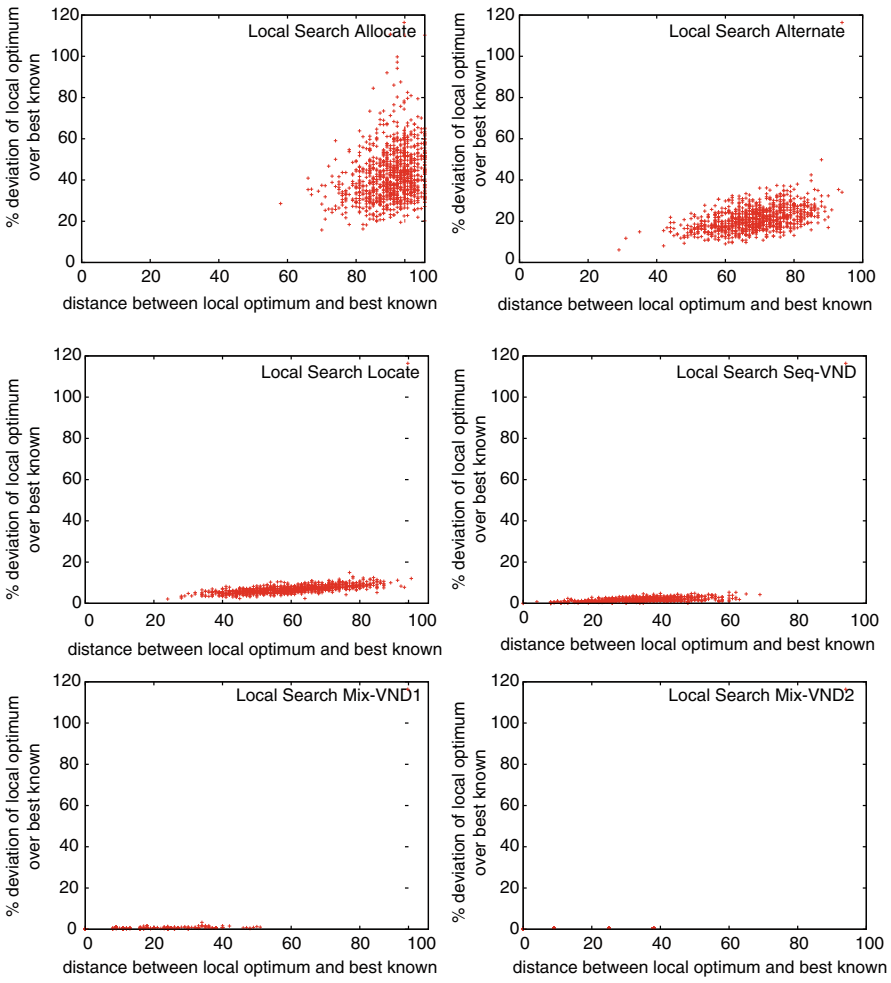

Fig. 13 Multistart on 1000 random initial solutions for AP instance with $n = 100$ and $p = 15$

Table 3 Comparison of 6 local searches on AP instance with $n = 100$ and $p = 15$

	Allocate	Alternate	Locate	Seq-VND	Mix-VND1	Mix-VND2
Avg. % Dev	41.28	21.17	7.41	1.62	0.35	0.16
Min. % Dev.	15.87	6.14	2.58	0.00	0.00	0.00
Max. % Dev.	110.63	49.84	14.6	5.37	3.41	0.68
Avg. Time (s)	0.002	0.004	0.15	0.06	3.36	27.15

found the best known solution in the AP instance; and (iv) the mixed VND versions give the best results, although, as expected, solution times are longer than solution time of Seq-VND.

We see in Fig. 13 that the number of local minima is reduced when VND is used. This is due to the larger neighborhood in VND. For example, the Seq-VND neighborhood clearly contains each of the individual neighborhoods, *Allocate*, *Alternate*, and *Locate*. It is remarkable that Mix-VND2, which utilizes the largest neighborhood, yields only four local minima for this problem instance.

Conclusions

Local search represents one of the most popular classical heuristic techniques that improves (locally) the current feasible solution of some continuous or discrete optimization problem. For that purposes, usually only one neighborhood structure is defined and explored to improve the incumbent solution. Searching for the best solution in such neighborhood is repeated until the local minimum with respect to that predefined neighborhood is reached.

Since the local minimum with respect to one neighborhood structure is not necessary local in another, one needs to construct deterministic local search in cases when more than one neighborhood is used. Such procedures are known as variable neighborhood descent (VND). In this VND survey, we first propose a possible classification of neighborhood structures in solving optimization problems and also provide some simple examples to clearly illustrate the basic ideas. Then, we discuss possible general ways of combining several neighborhoods in the deterministic fashion. Needless to say that the number of possible combination of VND local search variants is large, and they could include problem-specific knowledge in building heuristic for each particular problem. Therefore, VND area is an open avenue for the future research in the area of optimization.

Abstract

The indirect communication and foraging behavior of certain species of ants have inspired a number of optimization algorithms for NP-hard problems. These algorithms are nowadays collectively known as the ant colony optimization (ACO) metaheuristic. This chapter gives an overview of the history of ACO, explains in detail its algorithmic components, and summarizes its key characteristics. In addition, the chapter introduces a software framework that unifies the implementation of these ACO algorithms for two example problems, the traveling salesman problem and the quadratic assignment problem. By configuring the parameters of the framework, one can combine features from various ACO algorithms in novel ways. Examples on how to find a good configuration automatically are given in the chapter. The chapter closes with a review of combinations of ACO with other techniques and extensions of the ACO metaheuristic to other problem classes.

Keywords

Ant colony optimization · Automatic configuration · Combinatorial optimization · Metaheuristics

Introduction

Ant colony optimization (ACO) [35, 37, 39] is a metaheuristic that generates candidate solutions by repeated applications of a probabilistic solution construction procedure. In ACO, the probabilities that bias the solution construction are computed from two types of numerical information associated with construction decisions: *heuristic information*, which is derived from the problem instance being tackled, and *artificial pheromone trails*, which are adapted based on the search performance to bias the solution construction toward high-quality solutions. Pheromone trails are the result of a learning mechanism that tries to identify the solution components that, when appropriately combined, lead to high-quality solutions.

As the name suggests, ACO was inspired by entomological experiments on real ant colonies. These experiments demonstrated that some ant species can find the shortest path between their nest and a food source and showed how this mechanism is enabled by the ants' pheromone trail laying and following behavior [25]. The equations used in computer simulations that mimicked the probabilistic behavior of real ant colonies inspired computer scientists to define the way artificial ants

take decisions when solving combinatorial optimization problems [34, 40, 42]. Nonetheless, rather than faithfully simulating the behavior of natural ants, the focus of ACO research, since its early days, has been the computational performance of ACO algorithms and the quality of the solutions that can be generated. To this aim, additional algorithmic techniques have been quickly added to the first ACO algorithms to make them competitive with other metaheuristics. One example of such algorithmic techniques is the exploitation of heuristic information for guiding the construction of solutions [34, 40, 42]; another example is the use of local search algorithms for improving the solutions constructed by the ants [38, 39, 52, 137, 139].

The first ACO algorithm, *ant system*, was proposed by Dorigo et al. [34, 40–42]. After the publication of the first journal paper on ant system in 1996 [42], the research on ACO has gained momentum, and a large number of algorithmic improvements have been proposed. A first improvement over the basic form of ant system was elitist ant system (EAS) [34]. Among the most successful of these successors have been ant colony system (ACS) [38, 50] and max-min ant system (MMAS) [136, 137, 139]. Generally speaking, the main features of these improvements over the basic ant system include mechanisms to intensify the search around high-quality solutions and mechanisms to maintain a sufficient level of search space exploration.

When viewing algorithms from a component-wise perspective, that is, when considering that an algorithm is composed of algorithmic components that fulfill specific tasks for which alternative procedures may exist, there are similarities between various components of MMAS, ACS, and other ACO algorithms such as EAS [34, 42], rank-based ant system (RAS) [22], best-worst ant system (BWAS) [24], and others. In this chapter, we present the available ACO algorithms for combinatorial optimization from such a component-wise perspective. This perspective makes the contributions of each of the ACO algorithms more easily identifiable, which allows a more flexible approach toward their implementation. One additional contribution of this chapter is to provide such an implementation. The main advantage of this framework is that it enables the composition of new ACO variants. While one possible approach would be to manually explore different ACO algorithm designs and test their effectiveness, this exploration may also be done using automatic methods [70]. For illustration purposes, we demonstrate here how to find the best configuration of such a framework for the traveling salesman problem (TSP) and the quadratic assignment problem (QAP) using irace, an automatic algorithm configuration method [91].

This chapter is structured as follows. In section "Combinatorial Optimization Problems and Constructive Heuristics" we introduce some basic notions of combinatorial optimization and construction heuristics. Next, in section "The ACO Algorithmic Framework," we present the ACO metaheuristic as an algorithmic framework for single-objective combinatorial optimization problems, explaining ACO algorithms from a component-wise perspective. Section "ACOTSP/ACOQAP: A Unified Framework of ACO Algorithms for the TSP and QAP" describes how historical ACO algorithms are instantiations of this framework and how ACO

algorithms can be automatically configured. Section "Applications of ACO to Other Problem Types" describes recent developments in ACO applied to problems with particular characteristics, including continuous optimization and mixed-variable, multi-objective, and dynamic problems. Section "ACO in Combination with Other Methods" reviews hybridizations of ACO with other methods, such as tree search methods, exact methods, and surrogate models. We also briefly discuss recent experiments in dynamically changing the parameters of ACO algorithms during execution. Finally, section "Conclusions" concludes with some perspectives for future research in ACO.

Combinatorial Optimization Problems and Constructive Heuristics

Many problems of enormous practical and theoretical importance can be modeled as combinatorial optimization problems (COPs) [117]. Although practical problems usually have a large number of constraints to be satisfied and uncertainties or multiple objectives to be considered, even simpler COPs without such complicating factors may be very difficult to solve.

A COP can be defined as consisting of a set of instances [117]. An instance of a combinatorial optimization problem $(\mathscr{S}, \Omega, f)$ is defined by

- A search space $\mathscr{S}$ given by the possible value assignments to discrete decision variables x_i, with $i = 1, \ldots, n$;
- A set of constraints Ω among the decision variables;
- An objective function $f : \mathscr{S} \to \mathbb{R}$, which may have to be minimized or maximized.

The notion of *problem* refers to the general abstract task to be solved, while the *instance* is defined as a concrete instantiation of this task with fully specified data.

One of the most studied combinatorial optimization problems is the traveling salesman problem (TSP). In the TSP, a graph $G = (N, E)$ is given with $n = |N|$ nodes, a set E of edges fully connecting the nodes, and distances associated with the edges $d_{ij}, \forall (i, j) \in E$. The goal is to find a Hamiltonian tour of minimal length. Such a tour can be represented as a permutation $\pi = (\pi_1, \ldots, \pi_n)^t$ of the n nodes, where π_i is the node index at position i. Thus, $\mathscr{S}$ is the space of such permutations. The objective function in the TSP is

$$\min_{\pi \in \mathscr{S}} d_{\pi_n \pi_1} + \sum_{i=1}^{n-1} d_{\pi_i \pi_{i+1}} \tag{1}$$

It is important to note that the permutations in the TSP are cyclic, that is, for a TSP solution, the absolute position of a node in the permutation is not relevant.

Another well-known combinatorial problem is the quadratic assignment problem (QAP), where two matrices are given describing the distances between n locations and the flows (of persons, goods, etc.) between n facilities. The goal is to find an assignment of facilities to locations that minimize the sum of the products between distances and flows. More formally, given two $n \times n$ matrices $[d_{ij}]$ and $[f_{ij}]$ with $i, j = 1, \ldots, n$, a solution to the QAP is an assignment of facilities to locations (or, equivalently, of locations to facilities). Because the number of facilities is the same as the number of locations, such an assignment can be represented by a permutation π, where π_i is the facility assigned to location i. The objective function in the QAP is

$$\min_{\pi \in \mathscr{S}} \sum_{i=1}^{n} \sum_{j=1}^{n} d_{ij} \cdot f_{\pi_i \pi_j} \tag{2}$$

Solving a combinatorial optimization problem can often be described as choosing a subset from a finite set of *solution components* $\mathscr{C} = \{c_1, c_2, \ldots\}$ and determining their precise combination that results in a solution that satisfies the problem constraints, i.e., a *feasible* solution, and that optimizes the objective function, i.e., an optimal solution. (For what follows, we assume without loss of generality that the objective function is to be minimized.) In the TSP, for example, the solution components c_{ij} are typically taken to be the edges (i, j) of the given graph, whereas in the QAP, they are the possible individual assignments of a facility j to a location i. Commonly, problems are solved by either searching only in the feasible candidate solution space or, if this is deemed to be too difficult, by allowing the evaluation of infeasible candidate solutions but biasing the search in some way toward feasible ones. For both the TSP and the QAP, a search in the feasible space can be easily enforced, as any permutation is a feasible candidate solution.

Many COPs with practical applications belong to the class of NP-hard problems [54], and, hence, they are considered hard to solve. The NP-hardness of many of these problems, including the TSP and the QAP, implies that, in the worst case, the time needed to find the optimal solution for a given instance grows exponentially with instance size. Thus, instead of searching for an optimal solution and proving its optimality, which may require an infeasible amount of computation time, heuristic algorithms are used to generate good solutions within a reasonable time.

Perhaps the simplest heuristic methods are constructive heuristics. A constructive heuristic starts from an empty or partial candidate solution and then iteratively extends it by adding solution components to it. In many cases, a heuristic estimation of the quality of solution components is available and can be used to guide the choice of which solution components to add. Greedy constructive heuristics rank solution components according to their heuristic value, and, at each construction step, they add the best-ranked solution component to the current partial solution. If more than

one solution component has the best heuristic value, tiebreaking can be done either randomly or by a secondary heuristic.

An example of constructive heuristic for the TSP is the *nearest neighbor* heuristic. Starting from a random node i and an empty candidate solution $\pi = \langle\rangle$, it selects the solution component c_{ij}, $j \in N \backslash \{i\}$ with the smallest distance d_{ij} and adds it to π such that $\pi_1 = i$ and $\pi_2 = j$. The next solution component c_{jk} chosen is the one that minimizes the distance d_{jk}, $k \in N \backslash \{i, j\}$, and so on until a complete permutation π of the nodes in N is obtained.

A constructive heuristic for the QAP would be guided by the fact that facilities with a high total flow to other facilities should be placed at locations that are central and, thus, have a small sum of distances to other locations. Thus, one may precompute values $f = (f_1, \ldots, f_n)^t$, where $f_i = \sum_{j=1}^{n} f_{ij}$, and analogously $d = (d_1, \ldots, d_n)^t$, where $d_k = \sum_{l=1}^{n} d_{kl}$, and then assign the facility with the largest f_i to the locations with the smallest d_k and iterate these steps.

If the heuristic values of solution components remain constant during the solution construction, the construction heuristic is called *static*. Otherwise, when the heuristic values are a function of the partial solution generated so far, one talks of an *adaptive* construction heuristic. In the QAP case, one may obtain an adaptive heuristic by using the intuition that facilities with a high interaction with already assigned ones should be put on a location that is as close as possible to already chosen locations. Adaptive heuristics generally require higher computation times as the heuristic values need to be updated or even recomputed after each construction step; however, making decisions dependent on a partial solution may lead to higher-quality complete candidate solutions.

Constructive heuristics are basic ingredients of many metaheuristics. As an example, semi-greedy heuristics [69] are a randomized form of constructive heuristics; i.e., they make randomized decisions during the constructive search, thus generating many different solutions. The GRASP metaheuristic [47, 48] extends upon semi-greedy heuristics by combining randomized adaptive construction heuristics with local search algorithms. Another example is iterated greedy algorithms [142], which consist in the repeated application of constructive heuristics that start from partial solutions. A destruction mechanism generates these partial solutions by removing solution components from a complete candidate solution.

The ACO Algorithmic Framework

ACO algorithms can also be seen as an extension of construction heuristics. The main characteristics that distinguish an ACO algorithm from other metaheuristics and, in particular, other constructive metaheuristics are the following: (i) It is a population-based algorithm, where m solutions are generated at each iteration; (ii) solutions are generated by a probabilistic constructive mechanism that is biased by numerical information called pheromones (and possibly by heuristic information);

```
procedure ACO_Metaheuristic
    repeat
        for each ant do
            repeat
                ExtendPartialSolutionProbabilistically()
            until solution is complete
        for each ant ∈ SelectAntsForLocalSearch() do    // optional
            ApplyLocalSearch(ant)                       // optional
        EvaporatePheromones()
        DepositPheromones()
    until termination criteria met
end
```

Fig. 1 General pseudo-code of the ACO metaheuristic for NP-hard problems. First, each ant constructs a complete solution by probabilistically choosing solution components to extend their current partial solution (section "Solution Construction"). Some of these solutions are sometimes further improved by means of local search (section "Local Search"). Finally, pheromone values are updated according to the solutions constructed by the ants (section "Global Pheromone Update"). The update usually consists of two complementary steps: evaporation decreases pheromone values and deposit increases them

and (iii) the pheromones are updated during the run of the algorithm using the quality of generated solutions as feedback.

The general outline of an ACO algorithm is given in Fig. 1. After initializing data structures and parameters, an ACO algorithm generally iterates through two procedures: solution construction (procedure ConstructSolutions) and pheromone update (procedure UpdatePheromones). Additionally, a local search algorithm may be used to improve some or all the solutions constructed in the current iteration. Clearly, each of these procedures may in turn consist of different phases, and, depending on the particular ACO algorithm implemented, the particular choices taken within these phases may differ quite strongly. These differences, however, mainly concern specific building blocks or parameter settings that are used within the ACO algorithm phases. These building blocks and parameters are referred as algorithmic components.

In the following, we present the algorithmic components that have been proposed in typical ACO algorithms for combinatorial optimization and discuss alternative options proposed in the literature for implementing these components.

Choice of Pheromone Trails and Heuristic Information

In ACO, the solution construction is probabilistically biased by two types of information: pheromone trails and heuristic information.

The pheromone trails are a set $\mathcal{T}$ of numerical values associated, in principle, to all solution components, that is, $\forall c \in \mathcal{C}$, $\exists \tau_c \in \mathcal{T}$. Pheromone trails are updated during the run of an ACO algorithm according to the quality of previously generated solutions through the mechanisms of pheromone deposit and pheromone evaporation. During the solution construction procedure, pheromone trails bias the choice of solution components toward constructing high-quality solutions. A high value of τ_c represents a higher probability of adding solution component c to the solution being constructed. It is therefore important to appropriately define the set of solution components $\mathcal{C}$, and the corresponding pheromone trails $\mathcal{T}$, when applying an ACO algorithm to a particular problem.

For many problems, the appropriate definition of solution component and, thus, of pheromone trail is rather straightforward. In the TSP, the adjacency information is relevant, that is, which node is the direct successor or predecessor to another one, and therefore a solution component $c_{ij} = (i, j)$ typically refers to the edge connecting nodes i and j. Thus, τ_{ij} represents the pheromone trail associated with the edge. This definition of solution component is also related to the choices made in the nearest neighbor heuristic, which underlies the construction mechanism used in almost all ACO applications to the TSP. Differently, in the QAP, the individual assignments of facilities to locations are of crucial importance. Therefore, a solution component c_{ij} denotes that facility j is assigned to location i in a candidate solution π, that is, $\pi_i = j$ and the pheromone trails τ_{ij} then represent the desirability of assigning facility j to location i. When constructing solutions for the QAP, the order in which facilities are chosen for assigning them to locations may also have an impact on the solution that is eventually constructed. Such an order may also be determined during solution construction by the ants through pheromone trails that indicate which facility should be chosen next for an assignment to a location [134]. Hence, one could have two types of pheromones, the first type τ_{ij} would refer to the desirability of assigning facility j to location i and the second one τ'_{kl} would refer to the desirability of generating an assignment for facility l directly after having assigned facility k. However, no effective implementation of such a second type of pheromone trails seems to be available.

For more complex problems than the TSP and the QAP, alternative definitions of solution components, and the corresponding pheromone trails, may have to be considered [111]. How to define solution components and their associated pheromone trails is itself an ongoing research topic [20, 109]. However, a basic guideline would be to consider effective greedy constructive heuristics and then define the pheromone trails to bias the most important decisions done by this heuristic. Using this guideline, standard definitions of solution components and pheromone trails will be available for many known problems; however, for more complex problems, some research effort may be required to determine the most appropriate solution components and pheromone trails.

The heuristic information $\mathcal{H}$ is also a set of numerical values associated with solution components ($\forall c \in \mathcal{C}$, $\exists \eta_c \in \mathcal{H}$). However, in contrast to the pheromone trails, heuristic information is not updated during the run of the algorithm in

dependence of the quality of the solutions generated. Instead, η_c is a value that is either constant for each solution component, when static heuristic information is used, or a value that is a function of the partial solution generated so far, when adaptive heuristic information is used. The actual formulation of the heuristic information is specific to each problem. Even sometimes, recently, reinforcement learning has been used for generating heuristic information [116]. However, its computation should be fast as the value of η_c is used at every step of the solution construction by each ant. In some problems, there is no readily available heuristic information that effectively guides solution construction, and thus, no heuristic information is used. This is, for example, the case in most ACO applications to the QAP.

Solution Construction

Solution construction is the process by which a new set of solutions is generated at each iteration of an ACO algorithms. In ACO terms, a solution is constructed by an ant; in optimization terms, each ant corresponds to the execution of a probabilistic solution construction procedure. In particular, each ant constructs one solution by starting from an empty solution $s = \langle\rangle$ and adding, at each construction step i, one solution component c_j from a set of candidate components N_i. The probabilistic choice at each step of the solution construction can be modeled by a probability distribution that assigns to each solution component the probability with which it is chosen. Thus, for each c_j, there is a probability $Pr(c_j)$ of being chosen. This probability depends on the pheromone trails, the heuristic information, and the current partial candidate solution s, that is, $Pr(c_j|\mathscr{T}, \mathscr{H}, s)$. There are many different ways of computing this probability. Many ACO algorithms use the probabilistic rule that was introduced for ant system (AS) to choose one element from N_i as follows:

$$\Pr(c_j) = \frac{{\tau_j}^{\alpha} \cdot {\eta_j}^{\beta}}{\sum_{c_k \in N_i} {\tau_k}^{\alpha} \cdot {\eta_k}^{\beta}} \quad \forall\, c_j \in N_i, \tag{3}$$

where α and β are parameters that control the relative importance of pheromone trails and heuristic information on the decision probabilities. If α tends to zero, the solution construction becomes a probabilistic multi-start greedy algorithm; if β tends to zero, the solution construction is biased only by the pheromone trails, and heuristic information is neglected. This rule assigns a probability in a fashion similar to the well-known roulette wheel selection of evolutionary algorithms [56], where the value ${\tau_j}^{\alpha} \cdot {\eta_j}^{\beta}$ plays the role of the fitness assigned to a candidate. Clearly, many different ways can be used to define probability distributions for the solution components. For example, Maniezzo [92, 93] uses in his ANTS algorithm an additive way of combining pheromone trails and heuristic information:

$$\Pr(c_j) = \frac{\alpha \cdot \tau_j + (1-\alpha) \cdot \eta_j}{\sum_{c_k \in N_i} \alpha \cdot \tau_k + (1-\alpha) \cdot \eta_k} \quad \forall c_j \in N_i. \tag{4}$$

The above equation has the advantage over the most common one (Eq. 3) that the operations used (multiplication instead of exponentiation and sum instead of multiplication) are measurably faster in current CPUs. However, one needs to ensure that the range of values of the pheromone trails and of the heuristic information is similar to avoid undesired biases.

A method for making the construction more deterministic was proposed by Dorigo and Gambardella [38] with their ant colony system (ACS) algorithm. They introduced the *pseudorandom proportional rule*, which is controlled by a parameter q_0. At each construction step i, a random value q is drawn uniformly from [0, 1); if $q > q_0$, the probability of c_j is computed as in Eq. 3; otherwise (i.e., when $q \leq q_0$) the choice is made as

$$c_j = \arg\max_{c_k \in N_i} {\tau_k}^{\alpha} \cdot {\eta_k}^{\beta}, \tag{5}$$

that is, when $q \leq q_0$, the solution component with maximum probability is chosen deterministically. A larger value of q_0 is equivalent to a more "greedy" construction procedure, which usually results in faster convergence, whereas smaller values of q_0 lead to more varied solutions and, thus, to more exploration.

Solution construction is one of the critical components of ACO; thus, techniques have been proposed to improve its efficacy and efficiency. Efficacy is sometimes improved by using *lookahead* [106], that is, by considering more than one component at a time when choosing which component should be added to the current partial solution. Efficiency can be greatly improved, particularly in large problem instances, by restricting the choice of solution components to *candidate lists* [37, 38]. Candidate lists contain the most promising solution components, and their definition depends on the instance data and/or on the current partial solution. The most efficient candidate lists depend only on the instance data and are typically computed at the start of the algorithm. One example of candidate lists is the nearest neighbor lists in the TSP, which store the *cl* nearest neighbors to each city ordered according to nondecreasing distances. Even a small value of *cl*, such as 20, is sufficient to generate very-high-quality (or even optimal) solutions to the TSP. Such candidate lists are crucial when applying ACO algorithms to large TSP instances.

Candidate lists may also save memory if the algorithm only stores the pheromone values of those solution components that are part of the candidate lists. Another approach to save memory used in some ACO variants is to avoid explicitly storing the pheromone trails of all solution components by using, for example, a hash table [3] to store only the pheromone values associated with solution components that have appeared in previouslyconstructed solutions. This might be beneficial when the fraction of pheromone values explicitly stored is small enough (relative

to the total size of $\mathscr{T}$) to compensate for the fact that insertion, deletion, and lookup in the hash table require more than constant time.

Independent of the usage of candidate lists, solution construction may be speeded up when using static heuristic information by precomputing the values of ${\tau_j}^{\alpha} \cdot {\eta_j}^{\beta}$, $\forall c_j \in \mathscr{C}$, as all ants use the same total values in Eqs. 3 and 5, and each ant's partial solution only affects which precomputed values are considered at each construction step. If an adaptive heuristic information is used, the total values would depend on the partial solution of each ant; hence, they cannot be precomputed in this way.

Some ACO algorithms incorporate a type of negative learning. The first approaches can be traced back to Maniezzo [92], and Cordon et al. [24] used it to implement pheromone reduction for components that lead to lower-quality solutions during the solution construction process. Other variants of negative pheromone learning were developed in subsequent work [98, 114, 124, 154], which showed decent results compared to relying solely on the usual positive pheromone learning.

Most ACO algorithms construct solutions starting from an empty solution. However, a few proposals have studied the possibility of starting from partially constructed solutions with the goal of partially destroying a very good solution and reconstructing from it a, hopefully better, new one. This is the same concept applied by iterated greedy [?]. Examples of this kind of ACO algorithm are ACO algorithms using external memory [1], iterated ants [152], and cunning ants [151]. Considering the effectiveness of the solution construction, these methods are useful as they avoid the most expensive construction steps that happen when solutions are empty or almost empty. In the Enhanced ACO [52], solution construction is guided by the global-best solution, the best solution found since the start of a run of the algorithm, by adopting the choice done for that solution with a fixed probability at each construction step. This approach somehow introduces a guided perturbation into the best solution found so far and, thus, a straightforward way of increasing the exploitation of good solutions in ACO. It has also the advantage of resulting in faster solution construction as no probabilistic choices among several candidate components need to be done; thus, it is deemed to be useful particularly for tackling large instance sizes.

Typically, construction rules take into account the pheromone trails associated with only single solution components. However, for specific problems, it may be useful to include also the pheromone associated with other solution components. An example is scheduling problems, for which the *pheromone summation rule* was proposed [102]. Its goal is to avoid that jobs are scheduled in a position too far away from positions where they occur in high-quality solutions.

Global Pheromone Update

As mentioned above, the pheromone trails are modified during the run of an ACO algorithm in order to bias the construction of new solutions. Pheromone update usually consists of two complementary steps: pheromone evaporation and pheromone deposition. The general idea behind these two steps is to bias the

pheromone trails so as to favor the construction of high-quality solutions. This general idea can be implemented in a number of different ways.

Pheromone evaporation decreases the pheromone values by some factor with the goal of reducing the effect of previous pheromone depositions and, in this way, help to forget previous poor decisions. Pheromone evaporation itself can be applied, in principle, to some or all the pheromone trails. It can be described as

$$\mathscr{T}_{\text{new}} = \text{evaporation}(\mathscr{T}_{\text{old}}, \rho, S^{\text{eva}}), \tag{6}$$

where $\rho \in (0, 1)$ is a parameter called evaporation rate and S^{eva} denotes the set of solutions that are selected for evaporating the pheromone trails. Most of the existing ACO algorithms do not make use of the solutions in S^{eva} to implement the pheromone evaporation and simply reduce the pheromone trail value of all solution components by the same factor:

$$\tau_j = (1 - \rho) \cdot \tau_j \qquad \forall \tau_j \in \mathscr{T}. \tag{7}$$

A value of $\rho = 1$ would mean that pheromone trails are reset at each iteration of the algorithm, and, thus, no learning occurs. A value of $\rho = 0$ would mean that no evaporation occurs, which would result in an unlimited accumulation of pheromones. For intermediate values of ρ, the amount of pheromone decreases geometrically as a function of this parameter.

In some ACO algorithms, the global pheromone evaporation only applies to some specific solution components. For example, in ACS, pheromone evaporation affects only the solution for which pheromone is deposited in the current iteration:

$$\tau_j = (1 - \rho) \cdot \tau_j \qquad \forall \tau_j \mid c_j \in s^{\text{eva}}, \tag{8}$$

where $\forall \tau_j | c_j \in s^{\text{eva}}$ are all the pheromone trails associated with solution components that occur in the solution s^{eva} chosen for pheromone deposition (see also below). Equation 6 is also general enough to include the pheromone evaporation applied in population-based ACO [60], where the pheromone trails are defined as a function of the solution components occurring in a set of candidate solutions and where pheromone evaporation corresponds to the reduction of the amount of pheromone that is associated with components of the solutions that leave this set of candidate solutions.

Evaporation has the effect of slowing down the convergence of the algorithm as it reduces the probability of constructing again solutions previously constructed. However, while pheromone deposition selectively reinforces the pheromone trails associated with some solution components, pheromone evaporation has the effect of decreasing the probability of selecting those solution components less recently reinforced, thus allowing the algorithm to focus on the most recently found solutions and to "forget" previous pheromone depositions.

Pheromone deposition consists in increasing the pheromone values of a few selected solution components. These solution components belong to one or more

solutions previously constructed by the ACO algorithm. In a general form, the pheromone deposition can be written as

$$\tau_j = \tau_j + \sum_{s_k \in S^{\text{upd}} | c_j \in s_k} w_k \cdot F(s_k), \tag{9}$$

where $S^{\text{upd}} \subseteq S^{\text{eva}}$ is the set of solutions chosen to deposit pheromones, w_k is a weight that is associated with solution $s_k \in S^{\text{upd}}$, and $F(s_k)$ is a function that is nondecreasing with respect to the quality of the solution s_k—that is, whenever $f(s_i) < f(s_l)$ in the minimization case, then it follows that $F(s_i) \geq F(s_l)$. The amount $w_k \cdot F(s_k)$ therefore corresponds to the amount of pheromone that is deposited by a solution s_k.

The solutions used for updating the pheromone trails (S^{upd}) have a strong influence in the behavior of an ACO algorithm. Ant system (AS) selects all solutions constructed in the latest iteration. In contrast, there are alternative methods that consider one single solution for the pheromone deposition, e.g., the iteration-best update (ib-update), which uses the best solution from those generated in the most recent algorithm iteration; the global-best update (gb-update), which uses the best solution found since the start of the algorithm; and the restart-best update (rb-update), which uses the best solution found since the pheromones were reinitialized (see also below on pheromone reinitialization). Intermediate alternative methods would define a set of candidate solutions that may comprise a number of the best solutions of the latest algorithm iteration and solutions such as the global-best or the restart-best ones and use these to deposit pheromone. The particular set of solutions that is chosen to deposit pheromone has a direct effect on the speed of convergence and possible stagnation behavior of the algorithm, which occur when the pheromone trails have converged and the same solutions are constructed over and over again. The gb-update provides the fastest convergence but may more easily lead to such stagnation, while allowing all candidate solutions to deposit pheromones may delay the convergence of the algorithm [39].

In addition to the choice of solutions that form S^{upd}, the amount of pheromone deposited by these solutions also has a direct impact on the search behavior of ACO algorithms. A typical setting in ACO algorithms is to make the amount of pheromone deposited inversely proportional to the objective function value (in the minimization case), that is, to set $w_k \cdot F(s_k) = 1/f(s_k)$. This is the case, for example, for MMAS [139]. (Instead of making the amount of pheromone deposited a function of the quality of the solution, one may also deposit a constant amount of pheromone if the bias toward good solutions is ensured by choosing ib-update, gb-update, or similar biases toward the best candidate solutions.) Various other ACO algorithms add additional weighting factors that may be dependent or not on the quality of the solution relative to others. ACS uses a pheromone update by setting $w_k \cdot F(s_k) = \rho/f(s_k)$, where ρ is the evaporation rate. AS initially used a setting of $w_k \cdot F(s_k) = Q/f(s_k)$, where Q is a parameter; however, in many recent implementations, one simply uses $Q = 1$. Various ACO algorithms use an unequal

weighting for the amount of pheromone deposited. For example, RAS [22] makes the weight dependent on the rank of a solution in the current algorithm iteration by choosing $w_k \cdot F(s_k) = \max\{0, w - r\}/f(s_k)$, where $w = |S^{\text{upd}}|$ is the number of solutions that deposit pheromone after each iteration (this parameter is called *rasrank* in section "ACOTSP/ACOQAP: A Unified Framework of ACO Algorithms for the TSP and QAP") and r is a solutions' rank in the current iteration. The largest amount of pheromone ($w/f(s_k)$) in RAS is assigned to the global-best solution s_{gb}. This corresponds to a choice where S^{upd} comprises the global-best solution and the $w - 1$ best-quality solutions of the current iteration. In EAS [34, 40, 42], the usual AS deposition rule is followed, that is, all solutions generated in the current iteration deposit pheromone; in addition, the global-best solution deposits an amount of pheromone $w_{\text{gb}} \cdot F(s_{\text{gb}}) = Q \cdot m_{\text{elite}}/f(s_{\text{gb}})$, where Q is the same parameter as for AS and m_{elite} is the multiplicative factor that increases the weight of the global-best solution. In BWAS [24], not only the global-best solution deposits pheromone, but also further evaporation is applied, following Eq. 7, to the pheromone trails associated with the solution components that appear in the worst solution of the current iteration and that do not appear in the global-best one.

Pheromone Update Schedule

As said above, the choice of the solutions that deposit pheromone has a strong impact on the search behavior of ACO algorithms. The main goal of pheromone update schedules is to adapt the choice of the solutions that deposit pheromone during the ACO algorithm run. In the simplest case, this is done following a predefined schedule. The first algorithm to make such a predefined schedule explicit is MMAS in its application to the TSP [132, 139] (related ideas are also discussed in [100]). In particular, when local search is applied, the central idea is to shift from a frequent use of the ib-update, which is used by default, toward an increasing frequency of the gb-update (or an rb-update). This shift has the effect of changing the search behavior from a more explorative one toward a more exploitative one that searches for new, improving solutions around the best-so-far ones. When used after the reinitialization of the pheromone trails (see section "Pheromone Reinitialization"), the schedule can also switch in the pheromone deposit between ib-update, rb-update, and gb-update. In particular, if the restart-best solution is used every iteration and no new restart-best solution is found for a number of iterations, the schedule switches to gb-update. As a result, the pheromone trails will implicitly interpolate between the restart-best solution and the global-best solution in a way that resembles the ideas underlying path relinking [55].

The update schedule may have a critical impact on the performance of an ACO algorithm, because it determines the balance between speed of convergence and exploration capabilities. It is also very sensitive to the termination criteria: An update schedule that performs well for long computation times may converge too slowly if the algorithm is terminated much earlier.

Initialization of Pheromones

Two alternative ways of initializing the pheromone trails have been proposed: either using a very small initial value (ACS and BWAS) or using a rather large value (MMAS), where small and large are relative to the amount of pheromone deposited in the global pheromone update. A small value results in a rather quick bias toward the best solutions, while a large value results in a more explorative initial search phase (though depending also on other parameters such as the evaporation rate). Neither the original AS (nor EAS and RAS) specify how the pheromones are initialized and leave it open as a parameter τ_0 to be specified by the user.

Pheromone Reinitialization

It has been shown that resetting the pheromone values back to their initial value may help in long runs by increasing the exploration of the search space [139]. This procedure is often called *restart*, since it is equivalent to restarting the run, although the information about the global-best solution found is kept. While most ACO algorithms do not implement such restarts, restarting has been shown to be very effective for problems such as the TSP and the QAP where the use of strong local search algorithms leads to fast convergence.

MMAS was the first ACO algorithm to employ pheromone reinitialization to avoid stagnation. In particular, MMAS computes a measure, called branching factor, of the potential alternatives encoded in the pheromone trails. When the branching factor goes under a certain threshold value (close to 1), pheromone values are reset to their maximum value ($\tau_{\max}$).

Another ACO algorithm that uses pheromone reinitialization is best-worst ant system (BWAS) [24], which reinitializes the pheromone values to τ_0 whenever the distance, in the decision space, between the global-best solution and the worst solution found in the last iteration falls under a threshold value.

In order to avoid very frequent restarts, there is often a "grace period" when no restarts are allowed; for example, a certain number of iterations since the last restart-best solution was found.

Local Pheromone Update

Local pheromone update is a mechanism that works during solution construction. It modifies the amount of pheromone associated with solution components that have just been chosen by the ants. The first such mechanisms were studied during the design of AS in the so-called ant-density and the ant-quantity models [23,34,41] but were abandoned due to their poor performance. In later research, local pheromone update to diminish the pheromone trails associated with chosen solution components was explored in the design of the ACS algorithm [38]. In particular, ACS uses local pheromone update following

$$\tau_j = (1 - \xi) \cdot \tau_j + \xi \cdot \tau_0 \qquad \forall \tau_j \mid c_j, \tag{10}$$

where c_j is the solution component just selected by an ant during solution construction, $\xi \in (0, 1)$ is a parameter controlling the strength of the local update, and τ_0 is the initial pheromone value, which is set to a very small value, much lower than the expected amount of pheromone deposited in the global pheromone update. The effect of this update rule in ACS is to increase the search exploration during construction making used solution components less attractive.

Although the local pheromone update is very effective when combined with the other characteristics of ACS, it is difficult to incorporate it on its own to other ACO algorithms, because it relies on a strong gb-update and a lack of pheromone evaporation.

An important implementation detail is whether the solutions are constructed in *parallel*; that is, each ant chooses one solution component at a time, or *sequentially*, that is, each ant completes its own solution before the next one starts constructing their own. The different construction schemes may introduce differences in the effect of the local pheromone update.

Pheromone Limits

MMAS introduced the concept of explicit pheromone limits that restrict the possible values the pheromone strength can take to the range $[\tau_{\min}, \tau_{\max}]$. The goal is to prevent stagnation, which occurs when the pheromone values of some solution components are so low that there is no possibility the component will ever be selected (or alternatively, the pheromone values of some solution components are so high that there is no possibility that any other component will ever be selected).

The original proposal showed how to adapt the limits within a run of MMAS. In practice, however, the upper pheromone limit seems to be less important as the maximum amount of pheromone possible on any solution component is already limited by pheromone evaporation.

The definition of $\tau_{\min}$ and $\tau_{\max}$ is problem specific. In general, $\tau_{\max}$ should be an estimation of the pheromone added by the optimal solution. In the TSP, for instance, it corresponds to $\tau_{\max} = \frac{1}{\rho \cdot f(s_{\text{opt}})}$; however, since the optimal solution s_{opt} is not known, the global-best solution s_{gb} is used instead.

The main parameter controlling the pheromone limits is p_{dec}, which is the probability that an ant chooses exactly the sequence of solution components that reproduces the best solution found so far. The value $\tau_{\min}$ is given by

$$\tau_{\min} = \frac{\tau_{\max} \cdot (1 - \sqrt[n]{p_{\text{dec}}})}{n' \cdot \sqrt[n]{p_{\text{dec}}}} \tag{11}$$

where n' is an estimation of the number of solution components available to each ant at each construction step. This value often corresponds to $n/2$ (or to half the size

of the candidate lists if they are used). Nonetheless, in some implementations of MMAS, and specially when local search is used to improve the solutions constructed by the ants, the above computation may be simplified to $\tau_{\min} = \frac{\tau_{\max}}{2 \cdot n}$.

ACS also implicitly uses pheromone trail limits. Due to the way its local pheromone update rule is defined, the pheromone trails can never fall under the value τ_0, and they cannot grow above $1/F(s_{\text{gb}})$, thus limiting implicitly the pheromone trails to the range $[\tau_0, 1/F(s_{\text{gb}})]$.

Local Search

In many combinatorial problems, the use of local search algorithms is essential for obtaining competitive results. Local search algorithms start from an initial solution and iteratively apply small changes to it, as defined by a *neighborhood operator*, in order to find an improved solution. Two of the most basic local search algorithms are best improvement and first improvement, which replace the current solution with the best- and first-improving solution found in the neighborhood, respectively. These algorithms stop if, after examining the whole neighborhood of the current solution, no improved solution can be found, thus stopping at a local optimum. Other local search algorithms that do not necessarily stop at a local optima, such as tabu search or simulated annealing, have also been combined with ACO algorithms [90, 134].

When combined with an ACO algorithm, local search is typically applied to the solutions constructed by the ants. The decision about which ant applies local search to its solution depends on the effectiveness and efficiency of the specific local search [52]. If the local search is relatively fast and effective, it may be worth applying it to all ants' solutions. Otherwise, restricting it either to the iteration-best ant or to a candidate set of promising solutions may save computation time while still giving a chance to further improve the best solution found by the ants.

ACO Algorithms as Instantiations of the ACO Metaheuristic

Given the algorithmic components discussed above, then ACO algorithms from the literature can be described as combinations of specific components. (This list includes only a small subset of the ACO algorithms and algorithmic components proposed in the literature. A more comprehensive component view of ACO is left for further work.)

In particular, AS uses Eq. 3 for solution construction for all ants, Eq. 7 for pheromone evaporation, and Eq. 9 for the pheromone deposition with all ants using the same weight $w_1 = \cdots = w_m$, where m is the number of ants. EAS, RAS, BWAS, and MMAS all use the same solution construction rules and the same evaporation mechanism as AS, but they differ from AS in the way pheromone is deposited; also, they add new algorithmic components. In particular, the pheromone deposition of EAS uses the global-best solutions with a weight m_{elite}. Similarly, the only difference between AS and RAS is the way pheromone is deposited, which also

uses the global-best solution and weights defined according to a parameter called *rasrank*, already explained in section "Global Pheromone Update." The pheromone deposition of BWAS also uses the global-best solution and, in addition, applies further evaporation to pheromone trails associated with solution components that appear in the worst solution of each iteration and not in the global-best one. In addition, BWAS performs pheromone reinitialization depending on the average distance between the iteration-worst solution and the global-best one. MMAS adds several features: It enforces minimum and maximum limits to pheromone values and uses an update schedule to switch between iteration-best, global-best, and restart-best deposition and pheromone reinitialization according to branching factor, and pheromones are initialized to a high initial value. MMAS variants that use the pseudorandom proportional rule (Eq. 5) have also been considered in the literature [138]. Finally, ACS is the ACO algorithm that structurally differs the most from AS: It adds the pseudorandom proportional rule to AS solution construction, pheromone is deposited using the global-best solution, and evaporation is performed at the same time on those values updated during pheromone deposition (Eq. 8). Moreover, further evaporation is performed during solution construction (local pheromone update, section "Local Pheromone Update") by each ant.

ACOTSP/ACOQAP: A Unified Framework of ACO Algorithms for the TSP and QAP

We present in this section a software framework that unifies the implementation of several ACO algorithms found in the literature. The code is publicly available at http://iridia.ulb.ac.be/aco-tsp-qap/. The implementation aims at generality, by clearly separating the general components of the ACO metaheuristic from the problem-specific components that vary from one problem to another. In this chapter, we present an implementation for the TSP and the QAP. However, it is possible to extend the framework to other combinatorial optimization problems with far less effort than an implementation from scratch.

In its current form, the software implements AS, MMAS, EAS, RAS, ACS, and BWAS. In addition to the usual ACO parameters (α, β, ρ, m, ξ, etc), it also allows combining various algorithmic components by setting specific parameters. In particular:

- Pheromone limits as defined by MMAS can be enabled or disabled independently of the algorithm chosen (except for ACS).
- Pheromone reinitialization (restart) can also be enabled or disabled independently of the algorithm. In particular, when more than res_{it} iterations have passed since the last restart-best solution was found, a restart condition is tested. This restart condition may be the branching factor going under a threshold value (res_{bf}), as in MMAS, or the distance between the global-best and the iteration-worst ants going under a threshold value (res_{dist}). In addition, a setting of *always* (*never*) means that the restart condition is always (never) satisfied.

- Any algorithm may use the pseudorandom proportional rule of ACS (Eq. 5) by simply using a value $q_0 > 0$.

In the problem-specific part, the implementation for the TSP follows what is provided by the ACOTSP software [133], that is, heuristic information, candidate lists, and various types of local search, including three-opt first improvement with don't-look-back bits (*dlb-bits*) and nearest neighborhood lists (*nnls*). The part corresponding to the QAP does not implement heuristic information nor candidate lists, since these techniques have not proved useful for the QAP. It does implement, however, various local search algorithms, such as the fast two-exchange best- and first-improvement local searches proposed by Taillard [146] and the robust tabu search proposed in the same paper.

The update schedule (section "Pheromone Update Schedule") is implemented as specific to each problem and ACO algorithm; however, it would be straightforward to extend the update schedule to all ACO algorithms. In the case when MMAS is used together with local search, the user can control the frequency with which the restart-best (or global-best) solution, instead of the iteration-best one, is used to update the pheromone trails, by means of a parameter called *schedule length* (*slen*). Higher values mean longer emphasis on the iteration-best solution, thus possibly increasing exploration at the expense of faster convergence.

In the two following sections, we show how to find a good performing ACO algorithm for a specific class of instances of the TSP and the QAP by automatically configuring the proposed ACO framework. In particular, there is, for each problem, a set of training instances and another set of testing instances. The automatic configuration tool irace [91] is used here to find a parameter configuration given the set of training instances. Finally, this parameter configuration is compared with the default configuration for each problem by evaluating both configurations on the set of test instances.

The implementation of the proposed ACO framework assigns default values, consistent with the literature, to certain parameters depending on the particular ACO algorithm chosen. These default values are documented in Table 1 for completeness. For the purpose of automatic configuration, we consider a single default configuration based on MMAS. Table 2 summarizes, for each problem, the parameters of the proposed ACO framework, their domain, and default values considered in the automatic configuration experiments described below. Although some parameters are still exclusive to a particular ACO algorithm (e.g., ξ can only be used together with ACS), the framework allows using components from one ACO algorithm in others (e.g., the restart mechanism of BWAS can be enabled for any algorithm by setting parameter *restart* to the value "*distance*").

Finding a Better ACO Configuration for the TSP

In the case of the TSP, we consider random Euclidean TSP instances, in particular 50 instances of each size {1000, 1500, 2000, 2500, 3000} for training and other 50

Table 1 Default parameter settings for each ACO algorithm from the literature. Parameters that are available only for particular ACO algorithms are described under the table. The default parameter configuration used in the experiments is based on MMAS (see Table 2)

	m	ρ				
	TSP/QAP	TSP/QAP	q_0	*ph-limits*	*Restart*	Restart parameters
AS, EAS, RAS	25/5	0.5/0.2	0.0	No	Never	
BWAS	25/5	0.5/0.2	0.0	No	Distance	$res_{\text{dist}} = 0.05$
MMAS	25/5	0.2/0.2	0.0	Yes	Branch-factor	$res_{\text{bf}} = \begin{cases} 1.00001 & \text{(TSP)} \\ 1.1 & \text{(QAP)} \end{cases}$
ACS	10/5	0.1/0.2	0.98	No	Never	

$m_{\text{elite}} = n$ when using EAS, $rasranks = 6$ when using RAS, $\xi = 0.1$ when using ACS, $slen = 250$ (TSP) or 20 (QAP) when using MMAS

instances of each size for testing. A single run of irace has a maximum budget of 25,000 runs of the ACO software, and each run is stopped after 60 CPU seconds. Since the goal is to investigate whether it is possible at all to find a better ACO algorithm than the default one from the literature and in order to speed up the process, irace starts from the default configuration for the TSP (Table 2) as an initial solution. After irace finishes, the configuration found is evaluated on the test instances. In particular, we select two configurations found by irace that improve over the default (see Table 3): one is a tuned variant of MMAS and the other is a tuned variant of ACS. These two configurations use a higher value of β and a stronger evaporation ρ than the default configuration. Since $q_0 > 0$, this MMAS variant uses the pseudorandom proportional rule from ACS, which is a MMAS variant that has also been explored previously in the literature [138]. It is also interesting that the restart strategy is typically much more aggressive than the default, with a much larger threshold branching factor, which results in more frequent restarts, only limited by the grace period (res_{it}). Other parameters, such as the size of the candidate list (cl), remain mostly unchanged from the default configuration.

Figure 2 compares the results obtained by these two tuned configurations with those obtained using the default configuration on the test instances. We ran each configuration once on each test instance up to 60 CPU seconds, and we computed the relative percentage deviation (RPD), with respect to the optimal solution, of the best solution found throughout the run. Both plots show that the solutions obtained by the tuned configurations are, in most instances, better than those obtained by the default configuration, and the differences are specially large for the largest instances. These observations are further confirmed by comparing the mean and standard deviation of the values obtained by each configuration (Table 4). In particular, a 95% confidence interval around the mean difference between the default and the tuned configurations does not contain the value zero, which indicates that the observed differences are statistically significant.

Table 2 Domains and default values of the parameter settings of the ACO framework considered in the automatic configuration experiments for the TSP and the QAP. A value of n/a means that the parameter does not exist for the corresponding problem. A value of "–" means that the parameter has no value in the default configuration (because it depends on another parameter setting that is not enabled by default). The list of parameters enabled only for certain values of other parameters is given under the table

	TSP		QAP	
Parameter	Domain	Default	Domain	Default
Algorithm	{AS, EAS, RAS, ACS, MMAS, BWAS}	MMAS	{AS, EAS, RAS, ACS, MMAS, BWAS}	MMAS
m	[1, 500]	25	[1, 10]	5
α	(0.0, 5.0)	1.0	(0.0, 5.0)	1.0
β	(0.0, 10.0)	2.0	n/a	n/a
ρ	(0.01, 1.0)	0.2	(0.01, 1.0)	0.2
q_0	(0.0, 1.0)	0.0	(0.0, 1.0)	0.0
cl	[5, 50]	20	n/a	n/a
ξ	(0.01, 1.0)	–	(0.01, 1.0)	–
rasrank	[1, 100]	–	[1, 100]	–
m_{elite}	[1, 750]	–	[1, 750]	–
p_{dec}	(0.001, 0.5)	–	(0.001, 1)	0.005
ph-limits	{Yes, no}	Yes	{Yes, no}	Yes
slen	[20, 500]	250	[5, 250]	20
restart	{Never, branch-factor, distance, always}	Branch-factor	{Never, branch-factor, distance, always}	Branch-factor
res_{bf}	(1.0, 2.0)	1.00001	(1.0, 2.0)	1.1
res_{dist}	(0.01, 0.1)	–	(0.01, 0.1)	–
res_{it}	[1, 500]	250	[1, 50]	5
localsearch	{None, 2-opt, 2.5-opt, 3-opt}	3-opt	None, best-2-opt, short-tabu-search, long-tabu-search	Best-2-opt
dlb-bits	{Yes, no}	Yes	{Yes, no}	No
nnls	[5, 50]	20	n/a	n/a
rasrank	When *algo* = RAS			
m_{elite}	When *algo* = EAS			
ξ	When *algo* = ACS			
p_{dec}	when *ph-limits* = yes (and for the TSP only if also *restart* = never)			
ph-limits	When *algo* $\neq$ ACS			
slen	When *algo* = MMAS			
res_{bf}	When *restart* = branch-factor			
res_{dist}	When *restart* = distance			
res_{it}	When *restart* $\neq$ never			
dlb-bits, *nnls*	When *localsearch* $\neq$ *none*			

Table 3 Best configurations found by irace for the TSP

algo	*m*	α	β	ρ	q_0	ξ	*cl*	*nnls*	*ph-limits*	*slen*	*restart*	res_{it}
ACS	28	3.07	5.09	0.32	0.53	0.21	22	9	–	–	Branch-factor ($res_{\text{bf}} = 1.74$)	212
MMAS	40	0.94	4.11	0.72	0.14	–	18	12	Yes	191	Branch-factor ($res_{\text{bf}} = 1.91$)	367

Common parameters: *localsearch* = 3-opt + dlb-bits

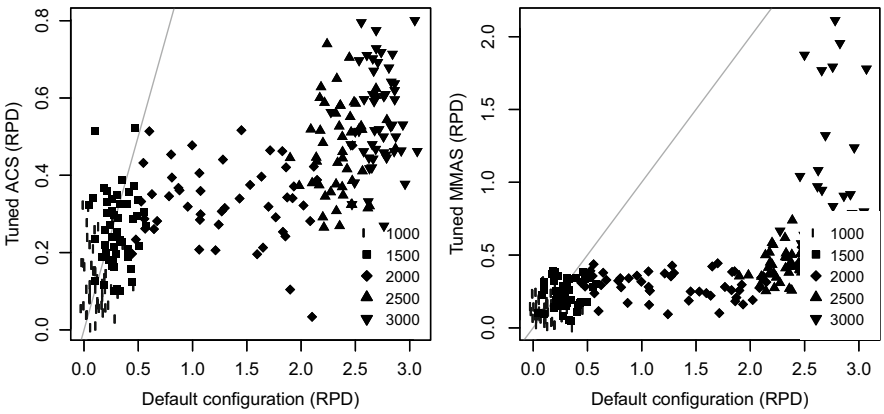

Fig. 2 Comparison of tuned vs. default configurations of ACOTSP on the test TSP instances. Tuned ACS configuration (*left*) and tuned MMAS configuration (*right*). Each point gives the relative percentage deviation from the optimal solution on one particular instance

Table 4 Results on the test TSP instances obtained by the default configuration and two tuned configurations found by irace. Objective function values are given as relative percentage deviation from the optimal solution. ΔCI denotes the 95% confidence interval around the mean difference between the default configuration minus the configuration in that column (thus, positive values would denote that the default configuration is worse)

	Default	Tuned ACS	Tuned MMAS
Mean	1.37	0.35	0.38
Sd	1.08	0.18	0.32
ΔCI		[0.904, 1.14]	[0.875, 1.1]

Finding a Better ACO Configuration for the QAP

In the case of the QAP, we consider two different instance sets: RR, where the distance matrix entries correspond to the Euclidean distances between points randomly generated in a square of side length 300 and the flow matrices are randomly generated according to a uniform distribution, and RS, where the distance matrix is generated as in the previous case and the flow matrix shows a structure

Table 5 Best configurations found by irace for the QAP

	algo	*m*	α	ρ	q_0	*dlb-bits*	*ph-limits*	*slen*	*restart*	res_{it}
RR	MMAS	6	0.324	0.29	0.062	Yes	No	153	Distance ($res_{\text{dist}} = 0.051$)	22
RS	MMAS	4	0.164	0.342	0.284	Yes	No	170	Branch-factor ($res_{\text{bf}} = 1.822$)	40

Common parameters: *localsearch* = best-2-opt

similar to that found in real-world QAP instances. Within each set, we consider 100 instances, and we use half of them for training and the other half for testing the ACO configurations generated. For tuning the ACO framework, we consider a similar setup as in the TSP case, that is, each run of irace has a maximum budget of 25,000 runs of the ACO software, and each run stops after 60 CPU seconds.

For each of the two training sets, RR and RS, Table 5 reports the best configuration found in three independent runs of irace. These two configurations are fairly similar but quite different from the default one. First of all, it is somehow surprising that none of them uses pheromone limits, despite this being one of the key characteristics of MMAS. This could be due to the stronger restart strategies, which do not allow pheromone values to reach the limits and, thus, enforcing the limits adds an overhead that never pays off. Also, the schedule-length (*slen*) value is more than five times higher than the default, which implies a much higher exploitation of the iteration-best solution.

The two configurations of Table 5 are run on each test instance for 60 CPU seconds. Since for these instances the optimal objective values are not known, the relative percentage deviation (RPD) is computed with respect to a reference solution, for each instance, obtained by running the default configuration ten times with a time limit of 600 CPU seconds and keeping the best solution found.

Figure 3 compares the above configurations with the default on the test instances. The improvements of the tuned configurations over the default are not so clear for the QAP as they were for the TSP. In general, most RPD values are extremely small, which indicate that the variations over the best-known solutions are very small for all configurations. In both cases, there are a few instances where the default configuration obtains better RPD values than the tuned one. The statistical analysis in Table 6 shows that the mean difference between the default and tuned configuration for the RS instances is very small but still statistically significant (since the confidence interval does not contain zero), whereas for the RR instances, the null hypothesis of zero difference cannot be rejected (since the corresponding CI contains the value zero). The latter result is likely caused by the relatively large RPD values obtained by the tuned configuration on three particular instances, as shown on the left side of Fig. 3. These results could provide the motivation for exposing additional algorithmic components to automatic configuration, such as

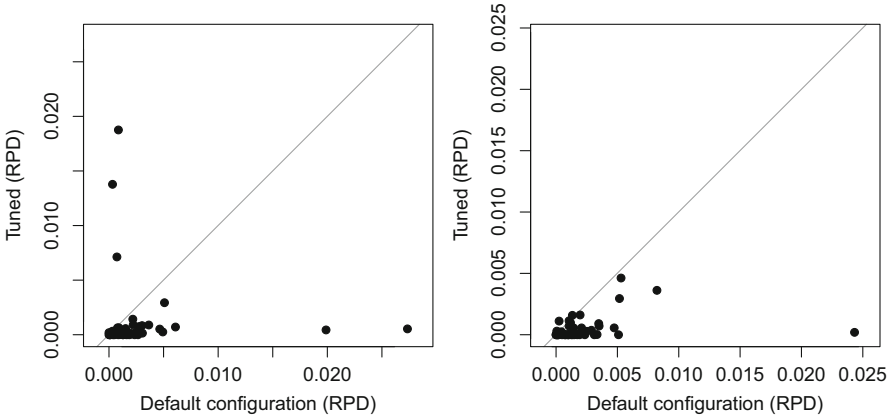

Fig. 3 Comparison of tuned vs. default configurations on the QAP test instances. RR instances (*left*) and RS instances (*right*). Each point gives the relative percentage deviation from the optimal solution on one particular instance

Table 6 Results on the QAP test instances obtained by the default configuration and the tuned configurations found by irace. CI denotes the 95% confidence interval around the mean difference between the default configuration minus the configuration in that column (thus, positive values would denote that the default configuration is worse)

RR instances		
	Default	Tuned ACO
Mean	0.00241	0.00109
Sd	0.00466	0.00335
ΔCI		[−0.000352, 0.00299]

RS instances		
	Default	Tuned ACO
Mean	0.00210	0.000485
Sd	0.00364	0.000941
ΔCI		[0.00062, 0.00261]

the precise update schedule of MMAS, which is known to be very sensitive to the instance characteristics [139]. Extending the proposed framework with new algorithmic components from other ACO algorithms may also further improve the results on the QAP.

Applications of ACO to Other Problem Types

Although the ACO metaheuristic was primarily designed for tackling single-objective combinatorial optimization problems, its main ideas have been extended to tackle other types of problems. In this section, we provide an overview of such problems and how ACO has been adapted to deal with their particular characteristics. Comprehensive reviews of ACO applications are available in the literature [39, 140].

Continuous Optimization Problems

In continuous optimization problems, the domain of the decision variables is the set of real numbers or a subset thereof. In some problems, the simplest approach is to discretize the real-valued domain, which would allow the direct application of ACO. This was, for example, the approach followed by Korb et al. [76] when applying ACO to the protein–ligand docking problem, where a discrete ACO algorithm was combined with a local search for continuous domains.

In many problems, this discretization approach is not feasible, and the problem must be tackled in the continuous domain. A first group of algorithms for continuous optimization is inspired by the behavior of some ant species [17,43,107]. However, these algorithms diverge from the basic framework of the ACO metaheuristic, for example, by requiring the direct communication among ants instead of a pheromone structure. Therefore, they should rather be considered a separate class of algorithms.

A second group of algorithms directly translates the ideas underlying the ACO metaheuristic to the continuous domain. For example, Socha and Dorigo [130] replace the discrete pheromone distributions by Gaussian kernel functions that take the role of the pheromone model that is updated by the ants. Other similar approaches are found in [128, 150]. More recently, Liao et al. [80, 82] proposed a unified model of various ACO algorithms for continuous optimization problems. Their model allows the automatic configuration of new ACO algorithms for continuous optimization very much in the line of what is presented in section "ACOTSP/ACOQAP: A Unified Framework of ACO Algorithms for the TSP and QAP." They show that their final configured continuous ACO algorithms are competitive to other state-of-the-art algorithms for continuous optimization.

These approaches have also been extended to mixed-variable (continuous and discrete) problems [81, 129] by using appropriate ways of representing pheromone trails when handling discrete and continuous variables.

Multi-objective Problems

In many real-world problems, a solution is evaluated according to multiple, conflicting criteria (objectives). If there is a priori information about the importance of each objective, the objectives can be aggregated according to a preference model, and solutions are compared in this way. In the absence of such preference model, one can only say that a solution is better than another if the former is not worse in all objectives and better in at least one of them. Thus, the goal becomes to find (an approximation of) the Pareto set, i.e., the set of solutions not dominated by any other feasible solution [44, 131].

There are several proposals in the literature on how to apply the ACO metaheuristic to multi-objective combinatorial optimization problems. A few of these proposals assume an order of importance among the objectives [51]; however, most proposals

attempt to approximate the Pareto set [5, 53, 88, 126]. As pointed out by López-Ibáñez and Stützle [87], many of these multi-objective ACO (MOACO) algorithms share similar algorithmic components combined in different ways. For example, Pareto ACO [31], BicriterionAnt [72], and COMPETants [30] use a different pheromone set $\mathscr{T}$ (a matrix, in their case) per objective, whereas MACS [12] and mACO-3 [2] use a single $\mathscr{T}$. Some papers have specifically compared both design choices [2, 90]. Moreover, there are basically two ways of updating the pheromone trails in MOACOs: either selecting the best solution for each objective, as done in COMPETants, Pareto ACO, and mACO-4 [2], or selecting (a subset of) all nondominated solutions, as done in BicriterionAnt, MACS, and mACO-3. Finally, a few MOACO algorithms make use of multiple colonies, where a colony is understood as a group of ants that construct solutions only according to the pheromone trails associated with their colony. The pheromone trails of each colony may correspond to multiple pheromone matrices (which are aggregated during solution construction), and colonies may exchange solutions [72]. Nonetheless, it is straightforward to define multi-colony variants of most MOACO algorithms [87].

Most of the MOACO algorithms were proposed for bi-objective problems. In the bi-objective case, the results presented in the literature indicate that the use of one pheromone matrix per objective and of multiple colonies, each of them with their own pheromone matrices, is necessary for MOACO algorithms to perform well on different regions of the objective space [53, 87, 88, 156, 157]. When applied to problems with more than two objectives, this approach quickly becomes too computationally expensive. To address this issue, MOACO algorithms based on population-based ACO have been proposed [4, 61]. More recently, Falcón-Cardona and Coello Coello [46] proposed a new indicator-based many-objective ant colony optimizer and Rivera et al. [125] proposed an ant colony algorithm based on interval outranking that also addresses many-objective problems.

Dynamic Problems

Dynamic problems are those in which some information about the problem changes or becomes available after the start of the algorithm. This is the typical case in network routing, where ACO algorithms specifically designed for these problems have achieved notable results [27, 28, 149]. These algorithms differ significantly from the classical ACO algorithms for combinatorial optimization problems: Ants are launched asynchronously in a distributed way, and no global pheromone update takes place. However, there are also in the literature dynamic variants of classical combinatorial problems, such as the dynamic TSP and the dynamic vehicle routing problem (VRP), where cities may appear or disappear and the distances between them may change. ACO algorithms for the dynamic TSP [26,45,58,99], the dynamic QAP [59], and the dynamic cVRP and variants of it [33, 108, 127] follow more closely the general outline of ACO algorithms discussed in section "The ACO Algorithmic Framework." In addition, they use specific routines to modify the pheromone trails after detecting changes in the problem data or structure. A real-

world application of ACO to the scheduling of hospital nurses in Austria is described by Gutjahr and Rauner [68]. More recently, Lissovoi and Witt [83] formally analyze which type of changes in the dynamic shortest path can be tracked by a constant number of ants using a simplified MMAS variant. An overview of ACO algorithms for dynamic optimization problems is given by these two papers of Leguizamón and Alba [79] and Rezvanian et al. [123]

Stochastic Problems

In some optimization problems, either the objective function, the decision variables, or the constraints are not deterministic but subject to uncertainty or noise, and they are specified only within certain bounds or in terms of a probability distribution. The first stochastic problem to which ACO algorithms have been applied is the probabilistic TSP (PTSP), where one is given for each city a probability that it requires a visit. The goal in the PTSP is to find a tour of minimal expected length over all the cities. The first ACO algorithm for the PTSP was proposed by Bianchi et al. [16], who were using ACS. This algorithm was later improved upon by Guntsch and Branke [57] and further by Balaprakash et al. [9]. The ACO algorithms developed in that latter paper were then shown to match or even surpass in some cases state-of-the-art performance for the PTSP [10], and extensions thereof are state-of-the-art for the vehicle routing problem with stochastic customers and demands [11]. Another early ACO proposal for problems under uncertainty is the S-ACO algorithm [64], which has been the basis of later applications, for example, to the selection of optimal screening policies for diabetic retinopathy [21]. The S-ACO algorithm was later extended by Birattari et al. [18] who integrated F-Race for determining the global-best solution in an ACO algorithm for stochastic optimization and have shown positive results for this latter integration. Another notable example is the application of ACO to the VRP with stochastic demands [14]. A survey of various metaheuristics, including ACO, for stochastic combinatorial optimization problems is provided by Bianchi et al. [15].

ACO in Combination with Other Methods

In this section, we briefly overview research on combining ACO with other methods.

ACO and Tree Search Methods

Ants in ACO perform a probabilistic solution construction that can be seen as a stochastic exploration of a search tree. Thus, a natural extension of ACO is to make use of tree search techniques such as branch and bound. An example is the approximate nondeterministic tree search (ANTS) algorithm by Maniezzo [92, 93], which uses lower bounds in three different ways. First, it incorporates a lower bound

estimate as the heuristic information. Second, it prunes feasible solution components during construction if the estimated solution cost is larger than a threshold (e.g., the cost of the best solution found so far). Third, the order of assignment of solution components during solution construction is influenced by lower bound computations.

A different alternative is to integrate concepts from ACO into tree search methods. An example of this approach is Beam-ACO [19], which incorporates the use of pheromone trails into beam search. Beam search is an incomplete tree search method that keeps a set of partial solutions (the beam) and, at each iteration, selects a number of potential extensions of each of them by adding an additional solution component. These potential extensions are selected based on heuristics [115]. The number of extensions is typically larger than the size of the beam; thus, only the best extensions, according to a lower bound estimate, are kept for the following iteration. Beam-ACO executes beam search several times, replacing the deterministic solution extension of beam search with the probabilistic construction of ACO. In this way, the extension of partial solutions is biased by pheromone trails that are updated with the best solutions found in previous executions of beam search [19]. If lower bound estimates are not reliable or computationally feasible for the problem at hand, an alternative is to perform *stochastic sampling* [86], that is, to complete partial solutions by means of the construction procedure of ACO and use the cost of the complete solution (or the best of several samples) as the cost estimate of the partial solution.

The integration of ACO into Monte Carlo tree search (MCTS) [75,145] is another type of combination between tree search algorithms and ant colony optimization with which good results have been obtained [6, 8].

ACO and Exact Methods

The combination of heuristic and exact methods, sometimes called *matheuristics*, is a promising trend in optimization. Roughly speaking, there are two types of matheuristics: those that use exact methods to solve simpler versions of a problem in order to improve the solutions generated by a heuristic or provide better estimates of solution quality and those that use heuristic methods to provide initial solutions or to constrain the search space of exact methods in order to make their application feasible to large problems. (The exploitation of tree search techniques such as branch and bound or beam search discussed before can actually also be seen as such a matheuristic approach.)

An example of the first type of matheuristic is the use of constraint programming (CP) techniques [94] to help ACO focus on feasible solutions. This is particularly useful in highly constrained problems, such as scheduling or timetabling, where a major challenge is to find feasible solutions among many infeasible ones. Classical ACO algorithms do not perform satisfactorily on such overly constrained problems. Meyer and Ernst [105] use CP techniques to identify in the ants' construction procedure whether specific solution components lead to infeasible solutions. An

example of the second type of matheuristic is the work by Massen et al. [96, 97]. Their pheromone-based column generation algorithm uses an ACO algorithm to generate a heuristic set of feasible routes, from which an optimal subset that is a solution to a vehicle routing problem is selected by an exact solver. The combined algorithm is still a heuristic, because the exact solver does not consider all possible routes, but it allows applying the exact solver to problems with many feasible routes and black box constraints. Recently, a slightly different approach has been developed for the column generation using ant colony optimization [153]. Their method reports better results on the bin packing problem with conflicts compared to various state-of-the-art methods and when integrated into a branch-and-price scheme it achieves significantly lower solution times.

ACO and Surrogate Models

When the evaluation of candidate solutions is very costly in terms of computation time, usually only a small number of candidates can actually be evaluated. Costly solution evaluation arises in the case of simulation-based optimization [7] and, frequently, in industrial settings [49, 147]. Applications with very small evaluation budgets have been rarely studied in the ACO literature, and preliminary results suggest that typical ACO parameter settings are not appropriate in such context [120]. In cases with very small evaluation budget, also the use of surrogate models during optimization may prove useful [73, 110, 155]. Surrogate modeling approaches build prediction models that estimate the quality of candidate solutions, such that only the most promising candidate solutions are actually evaluated. A first approach combining surrogate models and ACO algorithms for tackling combinatorial optimization problems was studied by Pérez Cáceres et al. [120]. More recently, methods that employ a surrogate model for expensive mixed-variable optimization problems that contains a multi-surrogate-assisted selection and a surrogate-assisted local search have been proposed Liu et al. [85]. The authors of [148] consider surrogate models for checking the inherent uncertainty in a mining supply chain problem and show that the use of a surrogate model increase the performance of an ant colony optimization algorithm.

Parameter Adaptation

Good parameter settings may not only be found "offline," as done in section "ACOTSP/ACOQAP: A Unified Framework of ACO Algorithms for the TSP and QAP," but modified or adapted "online," while the algorithm is running. Good parameter settings may also be predicted according to instance features [112]. In the context of ACO, several parameters have a strong effect on the balance between search space exploration and exploitation of the best found solutions, and their proper values may additionally depend strongly on how much computational time is available to the algorithm. Parameters β and ρ are the earliest and most frequently modified

parameters in the literature [100, 103]. A significant effort has been done to define adaptive parameter choices, where the algorithm parameters are modified as a predefined function of the ACO search behavior [78, 122], or to define self-adaptive parameter adaptation schemes, where the algorithm modifies the parameters itself during execution [74, 95, 121]. A relatively new technique is the integration of machine learning techniques in ant colony optimization. Promising results have been achieved by solution prediction via machine learning [144]. A paper [141] critically reviews the works that have applied parameter adaptation to ACO algorithms. The same paper also shows that the convergence speed of MMAS can be significantly improved, without leading to early stagnation, by means of very simple prescheduled parameter variations, such as starting with a very high value of β and reducing it to a much smaller value after a number of iterations. López-Ibáñez and Stützle [89] demonstrate how such prescheduled variations can be automatically tuned for the purpose of improving the convergence speed of ACO algorithms and show that fast increments in the number of ants, fast decrements of β, and, in particular, slow decrements of q_0 produce remarkable improvements on the TSP. (The software described in section "ACOTSP/ACOQAP: A Unified Framework of ACO Algorithms for the TSP and QAP" and published alongside this chapter is also able to replicate these parameter variation schemes.) Finally, Pellegrini et al. [119] empirically showed that parameter adaptation methods proposed in the literature (excluding prescheduled variations) may often worsen the performance of state-of-the-art ACO algorithms and only improve over static parameter settings when the latter produce very poor results and when only one parameter is carefully adapted.

Conclusions

In this chapter, we have reviewed ACO algorithms from a component-wise perspective, and we have provided an example implementation of ACO algorithms according to this perspective. We have also concisely reviewed trends in ACO research on applications to problems with challenging characteristics such as time-varying problem data, multiple objectives, and stochastic data as well as algorithmic developments that combine ACO algorithms with other techniques. We did not cover in this chapter research on the parallelization of ACO algorithms, which has the goal of either speeding up the execution of a single run of an ACO algorithm or of increasing the quality of the final solution obtained within the same wall-clock time (by evaluating more solutions than would be possible without parallelization) [118]. Another important area not covered in this chapter is the ongoing work on the theoretical understanding of ACO algorithms. Early theoretical work has focused on the convergence behavior of ACO algorithms [62, 63, 135]. Later work has analyzed the dynamics of ACO behavior [101] and its relationship to other algorithms [104]. An overview of early theoretical work on ACO is given by Dorigo and Blum [36]. More recent works theoretically analyze the convergence speed of ACO algorithms [13, 32, 65–67, 71, 77, 84, 113, 143].

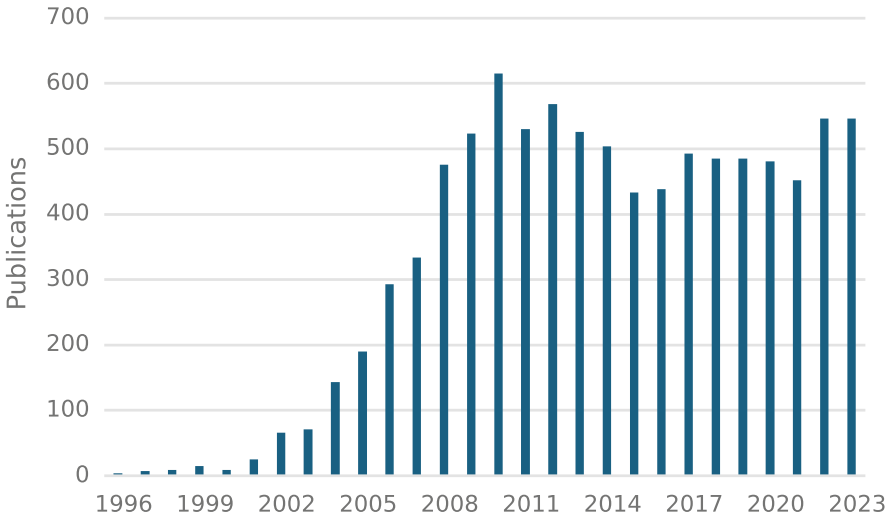

Fig. 4 Number of publications per year in the Scopus database whose titles contain the keywords "ant system," "ant colony system," "ant colony optimization," "ant colony optimisation"

These developments together with the large number of ACO algorithm variants that have been proposed in the literature and the large number of applications to a very diverse set of problems show that ACO has become a widely accepted and well-established metaheuristic. This fact is confirmed also by the number of publications that have as central topic some aspect related to ACO. Figure 4 shows the number of publications in the Scopus database that have one of the four terms "ant system," "ant colony system," "ant colony optimization," or "ant colony optimisation" in the article title. There is a very strong increase from the period 2000–2010, while after 2010, the number of publications remained at a high level. The success of ACO is also witnessed by a number of industrial applications. For example, AntOptima (www.antoptima.com) is a small company using the ACO methodology for tackling industrial problems in distribution and production management, while ArcelorMittal is using ACO algorithms in various areas relevant to steel production to improve operative production performance [29,49]. ACO is also a central topic of journals and conferences specializing in the area of swarm intelligence such as the ANTS conference series started in 1998 (http://iridia.ulb.ac.be/ants/) and the journal "*Swarm Intelligence*."

This success of ACO is due to (i) a truly original algorithmic idea inspired by a natural phenomenon, (ii) a strong versatility of the resulting algorithmic method, and (iii) a focus of ACO research on performance and a pragmatic approach trying to make it a useful technique. In the future, the ideas underlying the ACO metaheuristic promise to be of crucial importance when tackling challenging problems where aspects of constructive search, distributed information, and dynamic domains match well the inherent characteristics of ACO.

Abstract

In this chapter, estimation of distribution algorithms will be described. These algorithms belong to the evolutionary computation field and are characterized by evolving a population of candidate individuals as solutions of the optimization problem estimating at each generation the joint probability distribution of the selected individuals and then sampling new individuals from that distribution. Thus how to model (and sample from) that joint distribution is an important issue that in this chapter will be analyzed. The specificities of these algorithms when dealing with multimodal, multiobjective, or dynamic optimization problems will also be overviewed. Then parallelization and hybridizations with other

optimization heuristics will be presented. Next, applications of the algorithms will come in the last two sections. On the one hand, the use of these algorithms to solve real-world optimization problems in biomedicine, bioinformatics, energy, vehicle routing, and scheduling will be shown. On the other hand, applications in different machine learning tasks, such as supervised classification, clustering, and Bayesian networks, will be discussed. Finally, the conclusions will round the chapter off.

Keywords

Estimation of distribution algorithms · Joint probability distribution · Sampling from a distribution · Bayesian network · Probabilistic dependence · Applications in optimization · Applications in machine learning

Introduction

Estimation of distribution algorithms (EDAs) [1–6] are a class of evolutionary algorithms that build probabilistic models of promising solutions to guide the search process in optimization. Unlike traditional genetic algorithms, EDAs do not use crossover and mutation but instead learn and then sample from a probability distribution that represents the best solutions found so far, gradually refining this distribution to converge to optimal or near-optimal solutions.

This method of evolving populations of candidate individuals toward the optimum of a function offers several advantages. Firstly, the evolutionary process is stochastic and grounded in robust probability theory, making it easier to escape from local optima. Secondly, there is no need to design ad hoc operators for each specific problem, as is often required in other evolutionary computation methods. Thirdly, interactions among the variables encoding each individual, represented through conditional (in)dependence, can be explicitly observed if a probabilistic graphical model is learned from the selected population at each generation. This feature enhances the interpretability of the search process. Fourthly, it is possible to incorporate domain expertise from the optimization process by embedding expert knowledge directly into the graphical model, such as by enforcing certain must-link or must-not-link constraints between variables within the graph.

An Illustrative Example

To enhance comprehension of the distinct components and stages of EDAs, the most straightforward version of this method is applied to a basic optimization scenario. Consider the objective of maximizing the LeadingOnes function, that is, a function that maps a bit string of length n to its number of 1s before the first 0 in the bit string, wherein the goal is to achieve the function's maximum output [7].

Table 1 The initial population D_0. Each individual is evaluated with the LEADINGONES function

Individual	X_1	X_2	X_3	X_4	X_5	X_6	$f(\mathbf{x})$
1	0	0	1	0	1	0	0
2	0	1	0	0	1	0	0
3	0	0	0	1	0	0	0
4	1	1	1	0	0	1	3
5	0	0	0	0	0	1	0
6	1	1	0	0	1	1	2
7	0	1	1	1	1	1	0
8	0	0	0	1	0	0	0
9	1	1	0	1	0	0	2
10	1	0	1	0	0	0	1
11	1	0	0	1	1	1	1
12	1	1	0	0	0	1	2
13	1	0	1	0	0	0	1
14	0	0	0	0	1	1	0
15	0	1	1	1	1	1	0
16	0	0	0	1	0	0	0
17	1	1	1	1	1	0	5
18	0	1	0	1	1	0	0
19	1	0	1	1	1	1	1
20	0	0	1	1	0	0	0

Formally, for $\mathbf{x} = (x_1, \ldots, x_n)$, $\text{LEADINGONES}(\mathbf{x}) = \sum_{i=1}^{n} \prod_{j=1}^{i} x_j$. Its maximum is achieved at point $\mathbf{x}^* = (1, \ldots, 1)$ and its function value is n.

Consider a six-dimensional space, that is, $n = 6$. The initial population can be generated randomly. Let D_0 denote the dataset containing 20 instances (see Table 1) resulting from this generation process.

In a subsequent phase, the most fitted individuals are selected from D_0. In this case, truncation selection is used, whereby half of the population is retained. Let D_0^{Se} denote the dataset comprising the selected individuals, where in this case 9 out of the 20 individuals have fitness values greater than 0 and for the rest this value is 0. Thus, from the 11 individuals of fitness 0, one individual is selected, which is usually done at random. Following the selection of these 10 individuals (see Table 2), their characteristics are aimed to be captured through a joint probability distribution. While it should ideally account for all dependencies among the variables, in this example, the simplest model to represent the joint probability distribution is employed, where each variable is considered independent of the others. Mathematically, this assumption is formulated as follows: $p_1(\mathbf{x}) = p_1(x_1, \ldots, x_6) = \prod_{i=1}^{6} p_1(x_i \mid D_0^{Se})$.

Table 2 The selected individuals D_0^{Se} from the initial population

Individual	X_1	X_2	X_3	X_4	X_5	X_6
1	0	0	1	0	1	0
4	1	1	1	0	0	1
6	1	1	0	0	1	1
9	1	1	0	1	0	0
10	1	0	1	0	0	0
11	1	0	0	1	1	1
12	1	1	0	0	0	1
13	1	0	1	0	0	0
17	1	1	1	1	1	0
19	1	0	1	1	1	1

Thus, the model specification requires only six parameters. Each parameter, $p(x_i \mid D_0^{Se})$ for $i = 1, \ldots, 6$, is estimated from D_0^{Se} based on the corresponding relative frequency:

$$\hat{p}_1(X_1 = 1 \mid D_0^{Se}) = 0.9 \quad \hat{p}_1(X_2 = 1 \mid D_0^{Se}) = 0.5 \quad \hat{p}_1(X_3 = 1 \mid D_0^{Se}) = 0.6$$
$$\hat{p}_1(X_4 = 1 \mid D_0^{Se}) = 0.4 \quad \hat{p}_1(X_5 = 1 \mid D_0^{Se}) = 0.5 \quad \hat{p}_1(X_6 = 1 \mid D_0^{Se}) = 0.5$$

By sampling from this joint probability distribution, $p_1(\mathbf{x})$, a new population D_1 of 20 individuals is generated. Table 3 presents these individuals evaluated according to $f(\mathbf{x})$. Subsequently, the top 10 individuals are selected from D_1, resulting in the dataset D_1^{Se}, as shown in Table 4. From D_1^{Se}, the estimations are:

$$\hat{p}_2(X_1 = 1 \mid D_1^{Se}) = 1 \quad \hat{p}_2(X_2 = 1 \mid D_1^{Se}) = 1 \quad \hat{p}_2(X_3 = 1 \mid D_1^{Se}) = 1$$
$$\hat{p}_2(X_4 = 1 \mid D_1^{Se}) = 0.6 \quad \hat{p}_2(X_5 = 1 \mid D_1^{Se}) = 0.6 \quad \hat{p}_2(X_6 = 1 \mid D_1^{Se}) = 0.5$$

With these first two generations of the EDA, observe that the mean of $f(x)$ in D_0^{Se} was 1.9, while it has now increased to 4.1 in D_1^{Se}.

These three steps: (i) selecting individuals from the population, (ii) learning the joint probability distribution of the selected individuals, and (iii) sampling from the learned distribution, are repeated until a predetermined stopping criterion is met.

The primary challenge with EDAs lies in the estimation of the probability distribution $p_l(\mathbf{x})$ at each generation l. Clearly, estimating all parameters necessary to specify this joint probability distribution is impractical. Consequently, various approximations have been proposed, wherein the joint probability distribution is assumed to factorize according to a chosen probabilistic model.

Table 3 The population of the first generation D_1. Each individual is evaluated with the LEADINGONES function

General Scheme of EDAs

The probability distribution that governs the individuals selected in each generation based on their fitness is then sampled to generate a new population of candidate solutions. For a comprehensive recent review, see [8].

Algorithm 1 presents a general and unified pseudocode that encompasses all variants of EDAs introduced below. The process begins by generating an initial population of individuals.

Algorithm 1: Pseudocode for the EDA

1 $D_0 \leftarrow$ Generate M individuals (initial population)
2 **repeat** for $l = 1, 2, \ldots$
3 1. $D_{l-1}^{Se} \leftarrow$ Select $N \leq M$ individuals from D_{l-1} according to the selection method
4 2. $p_l(\mathbf{x}) = p(\mathbf{x}|D_{l-1}^{Se}) \leftarrow$ Estimate the probability distribution of an individual $\mathbf{x}$ being among the selected population
5 3. $D_l \leftarrow$ Sample M individuals (new population) from $p_l(\mathbf{x})$
6 **until** *the stopping criterion is met*

In the first phase, the M generated individuals are evaluated, and a subset of N individuals is chosen based on a predetermined selection criterion. This criterion can be deterministic (e.g., selecting the N individuals with the highest objective function values) or stochastic, where individuals are selected with a probability proportional to their evaluation.

The second phase involves estimating the joint probability distribution of the selected individuals under various assumptions on the interactions among the decision variables encoding each individual. In the EDA literature, three common scenarios are considered: (a) assuming that all variables are independent, (b) accounting for only bivariate dependencies, or (c) allowing for unrestricted dependencies among the variables. In most practical optimization problems, the independence assumption in (a) is unrealistic, whereas scenario (c) can be computationally prohibitive when dealing with a high number of variables.

The third phase uses the estimated probability distribution to sample a new population of individuals. In cases of constrained optimization problems, it is essential to ensure that the generated individuals satisfy the constraints during the sampling process.

These three steps—evaluation and selection of individuals, learning of the probabilistic model, and simulation—are repeated until a stopping criterion is met. The stopping condition could be based on the number of generations, the convergence toward a global optimum, or a predefined limit on execution time.

Initializing the Population

The simplest way to initialize the population is by sampling from a uniform distribution across each variable, thereby obtaining individuals that cover the entire search space in a balanced manner. If prior knowledge about the problem is available or even historical data, the initialization process could use them.

Selection of Individuals

The selection of individuals in each generation of an EDA can be carried out through common and straightforward procedures in evolutionary computation [9], such as elitist selection, roulette wheel selection, truncation selection, tournament selection, rank-based selection, or more sophisticated methods like Boltzmann selection or stochastic universal sampling.

Learning the Joint Probability Distribution

Discrete EDAs refer to a class of optimization algorithms grounded in the EDA framework, specifically tailored for addressing combinatorial optimization challenges. On the other hand, continuous EDAs are utilized to tackle optimization in continuous spaces. Both discrete [5] and continuous [10] EDAs are classified according to the probabilistic dependency structures allowed for $p_l(\mathbf{x})$ in Algorithm 1.

No dependencies The n-dimensional joint probability distribution of selected individuals in each generation is assumed to decompose as a product of n univariate probability distributions, one for each variable. In other words, $p_l(\mathbf{x}) = \prod_{i=1}^{n} p_l(x_i)$, where in continuous EDAs, densities replace p_l. Key algorithms in this category include: (a) the univariate marginal distribution algorithm (UMDA) [11] for discrete problems, the univariate marginal distribution algorithm for continuous domains (UMDA$_c^G$) where each variable assumes a univariate Gaussian distribution [10]; (b) population-based incremental learning (PBIL) [12], which updates the probability vector components using a Hebbian rule inspired by the selected individuals in each generation, and its continuous version [13], where Gaussianity is assumed for each marginal univariate distribution; and (c) the compact genetic algorithm (cGA) [14], which simulates only two individuals per generation from the current probability distribution, iteratively adjusting probabilities toward the more successful individual until convergence. A general framework for univariate discrete EDAs that encompasses UMDA, PBIL, and cGA is proposed in [15].

Bivariate dependencies The foundational works in this domain include: (a) mutual information maximization for input clustering (MIMIC), (b) combining optimizers with mutual information trees (COMIT), and (c) the bivariate marginal distribution algorithm (BMDA). In MIMIC [16], the best variable permutation is searched for in each generation to approximate the empirical distribution of selected individuals by minimizing the Kullback-Leibler divergence, where $p_l^{\pi}(\mathbf{x}) = p_l(x_{i_1}|x_{i_2})p_l(x_{i_2}|x_{i_3}) \cdots p_l(x_{i_{n-1}}|x_{i_n})p_l(x_{i_n})$, with $\pi = (i_1, i_2, \ldots, i_n)$ denoting a permutation of indices. MIMIC$_c^G$ [10] extends MIMIC for continuous problems by assuming Gaussianity for both marginal and conditional distributions. In COMIT [17], a tree structure

is learned using the maximum weight spanning tree algorithm in each generation. In [18] the dependency tree is based on bivariate copula functions. BMDA [19] factorizes the joint probability distribution according to an acyclic graph formed by a set of trees (forest), where dependencies between pairs of variables are considered based on a threshold. The search of the forest has also been carried out using normalized mutual information [20].

Multivariate dependencies EDAs in this category typically focus on learning a Bayesian network (or a Gaussian Bayesian network) [21] that best represents the selected individuals' distribution in each generation, followed by sampling from the learned model. Key examples include: (a) the estimation of Bayesian network algorithm (EBNA) [22,23], which explores the learning phase with both constraint-based and score-based approaches, with BIC and K2 being the prominent scores; EGNA [10], a variant for continuous problems that learns a Gaussian Bayesian network in each generation, and [24], which adapts EGNA for high-dimensional issues by controlling model complexity; (b) the Bayesian optimization algorithm (BOA) [25], which utilizes the so-called BDe score and a greedy search method starting from scratch in each generation; (c) the learning factorized distribution algorithm (LFDA) [26], which limits the Bayesian network's complexity via the BIC score and a restriction on the number of parent variables per node; (d) the estimation of multivariate normal algorithm (EMNA) [10], which assumes a Gaussian joint probability distribution and estimates the mean vector and covariance matrix using maximum likelihood; (e) regularization-based EDAs, which apply regularization during Bayesian network learning [27], or which introduce regularized Gaussian Bayesian networks to address high-dimensional continuous problems [28]; and (f) the extended compact genetic algorithm (EcGA) [29], which factorizes the joint probability distribution as a product of distributions of variable groups, without the need for learning a Bayesian network every generation. Recent works on continuous optimization include the use of denoising autoencoders [30], restricted Boltzmann machines using attention mechanisms [31], and semiparametric Bayesian networks [32].

Sampling of New Candidate Solutions

Sampling in EDAs is mainly based on stochastic simulation methods of Bayesian networks and Gaussian Bayesian networks. For the former, there are methods such as probabilistic logic sampling, rejection sampling, likelihood weighting, importance sampling, Gibbs sampling, Markov chain Monte Carlo or variational inference sampling, whereas for the latter, possible methods are the Cholesky decomposition, eigenvalue decomposition, principal component analysis sampling, or Box-Muller transformations.

Practical Issues

From a practical perspective, EDAs have been adapted to tackle special (although common) optimization settings. In problems involving the search for the best **permutation**, which naturally arises in the traveling salesman problem, vehicle routing, or scheduling, EDAs have fundamentally adopted four ways of representing individuals: (i) direct permutation representation, in which the individual directly represents a permutation; (ii) adjacency representation, where each position in the sequence indicates the next element in the permutation; (iii) position representation, where each element of the permutation is assigned a specific position in the sequence, rather than directly encoding the order of elements or their adjacency relationships; and (iv) a real-coded individual, where the sorted indices represent the order of items in the permutation. The probabilistic modeling of permutations of selected individuals in each generation (see a review in [33]) can be carried out using position-based models, where the probability distribution is defined over the position of each element in the permutation independently of the others. Alternatively, it can be done using probability distributions defined over the permutation space, such as the Mallows distribution, the generalized Mallows distribution, or the Plackett-Luce model. These special probability distributions for permutations capture dependencies across the entire permutation, making them better suited for more complex rankings and ordering scenarios, as they account for the relative positions of all elements in the permutation.

Multimodal optimization is the process of identifying multiple optimal solutions within a search space. This type of optimization is valuable for problems where diverse solutions are desired, allowing for a more comprehensive exploration of potential solutions rather than focusing solely on a single global optimum. Multimodal optimization problems can be very challenging for an EDA based on a single probability distribution. Therefore, the most common approach to such problems is to consider a finite mixture of probability distributions, each component of the mixture corresponding to one of the peaks of the objective function. Partition-based clustering is used in [34] for multimodal combinatorial optimization problems, while [35] applies it in continuous domains. The structural expectation-maximization (EM) algorithm for multimodal problems in combinatorial optimization (based on Bayesian networks), as well as in continuous domains (based on conditional Gaussian Bayesian networks), is proposed in [36].

Multiobjective optimization is the process of simultaneously optimizing two or more conflicting objectives, aiming to find solutions that balance trade-offs between them. Rather than a single optimal solution, a set of Pareto-optimal solutions is yielded, where improving one objective would worsen at least one another. Evolutionary computation in general and EDAs in particular are well-suited for multiobjective optimization because it naturally handles complex, conflicting objectives and efficiently explores diverse solutions within a population. There is a large number of references that use EDAs in multiobjective optimization. Among the most notable is the multiobjective hierarchical BOA [37] applied to multiob-

jective decomposable problems, and the proposal in [38] where a multidimensional Gaussian Bayesian network is used to learn a joint model of objectives and variables while at the same time differentiating their role in the network.

Dynamic optimization involves finding optimal solutions for problems where the decision variables and/or the objective function change over time. EDAs have been used in dynamic optimization for both single-objective problems [39], with a PBIL version based on multiple populations, and multiobjective problems [40], leveraging transfer learning.

The **parallelization** of EDAs is justified by the high computational cost associated with the three steps these algorithms comprise. Particularly costly is the learning of the joint probability distribution of the selected individuals when modeled through (Gaussian) Bayesian networks. While early parallel EDAs [41] focused on parallelizing only this step, later approaches extended parallelization to all three steps of EDAs [42].

While EDAs perform well in exploring the search space, they are not as effective in its exploitation [43]. This is the main reason why, in real-world problems, EDAs are often **hybridized** with other heuristic strategies. In the literature, there are some works on EDAs hybridized with local search, particle swarm optimization, genetic algorithms, variable neighborhood search, simulated annealing, ant colony optimization, scatter search, or tabu search. However, as we have checked in a literature review (unpublished) of EDA papers published in the Web of Science until 2024, the heuristic that appears most frequently in hybridization with EDAs is differential evolution [44].

Applications in Optimization

EDAs have been applied to solving real-world problems across a wide range of domains. In **biomedicine**, they have been used to predict the survival of cirrhotic patients who have undergone a transjugular intrahepatic portosystemic shunt, which is a procedure to create new connections between two blood vessels in the liver [45]. EDAs have also been applied to the treatment of epithelial ovarian cancer, the search for the optimal chemotherapy dose in cancer, variable selection in a severity classification system for Parkinson's patients based on non-motor symptoms, and a nurse shift scheduling problem. In **bioinformatics**, EDAs have been used to solve the problem of protein structure prediction in simplified models [46], along with other problems such as protein folding, side chain placement, motif discovery, and the search for genetic regulatory networks.

The determination of the best possible locations of depleted uranium bundles, which maximize fuel economy as well as safety, is a large-sized combinatorial optimization problem with constraints that have been approached with EDAs [47] in the **energy** domain. Other problems where EDAs have proposed accurate solutions in this domain are the optimal management of a large number of plug-in hybrid electric vehicles charging at a municipal parking station, the search for the optimal

model parameter estimation of solar and fuel cells, and the prediction of the possible gas emission quantity in coal mines.

In **vehicle routing**, EDAs have provided solutions to: the school bus routing problem with stops selection, an equitable risk routing problem for shipments of hazardous materials, truck and trailer routing problems, the vehicle routing problem with time windows, an agricultural route planning problem, trajectory optimization of space vehicle in rendezvous proximity operation, and signal optimization for large-scale traffic networks [48].

An artificial immune algorithm combined with an EDA for the **traveling salesman problem** (TSP) is proposed in [49]. EDAs have also been developed for some variants of the TSP: multiobjective multiple TSP or for the travelling thief problem [50].

Scheduling is the optimization problem for which the most EDA-based approaches have been developed. This includes some variants of the job shop scheduling problem, such as the job shop scheduling with sequence-dependent, the no-wait job shop scheduling, the flexible job shop scheduling and the multiobjective flexible job shop scheduling, as well as variants of the flow shop scheduling problem, such as the blocking flow shop scheduling, the hybrid flow shop scheduling, the hybrid flow shop scheduling with identical parallel machines, the hybrid flow shop scheduling with stochastic processing time, the reentrant hybrid flow shop scheduling, and the no-idle permutation flow shop scheduling.

Applications in Machine Learning

Machine learning is currently the area of artificial intelligence that is developing the most interesting methodological advancements and practical applications. A dataset serves as the input to an algorithm capable of inducing a model to make rational decisions. The search for the model (including its structure and parameters) that best fits the data or yields the best performance is conducted within a search space of such high dimensionality that an exhaustive search becomes unfeasible.

The exploration of high-dimensional search spaces is inherent to various machine learning tasks, as illustrated by the following examples:

- *Feature subset selection*, where the total number of possible feature subsets, denoted $f(n)$ for n features, is $f(n) = 2^n$
- *Partitional clustering*, where the number of possible partitions of N objects into K clusters is given by $S(N, K) = \frac{1}{K!}\sum_{i=0}^{K}(-1)^{K-i}\binom{K}{i}i^N$, for $K \in \mathbb{N}$, with initial conditions $S(0, 0) = 1$ and $S(N, 0) = S(0, N) = 0$
- *Learning a Bayesian network structure* with n nodes from data within the space of directed acyclic graphs (DAGs), where the number of possible structures is calculated using the recursive relation $f(n) = \sum_{i=1}^{n}(-1)^{i+1}\binom{n}{i}2^{i(n-i)}f(n-i)$ for $n > 2$, with initial conditions $f(0) = f(1) = 1$
- *Permutation-based problems*, such as optimal triangulation in the moral graph of a Bayesian network with n nodes, where the search space cardinality is $n!$

In each of these cases, the search is conducted in a discrete space, posing a highly complex combinatorial optimization problem. Additionally, determining optimal parameters for a machine learning model generally involves continuous optimization challenges, for instance, solving the likelihood equations in logistic regression which lacks a closed-form solution, or training an artificial neural network where its parameters are optimized using the backpropagation algorithm, a process often prone to local optima.

The complexity of this situation justifies the use of metaheuristics for searching the optimal machine learning model, leading to the field known as evolutionary machine learning when these heuristics are based on evolutionary computation. This section reviews several selected works in which EDAs are employed for this purpose. See [51] for a more complete discussion on this topic.

Supervised classification is one of the machine learning tasks where EDAs have been utilized. In feature subset selection for classifiers such as naive Bayes, the EBNA algorithm has been applied [52], as well as the UMDA$_c^G$ algorithm in logistic regression [53]. In artificial neural networks, the PBIL algorithm has been used as an alternative to backpropagation for finding optimal weights connecting nodes in consecutive layers of a multilayer perceptron [54], while the UMDA$_c^G$ has been applied to optimize weights in autoencoders [55]. Among Bayesian classifiers, a variant of naive Bayes that utilizes confidence intervals associated with each conditional probability in each predictor variable seeks the best combination of these parameters using the UMDA$_c^G$ algorithm [56]. Meanwhile, in semi-naive Bayes models, the UMDA algorithm has been applied to identify the model with the best performance [57]. In logistic regression, UMDA$_c^G$ has been used to search for parameter estimates that solve the system of $n+1$ equations and $n+1$ unknowns arising from the maximization of the conditional likelihood function [58].

The three most common types of **clustering**, namely hierarchical, partitional, and probabilistic, have been addressed using EDAs. In hierarchical clustering, UMDA has been applied to provide stochasticity to the subset merging process [59]. In partitional clustering, MIMIC, COMIT, and EBNA have been EDAs applied to the K-means algorithm [60], while UMDA and EBNA enhanced the search process for optimal exemplars in the affinity propagation algorithm [61]. Probabilistic clustering is based on the structural EM algorithm to search for probabilistic dependency relationships among variables. In [62], UMDA is incorporated to improve the greedy heuristic on which the structural EM typically relies.

In **Bayesian networks**, EDAs have been applied to optimization problems arising both in inference tasks and in learning the model from data. For inference, [63] uses a recursive EDA to search for the optimal triangulation of the moral graph associated with the Bayesian network, while [64] applies both UMDA and EBNA in counterfactual reasoning from Bayesian classifiers. Learning the structure and parameters of the Bayesian network in the space of DAGs has been carried out using UMDA and PBIL [65], while in the total ordering space, [66] has applied both discrete and continuous versions of UMDA and MIMIC.

Conclusions

EDAs are a type of evolutionary computation algorithm based on probability theory, enabling the evolution of a population of individuals through the learning of a probabilistic model that fits the selected individuals in each generation, followed by the simulation of this model to obtain the next generation of individuals. EDAs have been successfully applied to a wide range of real-world combinatorial optimization problems as well as in continuous domains and have also been utilized for providing the best model in various machine learning tasks.

In this chapter, the focus has been on EDAs where probabilistic (directed) graphical models like (Gaussian) Bayesian networks are learned from the selected individuals. Other probabilistic models that have supported EDA methodologies include (undirected) Markov networks [67].

EDAs can play a significant role in interpreting the process followed by the metaheuristic in reaching the optimal solution. In this regard, analyzing the evolution of (Gaussian) Bayesian network structures learned across generations, along with landscape analysis via search trajectory networks [68], can be highly beneficial.

Abstract

Scatter search is a population-based metaheuristic that has been shown to yield high-quality outcomes for hard combinatorial optimization problems. It uses strategies for combining solution vectors, making limited use of randomization, that have proved effective in a variety of problem settings. The fundamental concepts and principles were first proposed in the 1960s and 1970s as an extension of mathematical relaxation techniques for combinatorial optimization problems. Its framework is flexible, allowing the development of implementations with varying degrees of sophistication.

This chapter provides a grounding in the scatter search methodology that will allow readers to create successful applications of their own. To illustrate this, we present a scatter search implementation for a $\mathcal{NP}$-hard variant of the classic p-hub median problem, for which we describe search elements, mechanisms, and strategies to generate, combine, and improve solutions.

Keywords

Scatter search · Metaheuristic · Combinatorial optimization · Maximum diversity problem

Introduction

Scatter search (SS) was conceived as an extension of a heuristic in the area of mathematical relaxation, which was designed for the solution of integer programming problems: surrogate constraint relaxation. The following three operations come from the area of mathematical relaxation, and they are the core of most evolutionary optimization methods including SS and genetic algorithms (GAs):

- Building, maintaining, and working with a population of elements (coded as vectors)
- Creating new elements by combining existing elements
- Determining which elements are retained based on a measure of quality

Two of the best-known mathematical relaxation procedures are Lagrangean relaxation [9] and surrogate constraint relaxation [11]. While Lagrangean approaches absorb "difficult" constraints into the objective function by creating linear combinations of them, surrogate constraint relaxations generate new constraints to replace those considered problematic. The generation of surrogate constraints also involves the combination of existing constraints using a vector of weights. In both cases, these relaxation procedures search for the best combination in an iterative manner.

Scatter search is more intimately related to surrogate relaxation procedures, because not only surrogate relaxation includes the three operations outlined above but also has the goal of generating information from the application of these operations. In the case of surrogate relaxation, the goal is to generate information that cannot be extracted from the original constraints. Scatter search takes on the same approach, by generating information through the combination of two or more solutions. It strategically explores the solution space of an optimization problem by evolving a set of *reference* points. These points define a set, known as *Reference Set* (*RefSet*), which consists of good solutions obtained by prior solving efforts.

SS and GAs were both introduced in the 70s. While Holland [19] introduced genetic algorithms and the notion of imitating nature and the "survival of the fittest" paradigm, Glover [12] introduced scatter search as a heuristic for integer programming that expanded on the concept of surrogate constraints as mentioned above. Both methods fall in the category of evolutionary optimization procedures, since they build, maintain, and evolve a set (population) of solutions throughout the search. Although the population-based approach makes SS and GAs part of the so-called evolutionary methods, there are fundamental differences between the two methodologies. Typical differences between the scatter search methodology and other evolutionary methods rely on the use of randomization and the size of the population of solutions. Specifically, SS mainly implements deterministic strategies to generate, combine, and improve solutions, while other evolutionary methods, such as GAs, generally introduce random elements in their strategies. On the other hand, in SS, the *RefSet* tends to be small, usually around 10 solutions, while in GAs the population tends to be much larger, usually around 100.

The following principles can be seen as the foundations of the scatter search methodology:

- Useful information about the characteristics of optimal solutions is typically contained in a suitable diverse collection of elite solutions.
- This information is exploited by the combination of the elite solutions.
- The purpose of the combinations is to incorporate to the elite set both diversity (in terms of solutions' attributes) and quality (in terms of objective value).
- Search mechanisms and strategies are not limited to combinations but include solution generation and improvement combination methods.

The scatter search framework is flexible, allowing the development of alternative implementations with varying degrees of sophistication. It is based on the idea of limiting the scope of the search to a selective group of combination types, as a mechanism for controlling the number of possible combinations in a given reference set. A comprehensive examination of this methodology can be found in the book by Laguna and Martí [33]. In the following subsection we review the most relevant recent applications to illustrate the impact of this methodology.

Past and Present

As mentioned before, scatter search was first introduced in 1977 [12] as a heuristic for integer programming. However, it seems that it was never applied or studied again until 1990, when it was presented at the EPFL Seminar on Operations Research and Artificial Intelligence Search Methods (Lausanne, Switzerland). An article based on this presentation was published in 1994 [13], in which the range of applications was expanded to nonlinear (continuous) optimization problems, binary and permutation problems. The algorithmic principles and the structure of the method were finally proposed in the so-called scatter search template [14]. In a way, this template was a simplification of the previous descriptions and served as the main reference for most of the scatter search implementations up to date. There are two important milestones in the scatter search publications since then. In 2002, a book on this methodology was published by Kluwer [33], that included implementations in C to help the reader to create his/her own applications. In 2006, a special issue of the *European Journal of Operational Research* [43] was devoted to successful scatter search applications.

The scatter search methodology has become the method of choice for the design of solution procedures for many $\mathcal{NP}$-hard combinatorial optimization problems. Its use has been steadily increasing as shown in Figs. 1 and 2. Those figures show the number of yearly publications from 1994 to 2024 on scatter search. Figure 1 shows the number of cites or references for the query "scatter search" on Google Scholar (http://scholar.google.com), while Fig. 2 shows the counts for the same query on the Science Citation Index database of Thompson Reuter's Web of Science, which corresponds to the publications in this topic (http://thomsonreuters.com/thomson-reuters-web-of-science/). To restrict our search, we looked up on the Scopus website (http://www.scopus.com) the number of publications with the query "scatter search"

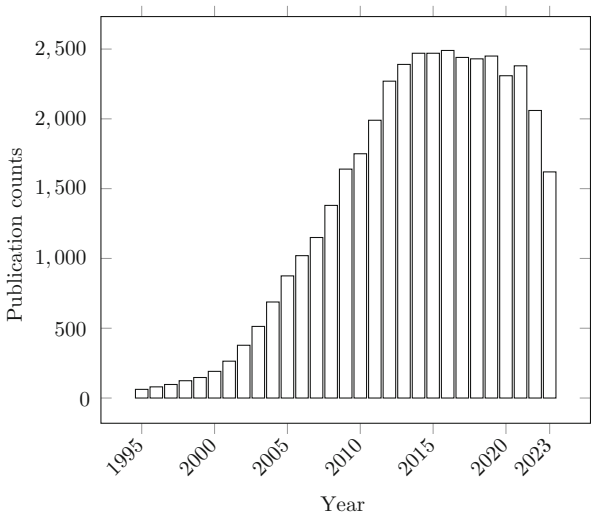

Fig. 1 Publication counts for the query "scatter search" on Google Scholar

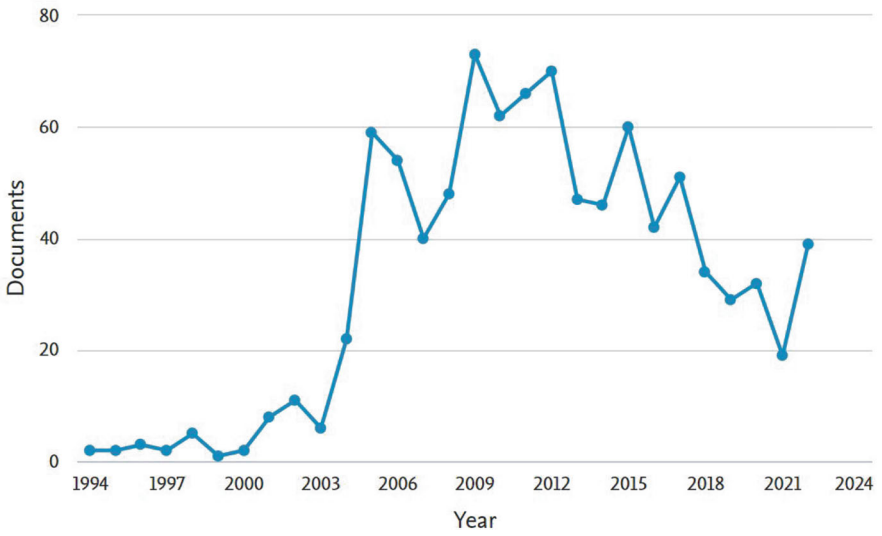

Fig. 2 "Scatter search" papers on the Web of Science

in the title and found that it was 383. We have shortlisted some of them (from 2012 to 2014) to have a restricted sample of journal papers with practical applications solved with scatter search. Table 1 summarizes the most relevant articles classified into six categories, according to the class of problem being solved. In particular, we consider classical problems such as TSP, VRP, and knapsack; scheduling and sequencing problems such as flowshop, jobshop, and project scheduling; manufacturing problems ranging from NoC mapping to coal and steel production; planning problems such as territory design and location problems; statistics and finance problems such as credit scoring and protein information prediction; and image registration problems such as image registration and segmentation, and craniofacial superimposition.

Although we can consider that the scatter search methodology is nowadays well established and that it has been used in many applications, if we compare SS with other metaheuristics, we can see that there is still significant room for improvement. In particular, a Scopus search with the query "genetic algorithm" returned almost 40,000 entries, while "tabu search" gave 2,273 hits. Consequently, one of this chapter's goal is to trigger the interest of researchers and practitioners to apply the scatter search methodology.

The Five Main Components

In scatter search, the search process is performed to capture information not contained separately in the original solutions. It takes advantage of auxiliary

heuristic methods for selecting the elements to be combined and generating new solutions. The combination strategy is devised with the belief that this information can be better exploited when integrated rather than treated in isolation. In general, the decision rules created from such combination strategies produce better empirical outcomes than the standard applications of local decision rules.

As mentioned, scatter search operates on a set of solutions, *RefSet*, combining them to create new ones. The method basically performs iterations over the *RefSet* and can be summarized in three steps: Select the solutions, combine them, and update the *RefSet* with the resulting solutions. As in many other metaheuristics, an improvement method, or local search, can also be applied to improve the generated solutions. Here, the outcome of the combination method can be sent to a local search procedure to obtain a local optima.

Although the scatter search origins are linked with the mathematical programming area, in which convex combinations are very popular, convex and non-convex combinations are used in this method to generate new solutions. The non-convex combinations project new "centers" into regions of the solution space that are external to the original *RefSet* solutions, a strategy that is based on the principle of input diversity in the search, to avoid getting trapped in local optima.

The scatter search template provides a concise and direct description about how to implement the methodology. Figure 3 shows the scheme of our selective scatter search in which the improvement method is only applied at the end of the search. The methodology basically consists of five elements or methods and their associated strategies and may be sketched as follows:

- A diversification generation method (DGM):
  The DGM can be seen as the mechanism that creates the initial set of solutions P of an optimization problem. This is what we would call "a first generation" in the evolutionary terminology. If the attributes of this first generation are good, there is some confidence of getting better solutions in the following iterations after strategically combining these initial solutions. The DGM typically implements frequency-based memory to generate P and employs controlled randomization. As opposite to the GAs that usually rely on randomization to generate the initial population, the DGM samples the solution space in a systematic fashion. The size of P, $|P|$, is denoted as $Psize$.
- An improvement method (IM):
  The IM transforms a given solution of the problem, s, into an enhanced solution s'. Usually, both solutions are expected to be feasible, but this is not a requirement of the methodology. The IM generally relies on local search (LS) procedures (also known as *iterative improvement* procedures). As it is well known, given s, the local search tries to improve it by making "small changes" in its structure. These changes typically consist of adding elements to s, removing elements from s, changing the way in which elements are grouped in s, or changing their order, to mention a few. If an improvement is achieved in this way, then a new solution s' is obtained. This process of *small changes* is continued until no further improvement can be obtained or a time bound is elapsed. If no improvement of s was found, s would be the output.
- A reference set update method (RSUM):
  This method builds *RefSet* for the first time using a reference set creation subroutine (RSCsr) and updates *RefSet* during the search process. In the RSCsr, a given solution from P enters *RefSet* according to its quality or diversity. Many

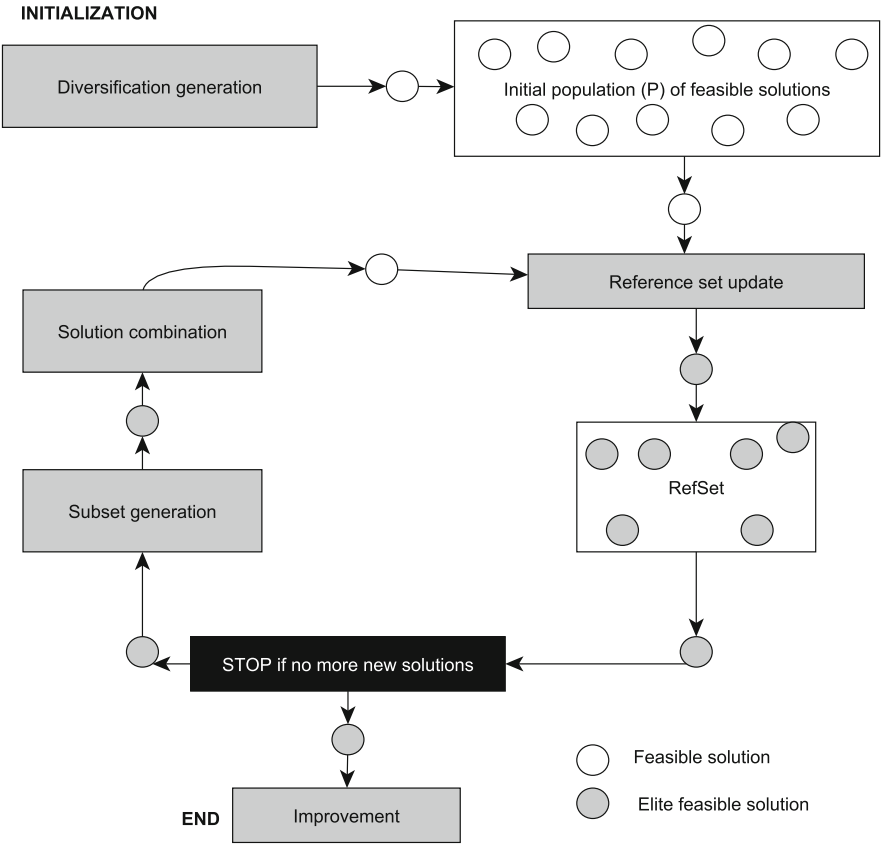

Fig. 3 Selective scatter search scheme

of the implementations of SS indicate that a good trade-off is to build 50% of *RefSet* by quality criterion, and the remaining 50% by a diversity criterion, but these proportions can be modified depending on the problem being solved.

A standard mechanism to build the initial *RefSet*, whose size will be denoted by b, follows. The construction starts with the selection of the best $b/2$ solutions from P. For each solution in $P \setminus RefSet$, the minimum of the distances to the solutions in *RefSet* is computed. Then, the solution that maximizes the minimal distances is selected. This solution is added to *RefSet* and deleted from P, and the minimal distances are updated. This process is repeated $b/2$ times. The resulting reference set has $b/2$ high-quality solutions and $b/2$ diverse solutions.

The update operation consists of maintaining a record of the b best solutions found, where the value of b is treated as a constant search parameter.

- A subset generation method (SGM):
  The SGM creates subsets of two or more solutions belonging to *RefSet*. These subsets will be subjected to the next SS process, the combination method. The general SS framework considers the generation of subsets with two, three, and four solutions but only generates a given subset if its solutions are being used to create this subset for the first time. This situation differs from those considered in the context of genetic algorithms, where the combinations are typically determined by the spin of a roulette wheel and are usually restricted to the combination of only two solutions.
- A solution combination method (SCM):
  The SCM creates new solutions from any subset of solutions previously created by the SGM. Although the process of creating new solutions that derive from other solutions can be achieved by a black-box procedure, it is generally more effective to design the SCM as a problem-specific mechanism, because it is directly related to the way we represent a solution in a problem. Depending on the specific form of the SCM, each subset can create one or more new solutions. This creation can be done in different ways, but the most common ones are systematic combinations of decision rules, path relinking, and randomization. We refer the reader to [15, 52] for some combination methods within SS.

In this second edition of the Handbook of Heuristics, we illustrate the SS methodology in this chapter by implementing its underlying framework to solve the Maximum Diversity Problem (MDP). Note that in the first edition [45], we implemented SS for the uncapacitated r-allocation p-hub median problem. Our results with these two problems show that the scatter search methodology is well suited for solving location problems. In line with our comment above, i.e., to encourage the reader to apply this methodology, here we can find a large family of problems in which the application of SS can result in a promising research area.

The Maximum Diversity Problem

The problem of maximizing diversity or dispersion deals with selecting a subset of elements from a given set in such a way that the distance among the selected elements is maximized. The definition of distance between elements is customized to specific applications, and the way that the overall diversity of the selected elements is computed results in different mathematical models. Maximizing diversity by means of combinatorial optimization models has gained prominence in Operations Research over the last two decades and constitutes nowadays an important area. In this handbook, there is a chapter specifically devoted to these problems in the Applications section. In this chapter, we consider the Maximum Diversity Problem (MDP) to illustrate the implementation of Scatter Search to solve an NP-hard optimization problem.

The MDP can be trivially formulated in mathematical terms as a quadratic binary problem, based on the pairwise distances d_{ij}, for elements i and j, where variable x_i takes the value 1 if element i is selected and 0 otherwise, $i = 1, \ldots, n$.

$$\begin{aligned} \text{Maximize} \quad & \sum_{i<j} d_{ij} x_i x_j \\ \text{subject to:} \quad & \sum_{i=1}^{n} x_i = m \\ & x_i \in \{0, 1\} \qquad i = 1, \ldots, n. \end{aligned} \tag{1}$$

Figure 4 shows a timeline diagram, which depicts the first contributions on diversity problems from an optimization perspective. In particular, it starts with the first publication on some discrete versions of dispersion problems in general graphs [31]. Kuby introduced the p-dispersion problem as locating p facilities on the nodes of a network, so that the minimum distance between any pair of facilities is maximized. The author proposed a linear integer formulation for this problem and applied it to a small example with 25 nodes. The author also extended the model to the MaxSum case, in which the objective is to maximize the sum of distances between all the pairs of selected facilities (nodes). These problems were later coined as the MaxMin Diversity Problem (MMDP) and MaxSum Diversity Problem (MDP), respectively.

Erkut and Neuman published in 1989 an invited review in the European Journal of Operational Research on location models for obnoxious facilities, where a function distance is maximized. Erkut also introduced a simple heuristic and a branch and bound exact method to solve small problems (with up to 40 elements) to optimality [8]. The construction is coupled with a local search method in the heuristic that scans the set of selected elements in search of the best exchange to replace a selected element with an unselected one. The method performs moves as long as the objective value increases, and stops when no improving exchange can be found. This local search has been applied to most of the algorithms proposed for both the MaxSum (MDP) and the MaxMin (MMDP). We will also apply it in our computational testing.

Kincaid proposed two heuristics for the MaxMin [28], also known as the discrete p-dispersion problem, based on exchanges: a simulated annealing (SA) heuristic

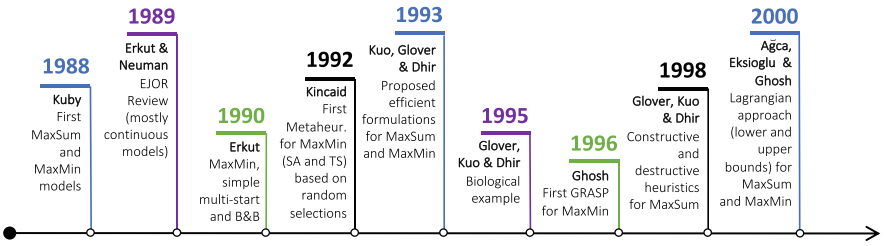

Fig. 4 Timeline of first diversity models and algorithms

and a tabu search (TS) heuristic. In a given iteration, these heuristics generate a random move (an exchange between a selected and an unselected element) and apply the standard acceptance rules of the methodology, the so-called temperature and cooling schedule in the SA, and the tabu status and aspiration criteria in tabu search. These methods were also adapted to the MaxSum problem and in the later years received a lot of attention, such as [10] and [32]. We refer the reader to the recent survey by Martí et al. [46] for a detailed description of the models and methods in diversity optimization.

Scatter Search for the MDP

As described in section "The Diversification Generator Method," and shown in Fig. 3, the SS method starts by generating a set P of diverse solutions. Then, b of them are selected to create the *RefSet*. In our implementation for the MDP, we follow the standard design of selecting the best $\frac{b}{2}$ solutions in P, and then the most diverse $\frac{b}{2}$ solutions with respect to the solutions already in *RefSet* (see section "Reference Set Initialization"). The main loop of the method consists of applying the combination method to all pairs of solutions in *RefSet* and updating this set with the new solutions obtained from these combinations. The method finishes when no new solutions are added to *RefSet*.

The Diversification Generator Method

A DGM for the MDP could consist of a random selection of m elements from all n elements in the problem, but we cannot expect such a random solution to have a good value. Although in the original design of some evolutionary methods the random generation of the initial population was a well-accepted strategy, Scatter Search generates solutions based on a principle that induces both quality and diversity in the original population. In the MDP, such principle should somehow reflect that we are searching for a subset of elements with a large sum of distances. In particular, we apply the GRASP metaheuristic to create the initial set of solutions.

Let $M \subseteq V$ be the set of selected elements. Initially, M is empty, and we add elements to M until it contains m elements (i.e., until $|M| = m$). For each element i, we define an evaluation function, $e(i)$, to measure its potential contribution to the partial solution under construction (i.e., the sum of its distances to the elements already in the solution).

$$e(i) = \sum_{j \in M} d_{ij}. \tag{2}$$

As described in the chapter on the GRASP methodology, at each iteration of the construction phase, GRASP maintains a candidate list of elements CL, which can

be added to the partial solution under construction, to obtain a complete solution. CL is simply computed in a given iteration as the list of elements not in the current partial solution. All candidate elements are evaluated to create a restricted candidate list RCL with the best elements in CL, i.e., those with the largest incremental contribution in a maximization problem such as the MDP.

Algorithm 1: Constructive randomized method

1: Let $G = (V, E)$ be a graph with distance matrix $D = (d_{ij})$
2: $i \leftarrow$ `SelectRandom`(V)
3: $M \leftarrow \{i\}$ and $f(M) = 0$
4: $CL = V \setminus M$
5: $e(j) = d_{ji}\ \forall j \in CL$
6: **while** $|M| < m$ **do**
7: $\quad e_{max} \leftarrow \max_{j \in \text{CL}} e(j)$
8: $\quad e_{min} \leftarrow \min_{j \in \text{CL}} e(j)$
9: $\quad RCL \leftarrow \{j \in CL \mid cont(j) \geq e_{max} - \alpha \cdot (e_{max} - e_{min})\}$
10: $\quad i \leftarrow$ `SelectRandom`(RCL)
11: $\quad M \leftarrow M \cup \{i\}$ and $f(M) = f(M) + e(i)$
12: $\quad$ CL $\leftarrow$ CL $\setminus \{i\}$
13: $\quad e(j) = e(j) + d_{ij}\ \forall j \in CL$
14: **end while**
15: **return** M, $f(M)$

Algorithm 1 shows a pseudo-code of the GRASP construction. The partial solution set M is initialized with a random element in step 3, and the candidate set of elements, CL, which contains all nonselected elements ($CL = V \setminus M$) is created in step 4. The initialization of the method finishes in step 5, in which the contribution of all the candidate elements is established as the sum of the distances to the element in M. The *While* loop in Algorithm 1 takes place from steps 6 to 15, reflecting the successive applications of this part of the code. In each one, the RCL is created, an element $i \in RCL$ is randomly selected, and the different elements of the algorithm are updated. We refer the reader to ▸ Chap. 23, "GRASP," for a detailed description on how this method works.

Reference Set Initialization

As mentioned above, to create the reference set, RefSet, the notion of best solutions is not limited to their quality, as measured by the objective function, since it also considers their diversity. In particular, our method first chooses $b/2$ solutions attending to their quality. We simply order the solutions in P according to their objective function value, and introduce them, one by one, in RefSet avoiding to repeat any solution. The rest of the solutions of the RefSet are then selected from P by a diversity criterion as follows.

The definition of distance between solutions is a key design issue in scatter search implementations. Distance is used to measure how diverse one solution is with respect to a set of solutions. Specifically, for the MDP, the distance between a trial solution x in P and the solutions in the RefSet is computed as the sum of the minimum distances from each element in x and the set formed with all the elements in the RefSet solutions. Note that if the element in x is in one or more solutions in the RefSet, then its corresponding minimum distance is 0. The trial element in P with the largest sum of minimum distances is selected for inclusion in the RefSet. Since the solutions are added one at a time, the distance calculations have to be updated before the next solution is selected.

The Subset Generation Method

The SGM that we propose for the MDP works by generating subsets defined by any two different solutions in *RefSet*. To avoid the repetition of solutions generated in previous iterations, each subset is generated only if at least one of its solutions was introduced in *RefSet* in the preceding iteration. Suppose that m subsets were not considered for this reason, then the number of resulting subsets at each iteration for which the combination method will be applied is $\frac{b^2-b}{2} - m$.

The Solution Combination Method

The combination method applies a restricted version of the constructive method based on a semi-greedy algorithm described in the Diversification Generation Method. In particular, given two solutions x and y, the combination method considers the set of elements formed with the union of the elements in x and y. We apply the constructive method to this set of candidate elements called $C(x, y)$. In other words, the candidate list CL with the elements that can be included in the solution M that we are creating as a combination of x and y is $CL = C(x, y)$, and therefore only the elements in CL can be selected to be included in M. The solution combination method applies the same steps of the constructive method, and it creates in each iteration the restricted candidate list, RCL, from which an element is randomly selected. The combination method stops when m elements have been selected from CL. Note that since the method makes random selections, it can be applied several times to the same pair of solutions and may result in different combined solutions (offspring in the evolutionary terminology).

The Reference Set Update Method

The *RefSet* update operation consists of maintaining a record of the b best solutions found so far by the procedure. The issues related to this updating function are straightforward: All the solutions in *RefSet* that are worse than those in the current

Pool will be replaced by these ones, with the aim of keeping in *RefSet* the b best and most different solutions found so far. Let $s \in Pool$ and $w \in RefSet$ such that the objective function value of s is less than that of w. In this case, s will replace w if s is different from all other solutions in *RefSet*. Note that the update method focuses on quality. In other words, although *RefSet* was created considering both quality and diversity, when updating it, we only consider the objective function value of the candidate solutions obtained from the combination method. In particular, once all the combinations have been performed and the new solutions have been moved to $Pool$, the new *RefSet* simply contains the best b solutions in the set formed with the previous $RefSet \cup Pool$. This strategy, based on quality, favors the convergence of the method.

The Improvement Method

Ghosh implemented in 1996 a simple local search method LS [10] in the context of GRASP. It scans the set of selected elements in search of the best exchange to replace a selected element with an unselected one. The method performs moves as long as the objective value increases, and it stops when no improving exchange can be found. Duarte and Martí [6] proposed in 2007 an improved variant of this classic local search. In particular, this variant selects the element $i*$ that provides the smallest contribution to the objective function value of the current solution. Then, it searches for an element j to be exchanged with element i*. The first element j that results in an improving move is selected, and the exchange is performed without examining the remaining unselected elements. If no improving move can be found to exchange element i*, then the selected element with the next smallest contribution is examined. This process continues until no improving exchange can be found. We implement this local search as the improvement method in scatter search.

Computational Experiments

This section describes the computational experiments performed first to find the parameter values of the scatter search method and then to study its performance. The procedure has been implemented in C using GCC 4.8.2, and the results reported in this section have been obtained with an Intel core i7–3770 at 3.40 GHz and 16 GB of RAM.

We have tested our algorithms on the three sets of instances previously reported. The benchmark instances for the MDP come from different sources that have been added over the years. The most used library is the MDPLIB available at www.uv.es/rmarti/paper/mdp.html with a mirror server in www.optsicom.es/mdp. It compiles a comprehensive set of benchmark instances representative of the collections used for computational experiments in the MDP. The library contains three sets of instances collected from different papers and named after their authors: GKD (Glover, Kuo,

and Dhir), MDG (Martí, Duarte, and Gallego), and SOM (Silva, Ochi, and Martins). We use these three sets in our experimentation.

The experiments are divided into three main blocks. The first block, described in section "Search Methods," is devoted to study the performance of the search methods, namely construction, improvement, and combination methods in scatter search. In the second subsection, Search profiles, we study the evolution of the best solution found in an attempt to disclose the contribution of the different steps of the algorithm to the final solution. Finally, in the third subsection, we determine the best values for the key search parameters. The paper finishes with a four subsection with a final comparison of the best SS variant and the reference GRASP algorithm. We employ two metrics to measure the performance of the algorithms tested. Dev is the average percentage deviation with respect to the best solution known (as reported in the MDPLIB), and CPU is the average computing time in seconds. We add into the final comparison a third metric reporting the number of best-known solutions that each method is able to match.

Search Methods

In our first experiment, we undertake to evaluate the contribution of the local search in the GRASP algorithm that we implement as the diversification generation method. Table 2 shows the Dev and CPU of the best solution obtained with the Constructive Method (CONST.) and the complete GRASP, in which the constructive is coupled with a local search. To do so, we generate 100 solutions with each method and report the value of the best solution across the 100. Additionally, this table also reports the best solution obtained with a pure random construction in which the m elements in the solution are randomly selected with a uniform distribution (RANDOM). This random method is repeated 100 times, as the other two in the comparison, and the best solution is returned as the output of the method.

As expected, results in Table 2 clearly show the important contribution of the local search method. In particular, it is able to reduce the deviation with respect to the best-known solution from 9.04 on average for the constructive method, to 0.04 when it is coupled with the local search. Note however that this reduction comes with a price in the computational time that increases from 2.36 for the construction

Table 2 Diversification generator method

	Dev. (%)			CPU		
Method	CONST.	GRASP	RANDOM	CONST.	GRASP	RANDOM
GKD	7.5	0.0	15.8	2.31	35.15	0.09
SOM	8.0	0.2	14.7	2.35	72.68	0.15
MDG	11.6	0.9	17.8	2.41	34.56	0.08
Average	9.04	0.4	16.1	2.36	47.47	0.11

to 47.47 s for the complete GRASP. This table also shows that the performance of the entirely random construction is poor, with a deviation of 16.1%.

We applied the nonparametric Friedman test for multiple correlated samples to the best solutions obtained by each of the three methods. This test computes, for each instance, the rank value of each method according to solution quality, and then it calculates the average rank values of each method across all the instances solved. If the averages differ greatly, the associated p-value or significance will be small. The resulting p-value of $2.2e-16$ obtained in this experiment clearly indicates that there are statistically significant differences among the three methods tested. We also compared GRASP and CONST. with the Wilcoxon nonparametric test for pairwise comparison. This test answers the question: Do the two samples (solutions obtained with the two methods in our case) represent two different populations? The resulting p-value of $5.7e-11$ indicates that the values are significantly different and confirms the superiority of GRASP as a diversification generation method.

This first experiment also permits us to identify the most challenging instances in the MDPLIB. We therefore do not include in our testbed those instances that can be considered easy to solve. Note that if the GRASP method that we used to populate the Reference Set is able to match the best-known solution in a given instance, then that instance could not help us to evaluate the contribution of the other elements in our scatter search algorithm. We therefore limit our testbed to 20 instances in the GKD-c set with $n = 500$ elements, 20 instances in the SOM-b set with n ranging from 100 to 500, and 20 instances in the MDG-a set with $n = 500$.

In our second experiment, we study the variability of the solutions generated with the constructive method and the complete GRASP applied in the first experiment. Table 3 shows the values of the best and the worst solutions across the 100 generated with each method. Specifically, the constructive method generates solutions that on average have a value ranging from 14,159.49 to 14,935.47, while the GRASP solutions range from 15,793.87 to 15,995.89, while the best-known value is on average in 16,028.32. This experiment not only confirms the important contribution of the local search, but also shows that there is room for improvement in the instances selected.

Figure 5 complements the information in Table 3 by showing a boxplot of the values obtained with each method on each instance. The distribution of the values in the figure clearly shows that GRASP is able to outperform the constructive method, since its box is in a higher position, and the random construction ranks the last one.

Table 3 Best and worst values of constructive method and GRASP

		CONST.		GRASP	
Method	Best known	Best	Worse	Best	Worse
GKD	19,502.55	18,042.80	16,985.07	19,502.55	19,489.46
SOM	20,811.30	19,896.95	19,078.45	20,781.25	20,459.05

Average	16,028.32	14,935.47	14,159.49	15,995.89	15,793.87

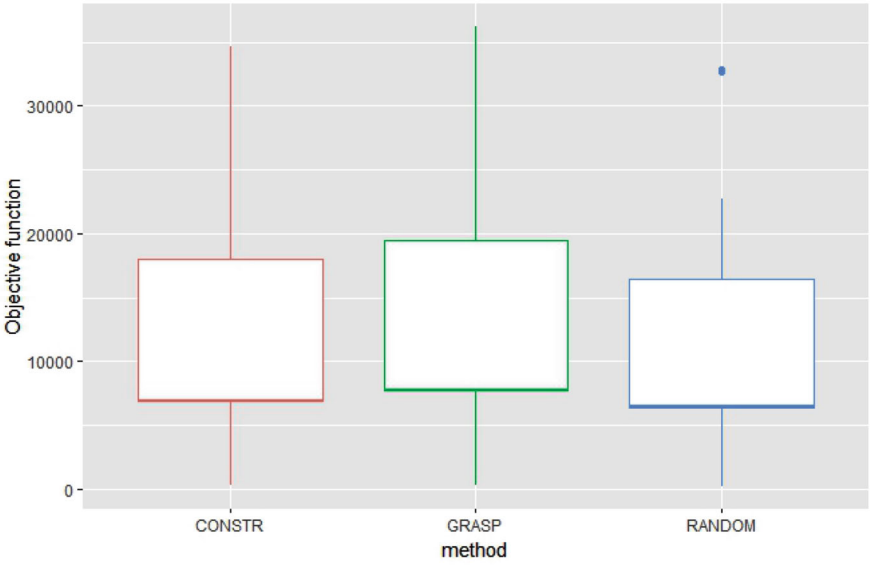

Fig. 5 Boxplot of solutions' values

The median value of GRASP is 9544, while the median values of CONST. and RANDOM are 8932 and 8248, respectively.

Figure 5 shows the superiority of GRASP with respect to the constructive method. However, in spite of removing from the figure two outlayers with values close to 100,000, the large magnitude of the units makes it difficult to estimate the relative improvement of GRASP over the constructive. Figure 6 represents this improvement for each type of instance. It shows that in the GKD and MDG instances the improvement is consistent, with values around 1,500 and 900, respectively, while in the SOM instances we can observe a large variability probably due to the variability in the data.

To evaluate the contribution of the combination method, our third experiment reports the solution of the entire Scatter Search, which includes the generation of initial solutions with GRASP and also the combination of the selected solutions in the RefSet. In this experiment, we report the best combined solution in the RefSet as the output of the method, and we do not consider its inclusion in the RefSet to perform further iterations. Table 4 clearly shows that when the entire SS method is applied, the deviation of the best solution with respect to the best known is very small. In particular, in the 20 instances of the GKD set, it is 0.00%, in the SOM 0.13%, and in the MDG 0.31%, with an overall average deviation of 0.15%, which compares favorably with the 0.4% obtained with GRASP, shown in Table 2. We can therefore conclude that the combination method applied to the elite solutions in the RefSet is able to improve the quality of the solutions in the initial population (those obtained with GRASP) in 0.25% (Table 4).

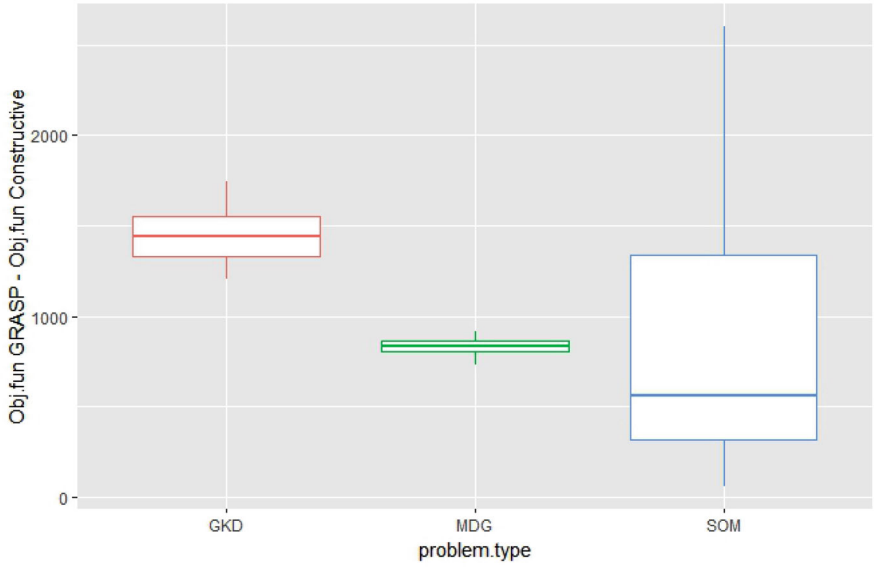

Fig. 6 Improvement of GRASP w.r.t. constructive

Table 4 Scatter search (one iteration)

	DEV. %	CPU
GKD	0.00	4.04
SOM	0.13	36.27
MDG	0.31	29.53
Average	0.15	23.28

Search Profiles

In this subsection, we apply the SS algorithm several iterations, which implies that we update the reference set with the solutions that result from the combination of the RefSet solutions in the previous iteration. Note that the update takes place when the combined solution qualifies to enter in the RefSet (i.e., if its value improves upon the worst value in the RefSet). In this way, we call a step to a complete iteration, and SS performs steps as long as the combined solutions qualify to enter in the RefSet. We consider four challenging instances in this experiment and report the best value obtained with SS in each step. We represent in a diagram the initial value obtained with the best value in the initial population (GRASP) and the best value in each step of the SS algorithm to visualize the search profile of the best value so far. The following four figures show respectively the search profile of the SOM-n400, SOM-n500, MDG-a2-n500, and MDG-a17-n500. Figure 11 shows the profile of the four instances in the same diagram for an easy comparison.

The figures with the individual search profiles (Figs. 7, 8, 9, and 10), together with the combined profiles in Fig. 11, show that in these four difficult instances,

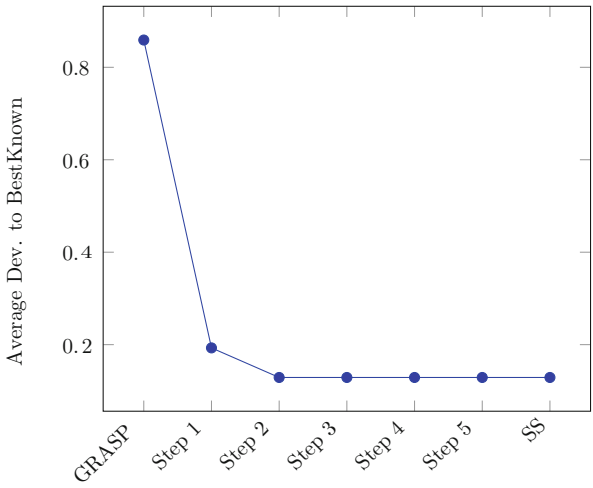

Fig. 7 Search profile of an SOM instance (n = 400, m = 40)

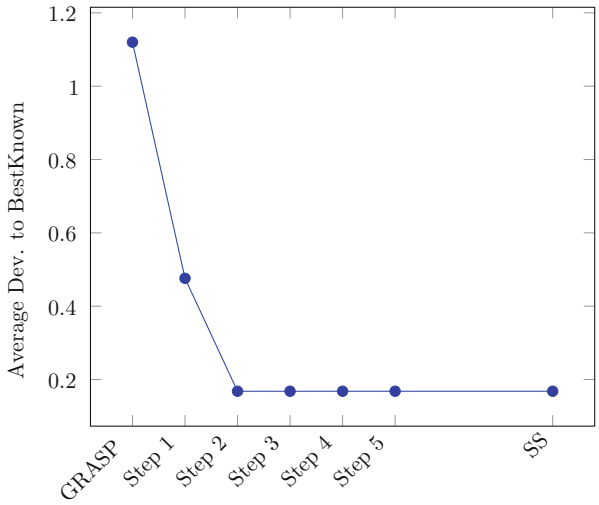

Fig. 8 Search profile of an SOM instance (n = 500, m = 50)

performing consecutive steps of the SS algorithm is able to marginally improve the best solution obtained in the first step of the method. As a matter of fact, after five steps, SS is able to match the best solution known for some instances (with a 0.0% deviation), while in other instances it exhibits a very small deviation value of 0.1%. In all the cases, after five complete iterations (steps), the method is not able to further improve the solutions, so this experiment also indicates the search horizon and termination criteria in terms of solution quality.

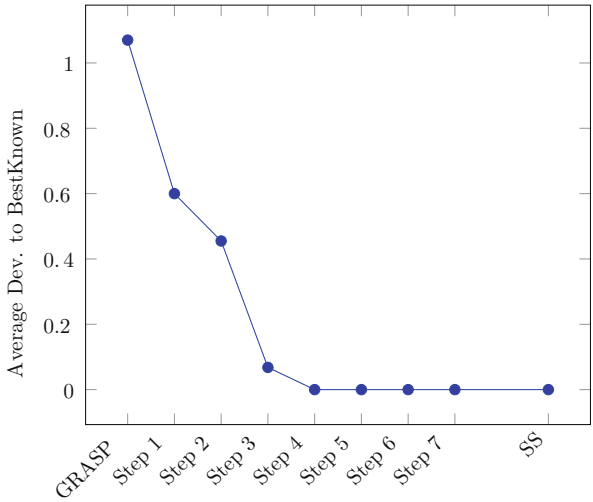

Fig. 9 Search profile of the MDG-a2 instance (n = 500, m = 50)

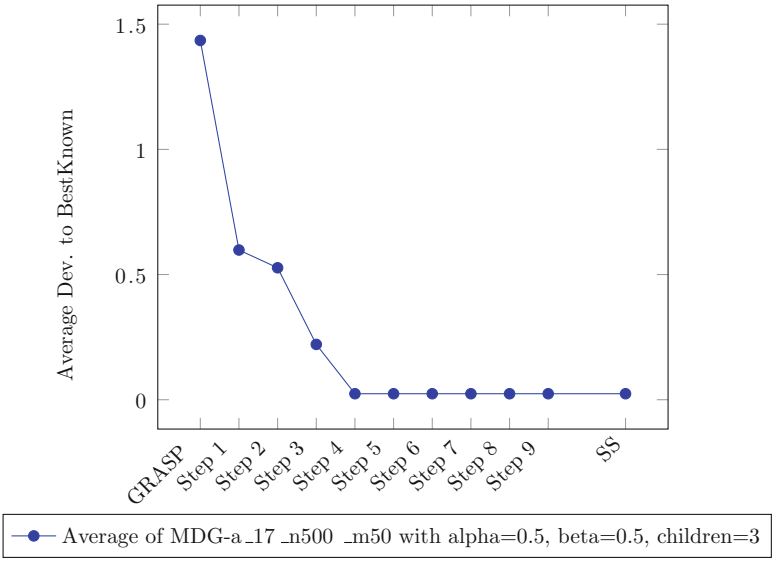

Fig. 10 Search profile of the MDG-a17 instance (n = 500, m = 50)

Search Parameters

In this subsection, we examine the impact of some parameters in the performance of the SS algorithm. In our first experiment here, we consider the so-called α value in GRASP, which determines the balance between randomization and greediness in the semi-greedy construction. Table 5 shows the results obtained with three different

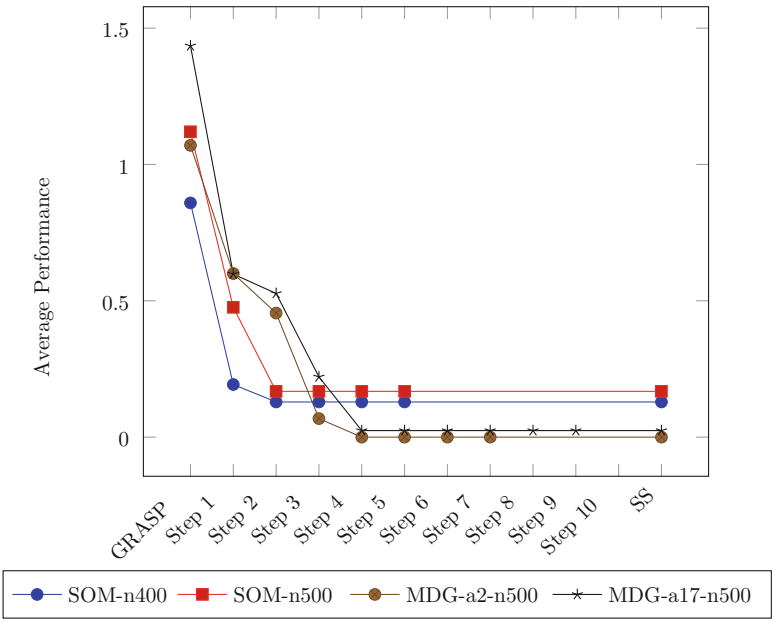

Fig. 11 Search profiles

Table 5 Construction parameter

	Dev. (%)			CPU		
α	0.3	0.5	0.7	0.3	0.5	0.7
GKD	0.00	0.00	0.00	5.28	5.41	5.25
SOM	0.07	0.07	0.04	69.46	63.00	73.67
MDG	0.09	0.08	0.13	66.00	61.65	63.60
Average	0.05	0.05	0.05	46.92	43.36	47.51

values of this parameter: 0.3, 0.5, and 0.7. This table shows that this parameter has no influence in the final solution's quality.

As explained in the algorithm's description, our combination method adapts the GRASP construction to the subset of elements in the union of the two solutions under combination. Then, it is also based on a search parameter to balance the RCL composition, as the α does in the constructive method. We call it β, and Table 6 reports the results of the SS algorithm with three values of this parameter: 0.3, 0.5, and 0.7. Results in this table show that $\beta = 0.7$ provides the best results.

We now consider the number of solutions obtained with the combination of two solutions in the reference set. As described above, the random component of the combination method permits to apply it repeatedly to the same pairs of solutions, thus obtaining more than one combined solution. We call Combined to this parameter. Table 7 shows the results of three values for this parameter: 1, 2, and 3. This table shows that the best results are obtained with Combined = 3.

Table 6 Combination parameter

	Dev. (%)			CPU		
β	0.3	0.5	0.7	0.3	0.5	0.7
GKD	0.00	0.00	0.00	3.78	5.41	5.84
SOM	0.03	0.07	0.02	50.37	63.00	85.49
MDG	0.08	0.08	0.07	40.60	61.65	76.67
Average	0.04	0.05	0.03	31.59	43.36	56.01

Table 7 Number of combined solutions

	Dev. (%)			CPU		
Combined	1	2	3	1	2	3
GKD	0.00	0.00	0.00	2.50	5.41	7.21
SOM	0.03	0.07	0.02	28.67	63.00	81.35
MDG	0.12	0.08	0.04	28.68	61.65	82.75
Average	0.05	0.05	0.02	19.96	43.36	57.11

Table 8 Parameters exploration

Variant	α	β	Combined
C1	0.5	0.5	2
C2	0.3	0.5	2
C3	0.7	0.5	2
C4	0.5	0.5	3
C5	0.5	0.5	1
C6	0.5	0.7	2
C7	0.5	0.3	2

We now complement the sequential design on the three parameters α, β, and *combined* shown above, in which we studied the value of one parameter, while the other two were kept fixed, with a more complete design. We consider seven variants of the scatter search algorithm according to the values shown in Table 8.

Figure 12 shows the boxplot obtained with the deviation of the solution values of each variant with respect to the best-known solutions. According to the boxplot represented in this figure, it seems that combination C4 with $\alpha = 0.5$, $\beta = 0.5$, and Combined = 3 is the one with the best performance. However, a Friedman test applied to the values depicted in this table resulted in a p-value of 0.509, so we cannot affirm that this variant is in general statistically better than the others, and just limit our conclusions to this set of data tested.

Final Comparison

Once we have established the contribution of each element and the best values of each search parameter in the SS algorithm, we present a final comparison with the previous GRASP method, considered a reference in the MDP. We run SS with $\alpha = 0.5$, $\beta = 0.5$, Combined = 3. We cannot present here the results of all previous heuristics for this problem because there are many, but instead, we consider the

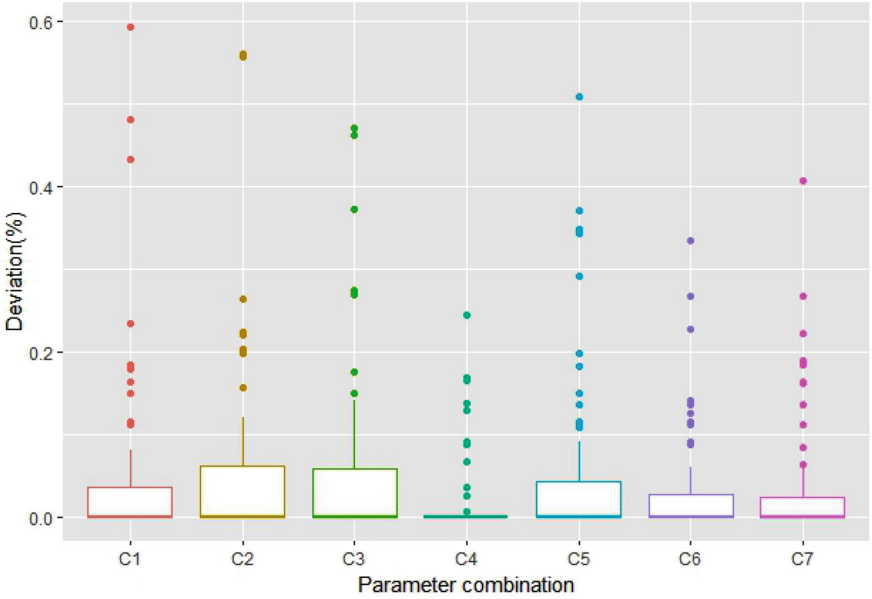

Fig. 12 Deviation of each SS variant w.r.t. best-known solutions

Table 9 Comparison between SS and GRASP

		DEV. (%)	CPU	NumBest			
Inst.	# Inst.	SS	GRASP	SS	GRASP	SS	GRASP

SOM	20	0.02	0.26	81.35	61.26	17	6
MDG	20	0.04	0.83	82.75	29.16	13	0
Summary	59	0.02	0.37	58.35	40.95	49	25

best-known values obtained with the most efficient, reported in the MDPLIB, which represent the state of the art in this problem. Table 9 reports the Average deviation (DEV.), computer time in seconds (CPU), and the number of best-known solutions (NumBest) that each method is able to find. These results clearly show the quality of the SS solutions in terms of both the previous GRASP and the reference best values.

To conclude our experimentation, we perform a nonparametric statistical test to compare the results of the two methods. The resulting p-value in the Friedman test of 5.5e-09 clearly indicates that there are significant differences between the methods. We represent in Fig. 13 a boxplot of the differences between the solutions' values of both methods divided by type of instance. The boxplot confirms the superiority of SS over GRASP. Additionally, it permits to identify that the GKD instances are solved by the two methods, while on the contrary in the MDG the differences are larger and can be considered more difficult to solve. Future studies should focus on these challenging instances.

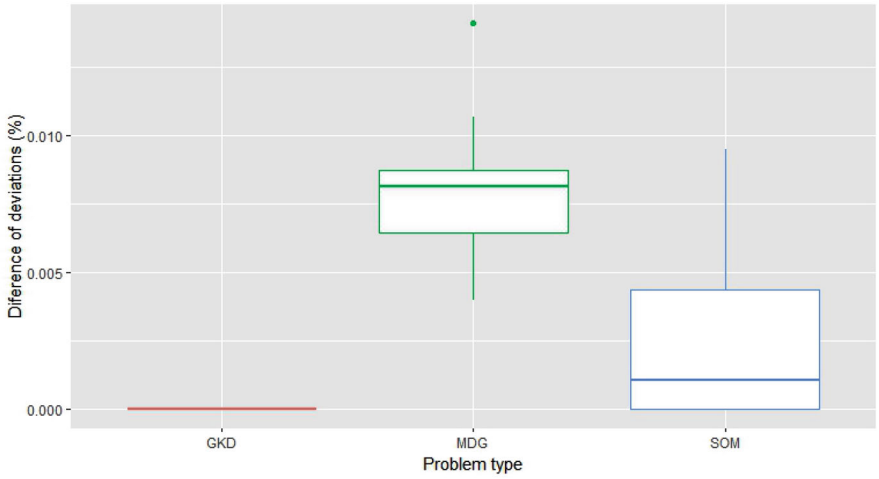

Fig. 13 Differences between SS and GRASP solution values by type of instance

Conclusions

In this chapter, we summarize our experiences on the subject of implementing scatter search. We have experimented with this methodology for a number of years, and as a result of implementing different search strategies, and performing extensive experimental testing, we have learned some valuable lessons condensed above. As it is well known, metaheuristic methodologies are based on principles and not necessarily on theory that can be spelled out with theorems and proofs. Hence, to illustrate and prove the efficiency of search mechanisms, strategies, and key elements in scatter search, we have shown how to solve an important and difficult combinatorial optimization problem: the maximum diversity problem. In particular, we describe in detail how to construct, improve, and combine solutions for this $\mathcal{NP}$-hard problem in an efficient way, i.e., with fast methods that are able to produce high-quality solutions. These research opportunities carry with them an emphasis on producing systematic and strategically designed rules, rather than following the policy of relegating decisions to random choices, as often is fashionable in evolutionary methods.

Abstract

This chapter presents the fundamental concepts of genetic algorithms (GAs) that have become an essential tool for solving optimization problems in a wide variety of fields. The first part of this chapter is devoted to the revision of the basic components for the design of GAs. We illustrate this construction process through its application for solving three widely known optimization problems such as knapsack problem, traveling salesperson problem, and real-parameter optimization. The second part of the chapter focuses on the study of diversification techniques that represent a fundamental issue in order to achieve an effective search in GAs. In fact, analyzing its diversity has led to the presentation of numerous GA models in the literature. Similarly, the hybridization with other metaheuristics and optimization methods has become a very fruitful research area. The third part of the chapter is dedicated to the study of these hybrid methods. In closing, in the fourth part, we outline the wide spectrum of application areas that shows the level of maturity and the wide research community of the GA field.

Genetic algorithms components · Evolutionary computation · Population diversity · Hybrid genetic algorithms · Genetic algorithms applications

Introduction

Genetic algorithms, or GAs, are nowadays an important field in artificial intelligence and operations research, with more than 3,500 publications per year in the last 15 years. Contrary to their most common type of application, GAs were not initially presented in the 1970s for problem-solving, but as an instrument for simulating the biological evolution of adaptive natural systems [69]. Nevertheless, it was precisely that simulated adaptive ability what promoted, in the subsequent years, the opportunity for tackling optimization problems successfully [27, 28, 50]. In this chapter, we focus on their utility for problem-solving, so GAs can operationally be described as iterative algorithms that sample candidate solutions for a given problem, with the aim of reaching the best configurations.

GAs take their inspiration from the biological evolution of species. Thus, the following ideas belong to their core foundations:

- Species evolve in populations of individuals that compete for survival within an environment.
- New individuals appear because of the recombination of previous individuals.
- Darwin's theory of *natural selection* establishes that the fittest individuals, those better adapted to the environment, get higher chances of surviving and breeding.

Thus, less fitted individual may probably perish at some point of the evolution process.
- Individuals' adaptation to the environment strongly depends on their phenotypic characteristics, which, in turn, are principally determined by their genotype.
- Individuals might eventually suffer mutations at their genotype level, which may affect the phenotype and adequacy to the environment.

Using these ideas, the following principles govern most of GAs for optimization:

- The environment is defined by the problem to be addressed.
- Individuals, also known as *chromosomes*, represent candidate solutions for the problem.
- Their *genotypes* encode the candidate solutions for the problem. The genotype-phenotype translation establishes how the chromosomes should be interpreted to get the actual candidate solutions.
- The *fitness* of individuals depends on their adequacy on the given problem, so fitter individuals are more likely to survive and breed.
- There is an evolving *population of individuals*, into which new individuals may enter and others may perish.
- New individuals are generated as the consequence of the *recombination* and/or the *mutation* of previous ones.

It should be pointed out that similar approaches were being developed since the 1960s, and thus, there are nowadays several optimization methods sharing a reasonable resemblance. All these approaches have been gathered up under the term *evolutionary algorithms* [33, 42], pointing out the fact that these strategies work with candidate solutions which evolve toward better configurations. However, a distinguishing feature of GAs at the time was the concept of recombination implemented as a crossover operator. This, in contrast with the neighborhood exploration of just one solution, carried out by the existing heuristics and by the operators of other algorithms, introduced the idea of combining the information from two candidate solutions to generate a new one. Years afterward, the idea of recombining two or more solutions was adopted by most representatives of evolutionary computation and also by many bioinspired methods [104].

The main aim of this chapter is to introduce the general and practical guidelines for designing GAs for given problems. Thus, we will gather up classical ideas from their origins and the latest tendencies without going into the specific and theoretical details. The interested reader is referred to Katoch et al. [77] for a survey of the works developed in this regard.

The chapter is organized as follows. The section "GA Construction" offers several hints to newcomers for the design and implementation of a GA. Three different and widely known classes of optimization problems are used for reviewing the basic GA components, and several classic alternatives are provided for each of them. The section "Diversification Techniques for GAs" analyzes the premature convergence problem of GAs produced by the lack of diversity and presents

different methods and operators that attempt to favor the diversity of the population in GAs. The section "Hybrid GAs" is devoted to another research area with an important number of algorithms reported in the last years and that is intended to exploit the complementary character of different optimization strategies. Finally, the section "GA Applications" outlines the application areas of GAs and the major challenges faced by GAs to deal with optimization problems in these areas.

GA Construction

In this section, we revise the basic ingredients for designing a GA. We comment some of the original and widely used strategies for each of these components without getting into a deep discussion whether they perform better or worse than other approaches.

Given an optimization problem with a set of decision variables arranged in a vector $\mathbf{x}$ and $f : X \rightarrow \Re$ a function that maps any configuration of the decision variables to a quality value, the aim is to find the combination of values for the decision variables that maximizes, or minimizes, function f. This function is usually known as the objective function. For the rest of this chapter, we will focus on maximizing the function f, noting that the required modifications for minimization problems are generally straightforward. In some cases, there are additional restrictions that solutions must satisfy, which are modeled by a set of inequality and equality constraints, $g_j(\mathbf{x}) \leq 0$ and $h_j(\mathbf{x}) = 0$ with $j = 1, \ldots, M$, respectively. We will use the following widely known optimization problems throughout the chapter to illustrate the application of GAs to problems with very different characteristics:

Knapsack Problem
In the classic knapsack problem [25] we are given a set of N objects with profits $p_i \geq 0$ and weights $w_i \geq 0$ and a container, the knapsack, with a maximum capacity C. The goal is to decide which objects should be included in the knapsack in such a way that the sum of the profits of the selected objects is maximized and the capacity C is not exceeded by the sum of their respective weights. Note that the decision variables of this problem should indicate which objects are included into the knapsack and which are not. Likewise, given a valid candidate solution that satisfies the capacity constraint ($g(\mathbf{x}) = -C + \sum_{i \in Knapsack} w_i$), the objective function f is the sum of the profits p_i of those objects in the knapsack.

Traveling Salesperson Problem
This problem [57] consists in the design of travel plans visiting a given set of cities or locations so that the traveled distance is minimized. The information given is the set of cities, all of them have to be visited, and the distances between each pair of cities. In this case, decision variables should represent the order in which the cities are visited, and the objective function is the sum of the distance between consecutive cities and the journey back to the first city from the last one.

Real-Parameter Optimization
Here, we are given an objective function whose decision variables take values from the continuous space $\Re$. In the context of optimization with metaheuristics, this objective function is treated as a *black box*, so analytical methods cannot be applied. This is often the case when the evaluation of candidate solutions involves the execution of an external simulation procedure, such as wind tunnels or driving simulators, whose internal processes are obscure or they are not subject of analysis. The distinguishing feature of these problems, with regard to combinatorial problem, is that decision variables take real values instead of binary or integer ones.

Whichever is the problem, the design of a GA goes throughout the following steps and not necessarily in this order:

Representation

The practitioner needs to specify how the decision variables of the problem are represented in the computer program to allow the GA to generate the different possible configurations. In particular, the GA community stresses the difference between the solution representation, *genotype*, from arrays of binary, integer (or elements from an alphabet), or floating-point variables to complex structures such as trees, graphs, or objects of specifically designed classes and the solution which is actually represented, *phenotype*. Consider the previous optimization problems:

Knapsack Problem: Representation
The classic representation for this problem is the *binary coding*, which is actually the traditional representation in GAs regardless of the problem. Solutions are represented by an array of N binary variables, as much as objects in the problem, where the value 1 at the i-th position indicates that the i-th object should be included into the knapsack, and 0 means the opposite. Therefore, the following example indicates that we should select the first, third, fourth, and seventh objects and discard the others:

$$[\,1\,0\,1\,1\,0\,0\,1\,]$$

Here, the array of binary variables is the genotype, and the interpretation of that genotype, the actual configuration of the knapsack, is the phenotype. However, note that we could have adopted a different representation such as a variable-length array or set with the integer indexes of the included objects ([1 3 4 7] in the case above). We assume from now on that binary coding is adopted for this problem.

Traveling Salesperson Problem: Representation
Given that the important information here is the order in which cities are visited, a natural way to represent solutions is by means of *permutations* [86], such as the following one:

[3 4 5 7 2 6 1]

These permutations are the genotype from which different interpretations could be developed, the phenotype. The most commonly used is the one that establishes traveling relations between consecutive values, i.e., in the example above the agent travels from the third city to the fourth one, from the fourth to the fifth, and so on; finally, the agent returns to the third city from the first one (the last value in the solution). As previously, other coding schemes could be adopted, such as the binary encoding of each of the integers in the example ([011 100 101 111 010 110 001]). Particularly, an indirect technique with relative success in the field is the *random key encoding* [55]. This represents a permutation as the sorting order of an array of numbers. Therefore, the array [3.0 4.1 0.2 0.3 −0.2 7 1] would be first translated into the permutation [5 3 4 7 1 2 6], from which the appropriate interpretation should be extracted. For the rest of the chapter, we adopt the former representation, which indicates the order by which cities are visited.

Real-Parameter Optimization: Representation
Initially, real (and integer) optimization problems were addressed with the binary coding scheme, considering either a natural or a gray transformation [17, 50, 69]. This latter intends to minimize the number of hamming differences between close final interpretations. However, real encoding is much widely used lately for real-parameter optimization problems, which avoids the differentiation between genotype and phenotype [66, 73, 101]:

[0.5 0.0001 0.2342 1.0 100.0 0.7 − 7.2]

Initial Population: Generating Candidate Solution from Scratch

At the beginning of the search process, GAs conform an initial population of candidate solutions. Usually, there is not much information to be exploited to generate these candidate solutions, and the following alternatives are commonly applied:

- *Random solutions*: When there is no other information apart from the considered representation (binary, integer, permutations, real, trees. . .), one of the easiest and most widely used methodologies is to generate the initial population at random. Thus, the task of generating the initial population becomes the one of producing arrays of random binary, integer or floating-point numbers, trees, graphs, or a mixture of them.
- *Diverse solutions*: As we will see later, the practitioner is often concerned with the presence of diverse solutions in the population. For the case of the initial population, many works recommend random procedures that incorporate some bias for generating diverse solutions and, thus, covering the search more uniformly [117]. One simple technique is a generalization of the Latin Hypercube [72] which works as follows. Suppose that N initial solutions should

Table 1 Latin Hypercube sampling with $N = 6$, $m = 3$, and $l = 7$. P_i are the generated permutations. Notice that each value, 1, 2, or 3, appears in two individuals at every gen

Individual	P_1	P_2	P_3	P_4	P_5	P_6	P_7	Genotype
I_1	2	5	5	6	2	3	2	[3 3 3 1 3 1 3]
I_2	5	2	2	4	1	6	6	[3 3 3 2 2 1 1]
I_3	6	3	6	2	5	4	4	[1 1 1 3 3 2 2]
I_4	4	1	1	3	4	2	5	[2 2 2 1 2 3 3]
I_5	1	4	4	5	6	5	1	[2 2 2 3 1 3 2]
I_6	3	6	3	1	3	1	3	[1 1 1 2 1 2 1]

be generated, whose genotype is an array with l variables that take values from an m-ary alphabet. First, l random permutations of $\{1, \ldots, N\}$ are composed. Then, solutions are generated concatenating the corresponding values of the permutations modulo m (plus 1 if needed), i.e., the first solution considers the first value of the permutations, and so on. See an example in Table 1. Note that N should be multiple of m to assure a uniform sample of the m values. In case of using a real encoding scheme, one possibility is to divide the domain of the variables in m disjoint intervals. The previous procedure is applied, and the variable finally takes a uniform random value from the selected interval.

- *Heuristic solutions*: In case you have some information of the problem at hand, you may exploit it to sample initial solutions better than those randomly generated. For example, in the knapsack problem, objects with better weight-profit ratios can be given higher probabilities of being included into the knapsack, or in the traveling salesperson problem, the nearest neighbor heuristic can be randomized to generate different solutions [150].

In Kazimipour et al. [79] different population initialization techniques are reviewed and categorized into a taxonomy.

Evaluation

Solutions are evaluated to decide whether they will, or will not, take part in the evolution process. This means assigning a fitness value to these candidate solutions. The most common practice is to assign a fitness value which is computed exactly as, or directly from, the objective function $f(\cdot)$. For example, the sum of the profits of the included objects can be used in the knapsack problem or the traveled distance, in the traveling salesperson problem. In some other occasions, you may be interested in another computation such as a scaling procedure to avoid the influence of the scale of the function, or including other information such as diversity maintenance or constraint violation, often addressed with penalty functions [127,153]. In case the calculation of the objective function requires excessive computational resources, it is very common to approximate it by means of a surrogate model [32,61,63], which is the one actually used by the GA.

A very different strategy is to consider a relative measure such as the ranking of the chromosomes in fitness order [122, 146]. Though the information loss, a clear advantage is that fitness values do not depend on the scale of the objective function.

Selection Operator

This operator is traditionally the only one in charge of assigning more reproduction possibilities to better solutions and, therefore, biasing the search process toward the pursued objective. GAs apply this operator to select those individuals allowed to breed and generate new candidate solutions.

The first selection operator applied is known as the *roulette-wheel* method. The idea is to assign selection probabilities, or roulette portions, to the solutions in the population, which are proportional to their fitness values. Thus, better individuals get higher probabilities of being selected. Then, the roulette is drawn as many times as a number of individuals are needed. An enhanced method is the *stochastic universal selection* of Baker [10]. In this case, the roulette has multiple equally spaced spinners, as much as individuals need to be selected, and is drawn just once. In contrast to roulette-wheel, Baker's method reduces the stochastic possibility of selecting the best individual too many or not enough times.

Tournament is another selection operator widely applied nowadays because of its simplicity [54]. This method is composed of a set of t_{size} random individuals from the population, and the best one is selected for breeding. Multiple tournaments are simulated to get the parent population. Note that parameter t_{size} controls the bias toward the best solutions, being $t_{size} = 2$ a classic setting, i.e., binary tournament.

Genetic Operators

Crossover and mutation operators are the GA components that generate new candidate solutions, which are afterward evaluated and considered for the subsequent evolution iteration. Between these two, the crossover has traditionally got a superior significance, and mutation often acts in the background, being applied less frequently. The goal of the former is to combine the information of two or more parent chromosomes from the current population, while the second usually modifies a chosen chromosome randomly and locally.

It is necessary to mention that, according to the *No Free Lunch* theorems for optimization [147], the performance of the GA will be determined by the ability of its components, particularly its genetic operators, to exploit useful knowledge of the concrete problem at hand or real-world problems in general [47]. It is for this reason that we can find a multitude of proposals for crossover and mutation operators particularly helpful for different problems or families of problems in the literature [97, 121, 139]. As an example, Dynastic Potential Crossover Operator [20] is an instance of optimal recombination operators [36], that exploiting the knowledge of the problem is able to produce or approximate the best offspring, from two parents, at a reduced computational cost.

There is not a clear methodology for the order in which these operators should be applied. Commonly, two GA parameters govern the frequency of crossover and mutation applications, namely crossover and mutation probabilities, and the process is often carried out as follows. The selected parent solutions firstly undergo crossover according to the crossover probability, and offspring is transferred to the mutation step; parents are otherwise transferred to the mutation phase. Subsequently, mutation is applied on the received solutions according to the mutation probability, and the result is temporarily stored for the next generation.

Given the strong interaction between the solution representation and genetic operators, we revise some classical proposals in the context of previous problems.

Crossover Operator

We show in this section some examples for combining the information from more than one parent through crossover application.

Knapsack Problem: Crossover Operator

The firstly proposed crossover operator took its inspiration from biology and is widely known as *one-point crossover* operator. Given two binary strings representing the corresponding parent solutions, this operator chooses a random position (4 in the example in Table 2) and combines the head of the first parent with the tail of the second one, generating a new candidate solution, and vice versa for a second candidate solution. However, other crossover operators such as uniform crossover [131] and half-uniform crossover [38] (see also section "The Crossover Operator as Diversification Agent") usually perform better [115]. Both create a new offspring by selecting randomly each of the gene values from the parents, but the latter assures that half of the number of differences are taken from one parent and the other half from the other parent. In the particular case of the knapsack problem, the resulting solutions may violate the capacity constraint, so penalty functions or repair operators would be needed.

Traveling Salesperson Problem: Crossover Operator

Problems using the permutation coding, such as this one, require crossover operators to accept permutations as input and to produce valid permutations as output. Note

Table 2 Example of binary crossover operators with parents $P_1 = [\,0\,1\,1\,0\,1\,0\,0\,]$ and $P_2 = [\,1\,1\,1\,1\,0\,0\,1\,]$

Name	Intermediate steps			Result
One-point	Cut point	Heads	Tails	Offspring
crossover	4	[0 1 1 0	1 0 0]	[0 1 1 0 0 0 1]
		[1 1 1 1	0 0 1]	[1 1 1 1 1 0 0]
Uniform		Genes from P_1	Genes from P_2	Offspring
crossover		1, 3, 5, 6	2, 4, 7	[0 1 1 1 1 0 1]
Half-uniform	Differences	Genes from P_1	Genes from P_2	Offspring
crossover	1, 4, 5, 6	4, 5	1, 6	[1 1 1 0 1 0 1]

Table 3 Example of crossover operators for permutations with parents $P_1 = [\ 1\ 2\ 3\ 4\ 5\ 6\ 7\ ]$ and $P_2 = [\ 2\ 4\ 5\ 7\ 1\ 6\ 3\ ]$

Name	Intermediate steps			Result
Partially	Cross. points	Comb. and rep. removal	Mappings	Offspring
mapped	2–4	[2 | 2 3 4 | 1 6 3]	2 → 4, 3 → 5, 4 → 7	[7 | 2 3 4 | 1 6 5]
crossover		[1 | 4 5 7 | 5 6 7]	4 → 2, 5 → 3, 7 → 4	[1 | 4 5 7 | 3 6 2]
Order	Cross. points	Inner segment	Valid values	Offspring
crossover	4–6	[− − − | 4 5 6 | −]	[2 4 | 5 7 1 6 | 3]	[2 7 1 | 4 5 6 | 3]
		[− − − | 7 1 6 | −]	[1 2 | 3 4 5 6 | 7]	[3 4 5 | 7 1 6 | 2]

that previous operators do not satisfy this necessity. Therefore, specific operators are proposed for this type of problems (see Table 3). The firstly proposed one was *partially mapped crossover* [52], which is aimed precisely at generating sequences of numbers without repetition. Its idea is to divide the two-parent permutations in three segments each according to two randomly chosen positions (2–4 in Table 3). Then, the inner segment of one parent is combined with the outer ones of the other, and repeated genes in the outer segments are changed according to the mapping rules defined in the inner segment. *Order crossover* [26] is another option which intends to exploit the relative order of the gene values instead of their absolute positions, as the previous operator does. Firstly sampling two random positions, this operator copies the inner segment into the offspring and continues copying those valid gene values from the secondly sampled position of the other parent (see Table 3). Given that different operators focus on different interpretations of the information transmitted, the practitioner should identify what is the one most appropriate for the adopted problem representation.

Real-Parameter Optimization: Crossover Operator

Similarly to previous cases, there are many proposals for the combination of the information in two real-coded parent solutions. In this case, researchers pay attention to the capacities of the crossover to converge, expand, or even correlate the changes on the decision variables [67]. An interesting characteristic of most real-parameter crossover operators is whether they tend to sample new solutions near the centroid of the parents or near the parents. BLX-α [39] is an example of centroid-centered operator, and PBX-α is its parent-centered version [45, 91]. For each offspring gene o_i, both operators create an interval $I = [a, b]$ from which the actual value is uniform randomly drawn. In both cases, the amplitude of the interval depends on the difference between the parent gene values, $I_i^a = abs(p_i^1 - p_i^2)$, and the domain of the variable, $[l_i, u_i]$. The difference is the location of that interval, biased toward the average of the previous parent gene values, in the case of BLX-α, or the value of the first parent, PBX-α. Table 4 shows an example of how both operators compute the intervals from where offspring gene values are sampled.

Table 4 Example of real-parameter crossover operators with parents $P_1 = [\ 0.3\ \ 7\ ]$ and $P_2 = [\ 0.4\ \ 1\ ]$, $\alpha = 0.5$, and domains $x_1 \in [0, 1]$ and $x_2 \in [-10, 9]$

Name	Intermediate steps			
BLX-α	I_i^a	Lower bound	Upper bound	Actual interval
	$abs(p_i^1 - p_i^2)$	$max\{l_i,\ min\{p_i^1, p_i^2\} - \alpha I_i^a\}$	$min\{u_i,\ max\{p_i^1, p_i^2\} + \alpha I_i^a\}$	
o_1	0.1	$max\{0,\ 0.3 - 0.05\}$	$min\{1,\ 0.4 + 0.05\}$	[0.25, 0.45]
o_2	6	$max\{-10,\ 1 - 3\}$	$min\{9,\ 7 + 3\}$	$[-2, 9]$
PBX-α	I_i^a	Lower bound	Upper bound	Actual interval
	$abs(p_i^1 - p_i^2)$	$max\{l_i,\ p_i^1 - \alpha I_i^a\}$	$min\{u_i,\ p_i^1 + \alpha I_i^a\}$	
o_1	0.1	$max\{0,\ 0.3 - 0.05\}$	$min\{1,\ 0.3 + 0.05\}$	[0.25, 0.35]
o_2	6	$max\{-10,\ 1 - 3\}$	$min\{9,\ 1 + 3\}$	$[-2, 4]$

Mutation Operator

As for the crossover operator, mutation is strongly connected with the adopted representation. Therefore, we will see some simple examples for any of the three problems considered through this chapter. Apart, we shall mention that the community usually distinguishes between applying mutation at individual or gene level. In the first case, the chromosome is mutated only once according to the mutation probability. One gene is randomly selected and modified, which could involve additional modifications in one or a few other genes. In the latter, all the genes of the chromosome are visited, and each one is mutated according to the mentioned probability, so chromosomes might suffer stronger alterations. In this case, the mutation probability is often much smaller.

Knapsack Problem: Mutation Operator

Flipping is the simplest mutation operator for binary strings. If mutation applies at the individual level, a random gene is selected, and its value is changed, from 0 to 1 or the other way around. If mutation is at the gene level, each variable is visited once and flipped according to the mutation probability. One should notice that other operators might be more appropriate for the problem at hand. For example in the case of the knapsack problem, flipping one bit from 1 to 0 might leave room for inserting another object in the knapsack, and changing one bit from 0 to 1 may make the solution unfeasible. Thus, flipping two bits with different values might be preferable.

Traveling Salesperson Problem: Mutation Operator

Assigning random values to one or several genes is often applied in integer-coded problems; however, this strategy is not appropriate for permutation codings. Instead, mutation operators usually apply swappings, insertions, reorderings, or sublist inversions [33, 126]. Table 5 shows the application of swap [12, 112] and sublist inversion [69]. In both cases, two positions are randomly drawn. Notice, however, that sublist inversion modifies less arcs of the solution path in symmetric graphs than swapping the selected positions. This is due to the fact that traveling direction

Table 5 Example of mutation operators for permutations with chromosome $S = [\ 2\ 4\ 5\ 7\ 1\ 6\ 3\ ]$

Swap	Mut. points	Result	Arcs removed	Added arcs
	2–5	[2 | 1 | 5 7 | 4 | 6 3]	$2 \to 4,\ 4 \to 5,$	$2 \to 1,\ 1 \to 5$
			$7 \to 1,\ 1 \to 6$	$7 \to 4,\ 4 \to 6$
Sublist	Mut. Points	Result	Arcs removed	Added arcs
Inversion	2–5	[2 | 1 7 5 4 | 6 3]	$2 \to 4,\ 1 \to 6$	$2 \to 1,\ 4 \to 6$

does not affect the solution cost in this kind of graphs. Thus, sublist inversion is often preferred for this problem.

Real-Parameter Optimization: Mutation Operator
Uniform and norm random variables, with a symmetric distribution around zero, are commonly used to perturb a given real-coded solution locally. In contrast to previous cases, it is usual to modify more than one and often all the variables of the solutions at the same time, by adding up a complete randomly drawn vector. Altering either one or all the variables, practitioners often pay attention at the global impact of the mutation so that the difference between the original and the mutated solution, under the Euclidean metric, for instance, is controlled. A widely used operator is the nonuniform mutation [73, 101], which reduces the intensity of mutation with the number of generations. Particularly, a variation vector $\Delta = [\ \delta_1\ \ldots\ \delta_i\ \ldots\ \delta_N\ ]$, computed as follows, is added up to the given solution $X = [\ x_1\ \ldots\ x_i\ \ldots\ x_L\ ]$:

$$\delta_i = \begin{cases} (u_i - x_i)(1 - z_i)^{\gamma}, & \text{with probability } 1/2 \\ (l_i - x_i)(1 - z_i)^{\gamma}, & \text{otherwise} \end{cases}$$

$$\gamma = \left(1 - \frac{t}{t_{max}}\right)^{\beta}$$

where z_i is a uniform random variable in $[0, 1]$, u_i and l_i are the box bounds of variable x_i, β is a parameter with $\beta > 0$, and t and t_{max} are, respectively, the current and maximal number of generations.

Evolution Model and Replacement Strategy

The traditional GA applied a *generational* evolution strategy. This means that evolution occurs at generations where a complete new population is generated from the current one, which, in turn, becomes the current population for the next generation. The pseudocode of this generational GA is shown in Fig. 1. A possible undesirable effect of this model is that the new population might be worse, in quality terms, than the current population. So usually, the best solution from the current population is artificially inserted in the new population, particularly when there is

Fig. 1 Basic scheme of a generational GA

```
begin GENERATIONAL-GA(NP, p_c, p_m)
1   for i = 1, ..., NP do
2       p_i ← GENERATE-SOLUTION;
3       p_i.fitness ← EVALUATE(p_i);
4       P ← P ∪ {p_i};
5   end-for;
6   repeat do
7       P_O ← ∅;
8       repeat do
9           parents ← SELECTION(P);
10          offspring ← CROSSOVER(parents, p_c);
11          offspring ← MUTATION(offspring, p_m);
12          offspring.fitness ← EVALUATE(offspring);
13          P_O ← P_O ∪ {offspring};
13      until |P_O| = NP;
14      P ← P_O;
15  until STOP-CONDITION;
16  return BEST-SOLUTION;
end GENERATIONAL-GA.
```

not any better solution in the new population. This evolution model is known as *generational with elitism* [11].

Another commonly applied model is the *steady-state GA* [29], which contrarily generates a reduced set of new chromosomes, usually just one solution, that compete to enter into the population (see pseudocode in Fig. 2). In steady-state GAs, the designer has to specify a replacement policy, which determines whether the new solution enters the population or it is discarded, and, which solution from the population is removed to make room for the new one, if this is accepted. A simple policy to introduce the new solution into the population is replacing the worst

Fig. 2 Skeleton of a steady-state GA

```
begin STEADY-STATE-GA(NP, p_c, p_m)
1   for i = 1, ..., NP do
2       p_i ← GENERATE-SOLUTION;
3       p_i.fitness ← EVALUATE(p_i);
4       P ← P ∪ {p_i};
5   end-for;
6   repeat do
7       parents ← SELECTION(P);
8       offspring ← CROSSOVER(parents, p_c);
9       offspring ← MUTATION(offspring, p_m);
10      offspring.fitness ← EVALUATE(offspring);
11      P ← REPLACEMENT(offspring, P);
12  until STOP-CONDITION;
13  return BEST-SOLUTION;
end STEADY-STATE-GA.
```

solution if the new one is better. Other strategies consider diversity measures, like replacing the most similar solution [62] (see also the section "Strategies to Maintain Diversity," crowding methods) or the worst parent.

Stop Condition

GAs evolve until a certain stopping criterion is met. Practitioners commonly consider a maximum number of generations, fitness evaluations, or a maximal processing time. These criteria are widely used when one is interested in comparing the performance of several algorithms, and the same computational resources have to be provided for a fair study.

On other occasions, especially when one is aimed at solving a particular problem, GAs are executed until a minimal solution quality is attained or the population

converges, so further progress is very difficult. In these cases, practitioners often need to be able to consult the progress of the search to decide at the moment, whether continuing the evolution or truncating it and applying a restart procedure (see also the section "Methods to Generate Raw Diversity").

Diversification Techniques for GAs

There are two primary factors in the search carried out by a GA [105, 142]: population diversity and selective pressure. In order to have an effective search there must be a search criterion (the fitness function) and a selection pressure that gives individuals with higher fitness, a higher chance of being selected for reproduction, mutation, and survival. Without selection pressure, the search process becomes random, and promising regions of the search space would not be favored over regions offering no promise. On the other hand, population diversity is crucial to a GA's ability to continue the fruitful exploration of the search space [70]. If the lack of population diversity takes place too early, a premature stagnation of the search is caused. Under these circumstances, the search is likely to be trapped in a region not containing the global optimum. This problem, called premature convergence, has long been recognized as a serious failure mode for GAs [64, 154]. In the literature, many approaches have been proposed to introduce new methods and operators that attempt to favor the diversity of the population to overcome this essential problem of genetic algorithms. Next, we present a quick overview of them.

Methods to Generate Raw Diversity

Premature convergence causes a drop in the GA's efficiency; the genetic operators do not produce the feasible diversity to tackle new search space zones, and thus the algorithm reiterates over the known zones producing a slowing down in the search process. Under these circumstances, resources may be wasted by the GA searching an area not containing a solution of sufficient quality, where any possible improvement in the solution quality is not justified by the resources used. Therefore, resources would be better utilized in restarting the search in a new area, with a new population. This is carried out by means of a restart operator [49, 51], which introduces chromosomes with high *raw diversity* to increase the average diversity level, thus to ensure the process can jump out the local optimum and to revolve again.

Eshelman's CHC algorithm [37] represents a GA with elitist selection and a highly disruptive recombination operator that restarts the search when the population diversity drops below a threshold level. The population is reinitialized by using the best individual found so far as a template for creating a new population. Each individual is created by flipping a fixed proportion (35%) of the bits of the template chosen at random without replacement. If several successive reinitializations fail to yield an improvement, the population is completely (100%) randomly reinitialized.

Another GA that utilizes population reinitialization is the micro GA [50]. In general, a micro GA is a small population GA which evolves for many generations. When after a number of generations the micro GA population converges, the evolutionary process is reinitialized by preserving the best individual and substituting the rest of the population with randomly generated individuals. The first implementation of a micro GA was reported by Krishnakumar [83], who used a population size of five individuals, tournament selection, single-point crossover with probability, elitism, and restart operator. The population was considered converged when less than 5% of the population bits were different from the bits of the best individual.

A GA model, called saw-tooth GA [82], manages a variable population size with periodic reinitialization following a saw-tooth scheme with a specific amplitude and period of variation. In each period, the population size decreases linearly, and at the beginning of the next period randomly generated individuals are appended to the population.

Strategies to Maintain Diversity

Pioneer works on the way diversity may be retained throughout the GA run focused on the design of alternative selection mechanisms. For example, in the linear ranking selection [9], the chromosomes are sorted in order of raw fitness, and then the selection probability of each chromosome is computed according to a linear function of its rank. With this selection mechanism, every individual receives an expected number of copies that depends on its rank, independent of the magnitude of its fitness. This may help prevent premature convergence by preventing super individuals from taking over the subpopulations within a few generations.

Disruptive selection [84] attempts to accomplish this objective as well. Unlike conventional selection mechanisms, this approach devotes more trials to both better and worse solutions than it does to moderate solutions. This is carried out by modifying the objective function of each chromosome, C, as follows: $f'(C) = |f(C) - \bar{f}|$, where $\bar{f}$ is the average value of the fitness function of the individuals in the population. A related selection method is the fitness uniform selection scheme (FUSS) [71]. FUSS generates selection pressure toward sparsely populated fitness regions, not necessarily toward higher fitness. It is defined as follows: If f_{min} and f_{max} are the lowest and highest fitness values in the current population, respectively, we select a fitness value uniformly in the interval $[f_{min}, f_{max}]$. Then, the individual in the population with fitness nearest to this value is selected. FUSS results in high selection pressure toward higher fitness if there are only a few fit individuals, and the selection pressure is automatically reduced when the number of fit individuals increases. In a typical FUSS population, there are many unfit and only a few fit individuals. Fit individuals are effectively favored until the population becomes fitness uniform. Occasionally, a new higher fitness level is discovered and occupied by a new individual, which then, again, is favored. Finally, another technique being worthy of mention is the repelling algorithm [148], which modifies the fitness function to increase the survival opportunity of chromosomes with rare alleles.

There are different replacement strategies for steady-state GAs that try to maintain population diversity, as well. In Lozano et al. [92], the authors propose a replacement strategy that considers two features of the individual to be included into the population: a measure of the contribution of diversity to the population and the fitness function. It tries to replace a chromosome in the population with worst values for these two features. In this way, the diversity of the population increases, and the quality of the solutions improves, simultaneously. The goal of this strategy is to protect those individuals that preserve the highest levels of useful diversity.

Other replacement methods to promote population diversity are the crowding methods [124]. They work as follows: New individuals are more likely to replace existing individuals in the parent population that are similar to themselves based on genotypic similarity. In this manner, the population does not build up an excess of similar solutions. Crowding methods promote the formation of stable subpopulations in the neighborhood of optimal solutions (niches), favoring the preservation of multiple local optima in multimodal problems. An effective crowding method is the restricted tournament selection (RTS) [62]. RTS initially selects two elements at random, A and B, from the population and performs crossover and mutation on these two elements resulting in a new element A'. Then, RTS scans ω (window size) more members of the population and picks the individual that most closely resembles A' from those ω elements. A' then competes with this element, and if A' wins, it is allowed to enter the population. Another type of crowding methods assumes that the parents would be those members of the population that are closer to the new elements. In this way, children compete with their parents to be included in the population, i.e., a family competition is held. These methods include deterministic crowding [94] and elitist recombination [135].

Some GA models were proposed in the literature which explicitly avoid the existence of duplicate individuals in the population, as a way to encourage diversity. In fact, early empirical studies confirmed that duplicate removal can enhance the performance of GA significantly [99]. For example, the non-revisiting GA [154] guarantees that no revisits ever occur in its fitness evaluations. It achieves this by interacting with a dynamically constructed binary space partitioning archive that is built up as a random tree for which its growth process reflects the evolution history of the GA and is a quick method to query whether there is a revisit. The entire previous search history is then used to guide the search to find the next unvisited position. A similar approach may be found in Gupta and Garg [59].

Finally, it is worth to mention that diploid GAs [81, 140] are evolutionary algorithms that manipulate a specific kind of diversity that becomes profitable to deal with dynamic optimization problems (in which some elements of the underlying model change over the course of the optimization). Most organisms in nature have a great number of genes in their chromosomes, and only some of the dominant genes are expressed in a particular environment. The repressed genes are considered as a means of storing additional information and providing a latent source of population diversity. Diploid GAs use diploid chromosomes which are different from natural ones in that the two strands of the diploid chromosomes are not complementary. Only some genes in a diploid chromosome are expressed and

used for fitness evaluation by some predetermined dominance rules. Unused genes remain in the diploid genotype until they may later become useful (*latent diversity*).

The Crossover Operator as Diversification Agent

The mating selection mechanism determines the way the chromosomes are mated by applying the crossover to them. In the conventional GA, no mating strategy is applied to the results of selection; that is, parents are approved without any further examination after they are chosen at random or just by fitness. However, mates can be selected so as to favor population diversity [37, 136]. A way to do this is the negative assortative mating mechanism. Assortative mating is the natural occurrence of mating between individuals of similar genotype more or less often than expected by chance. Mating between individuals with similar genotype more often is called positive assortative mating and less often is called negative assortative mating. Fernandes et al. [40] assume these ideas in order to implement a parent selection mechanism for the crossover operator. A first parent is selected by the roulette-wheel method, and n_{ass} chromosomes are selected with the same method. Then, the similarity between each of these chromosomes and the first parent is computed. If assortative mating is negative, then the one with less similarity is chosen. If it is positive, the genome that is most similar to the first parent is chosen to be the second parent. Clearly, the negative assortative mating mechanism increases genetic diversity in the population by mating dissimilar genomes with higher probability.

The crossover operator has always been regarded as one of the main search operators in GAs [80] because it exploits the available information in previous samples to influence future searches. This is why research has been focused on developing crossover operators with an active role as effective diversification agents. The half-uniform crossover used in the CHC algorithm [37] is a highly disruptive crossover that crosses over exactly half of the non-matching alleles (the bits to be exchanged are chosen at random without replacement). This way, it guarantees that the two offspring are always at the maximum Hamming distance from their two parents, thus proposing the introduction of a high diversity in the new population and lessening the risk of premature convergence. It is worth of mention that CHC applies this operator along with (1) a reproduction restriction that assures that selected pairs of chromosomes would not generate offspring unless their Hamming distance is above a certain threshold and (2) a conservative selection strategy with high selective pressure (it keeps the N best elements appearing so far). In fact, Kemenade et al. [141] suggest that higher selection pressures allow the application of more disruptive recombination operators.

A crossover operator that was specifically designed with the aim of diversifying the search process of the real-coded GAs is BLX-α [39] (see also the section "Crossover Operator" where its operation is described, and moreover, an illustrative example is presented). Nomura et al. [109] provide a formalization of this operator to analyze the relationship between the chromosome probability density

functions before and after its application, assuming an infinite population. They state that BLX-α spreads the distribution of the chromosomes when $\alpha > \frac{\sqrt{3}-1}{2}$ or otherwise reduces it. This property was verified through simulations. In particular, the authors observed that BLX-0.0 makes the variances of the distribution of the chromosomes decrease, reducing the distribution, whereas BLX-0.5 makes the variances of the distribution increase, spreading the distribution.

BLX-α has a self-adaptive nature in that it can generate offspring adaptively according to the distribution of parents without any adaptive parameter [13]. BLX-α uses probability distributions that are calculated according to the distance between the decision variables in the parents. If the parents are located closely to each other, the offspring generated by this operator might be distributed densely around the parents. On the other hand, if the parents are located far away from each other, then the offspring will be sparsely distributed around them. Therefore, it may fit their action range depending on the diversity of the population by using specific information held by the parents. In this way, depending on the current level of diversity in the population, it may favor the production of additional diversity (divergence) or the refinement of the solutions (convergence). This behavior is achieved without incurring into extra parameters or mechanisms to achieve the mentioned behavior.

Diversification by Adapting GA Control Parameters

Finding robust control parameter settings (such as mutation probability, crossover probability, and population size) is not a trivial task, since their interaction with GA performance is a complex relationship and the optimal ones are problem-dependent. Furthermore, different control parameter values may be necessary during the course of a run to induce an optimal exploration/exploitation balance. For these reasons, adaptive GAs [34, 65, 76, 128, 138] have been built to dynamically adjust selected control parameters or genetic operators during the course of evolving a problem solution. Their objective is to offer the most appropriate exploration and exploitation behavior [130].

Some adaptive techniques were presented to endow the GA with useful diversity. Specifically, the mutation probability (p_m) was considered as a key parameter to accomplish this task [114, 154]. Next, we describe different adaptive mechanisms presented in the GA literature to control this parameter.

- *Deterministic control of* p_m. A direction followed by GA research for the variation of p_m lies in the specification of an externally specified schedule which modifies it depending on the time, measured by the number of generations. One of the most considered schedules consists in decreasing p_m during the GA run [41]. For example, Hinterding et al. [68] suggested the equation $p_m = 0.1 - 0.09 \cdot \frac{g}{G}$, where g is the generation number from 1 to G. This schedule follows the heuristic *"to protect the exploration in the initial stages and the*

exploitation later," which has been considered to design other metaheuristics, such as simulated annealing.

- *Adaptive control of* p_m. In Srinivas and Patnaik [129], a technique for the adaptive control at individual level of p_m was proposed, in which p_m is varied depending on the fitness values of the solutions. Each chromosome C_i has its own associated p_m value, p_m^i, which is calculated as (maximization is assumed)

$$p_m^i = \frac{f_{max} - f_i}{f_{max} - \bar{f}} \text{ if } f_i \geq \bar{f}, \text{ and } p_m^i = 1 \text{ if } f_i < \bar{f}$$

where f_i is the chromosome's fitness, f_{max} is the population maximum fitness, and $\bar{f}$ is the mean fitness. In this way, high-fitness solutions are protected ($p_m^i = 0$), while solutions with subaverage fitnesses are totally disrupted ($p_m^i = 1$). This technique increases p_m when the population tends to get stuck at a local optimum and decreases it when the population is scattered in the solution space.

- *Self-adaptive control of* p_m. An extra gene, p_m^i, is added to the front of each chromosome, C_i, which represents the mutation probability for all the genes in this chromosome. This gene evolves with the solution [8, 138]. The values of p_m^i are allowed to vary from p_m^l to p_m^h. The following steps are considered to mutate the genes in a chromosome C_i:

  1. Apply a meta-mutation on p_m^i obtaining q_m^i. This is carried out by choosing a randomly chosen number from the interval $[p_m^i - d, p_m^i + d]$, where d is a control parameter.
  2. Mutate the genes in C_i according to the mutation probability q_m^i.
  3. Write the mutated genes (including q_m^i value) back to the chromosome.

  Crossover is presently applied only to the chromosome and has no impact on p_m^i. Each offspring resulting from crossover receives the p_m^i value of one of its parents. The initial p_m^i values are generated at random from $[p_m^l, p_m^h]$.

  The self-adaptive control of GA parameters attempts to exploit the indirect link between favorable control parameter values and fitness values, with the parameters being capable of adapting implicitly, according to the topology of the objective function [8].

Diversity Preservation Based on Spatial Separation

GA models based on the spatial separation of individuals were considered as an important way to research into mechanisms for dealing with the premature convergence problem. One of the most important representatives is the distributed GAs (DGAs) [6,35,64]. Their premise lies in partitioning the population into several subpopulations, each one of them being processed by a GA, independently of the

others. Furthermore, a migration mechanism produces a chromosome exchange between the subpopulations. DGAs attempt to overcome premature convergence by preserving diversity due to the semi-isolation of the subpopulations. Another important advantage is that they may be implemented easily on parallel hardware. Moreover, we should also point out that it is possible to improve the diversification in DGAs by designing specific migration policies [7].

Making distinctions between the subpopulations of a DGA through the application of GAs with different configurations (control parameters, genetic operators, codings, etc.), we obtain the so-called heterogeneous DGAs [64]. They are suitable tools for producing parallel multiresolution in the search space associated with the elements that differentiate the GAs applied to the subpopulations. This means that the search occurs in multiple exploration and exploitation levels. In this way, a distributed search and an effective local tuning may be obtained simultaneously, which may allow premature convergence to be avoided and approximate final solutions to be reached. An outstanding example is GAMAS [116], a DGA based on binary coding that uses four subpopulations, denoted as species I-IV. Initially, species II-IV are created. Species II is a subpopulation used for exploration. For this purpose, it uses a high mutation probability ($p_m = 0.05$). Species IV is a subpopulation used for exploitation. So, its mutation probability is low ($p_m = 0.003$). Species III is an exploration and exploitation subpopulation; the mutation probability falls between the other two ($p_m = 0.005$). GAMAS selects the best individuals from species II-IV and introduces them into species I whenever those are better than the elements in this subpopulation. The mission of species I is to preserve the best chromosomes appearing in the other species. At predetermined generations, its chromosomes are reintroduced into species IV by replacing all of the current elements in this species.

The cellular GA (cGA) [5] is another kind of decentralized GA in which the population is arranged in a toroidal grid, usually of dimension 2. The characteristic feature of cGAs is a neighborhood for each individual that is restricted to a certain subset of individuals in the immediate vicinity of its position. Individuals are allowed to interact only with other individuals belonging to their neighborhood. The overlapped small neighborhoods of cGAs help in exploring the search space because the induced slow diffusion of solutions through the population provides a kind of exploration (diversification). In contrast, the exploitation (intensification) is provided inside each neighborhood to improve the quality of solutions and could be controlled by the use of appropriate genetic operators. Several studies have been carried out in order to investigate mechanisms to dynamically control the exploration/exploitation trade-off kept by cGAs. This task may be achieved through tuning the relationship between the size and/or shape of the neighborhood and the grid [4] or by adjusting the local selection method [3]. It is worth remarking that since cGAs only require communication between few closely arranged individuals, they are very suitable for a parallel implementation, as well.

Interestingly, accelerating DGAs and cGAs on GPU (graphical processing unit) architectures has received significant attention from both practitioners and researchers ever since GPUs emerged [19, 156].

Hybrid GAs

Over the last few years, a large number of search algorithms were reported that do not simply follow the paradigm of one single classical metaheuristic, but they combine several components of different metaheuristics or even other kind of optimization methods. These methods are commonly known as *hybrid metaheuristics* [15,16,56,90,132]. The main motivation behind the development of hybrid metaheuristics is to take advantage of the complementary character from a set of metaheuristics and other optimization methods to produce a *profitable synergy* [123] from their combination.

In particular, the *hybridization of GAs*, and evolutionary algorithms in general, is becoming popular due to its ability to handle several problems involving complex features such as complexity, noise, imprecision, uncertainty, and vagueness [56,95, 118, 145]. We may also highlight that many different instantiations of hybrid GAs have been presented to solve real-world problems in many different fields such as protein structure prediction [134], image processing [14], job-shop scheduling [44], machine learning [111], and engineering design [48], to name but a few.

The flexibility offered by the GA paradigm allows specialized models to be obtained with the aim of providing intensification and/or diversification, i.e., GAs specializing in intensification and/or diversification. The outstanding role played by GAs at present along with the great interest raised by their hybridizations with other algorithms endorses the choice of their specialist approaches as suitable ingredients to build hybrid metaheuristics with other search techniques [90].

As mentioned above, these hybridizations encompass not only other metaheuristics but also other methods such as mathematical programming and simulation methods. Hybridization with mathematical programming methods is commonly known as *matheuristics* [96], and we can find in the recent literature several proposals to address real-world problems such as production and distribution planning in the supply chain [60], radiotherapy planning [110], and parallel machine scheduling [149]. *Simheuristics* [75] are a class of optimization techniques that combine elements of simulation and heuristics to tackle complex optimization problems. These techniques take advantage of the ability of simulations to model real-world systems characterized by uncertainty and heuristic strategies to explore and find promising solutions in large search spaces. Examples of integrating GAs with simulation methods can be found in several areas such as supply chain scheduling [119] and management of assets [107].

At this point, our objective is to illustrate the different strategies used successfully in the literature to hybridize GAs and classify them according to a taxonomy based on those proposed by Talbi [132] and Raidl [120] for hybrid metaheuristics.

We firstly have split the different instances of hybrid metaheuristics into two main groups according to the architecture of the algorithms:

- *Collaborative hybrid metaheuristics*. In this category, different self-contained metaheuristics interchange information between them running sequentially or in parallel. These hybrid metaheuristics can be considered as black boxes, and the

only cooperation takes place through the exchange of solutions, parameters, and so on from time to time.
- *Integrative hybrid metaheuristics*. In this case, one algorithm is in charge of the search process, whereas a subordinate method is embedded as a component of the master metaheuristic. This kind of hybridization addresses the functional composition of a single optimization method, replacing or improving a particular function within a metaheuristic with another metaheuristic.

At the same time, according to the way metaheuristics are executed, *collaborative* metaheuristics can be subdivided into two different categories:

- *Collaborative teamwork*. There are several metaheuristics that work in parallel and exchange some kind of information once in a while.
- *Collaborative relay*. Several metaheuristics are executed in a pipeline fashion. The output of each algorithm becomes the input of the next one.

Integrative hybrid metaheuristics can also be subdivided into teamwork or relay categories:

- *Integrative teamwork*. One metaheuristic (subordinate) becomes a component of another population-based metaheuristic (master) [132].
- *Integrative relay*. This kind of hybrid metaheuristics represents algorithms in which a given metaheuristic is embedded into a trajectory-based metaheuristic [132].

Collaborative Teamwork Hybrid GAs

In the case of *collaborative teamwork hybrid GAs*, we can highlight two schemes commonly used in the literature. In the first scheme, a single population is decentralized by partitioning it into several subpopulations (islands or demes), where island GAs are run performing sparse exchanges (migrations) of individuals. This kind of models are usually referred to as distributed GAs [64] (see also the section "Diversity Preservation Based on Spatial Separation"). Specifically, in this work several subpopulations are processed by GAs with different exploration or exploitation degrees. With this mechanism, refinement of the best solutions and expansion of the most promising zones are achieved in a parallel way. Communication between different GAs is done by sending the best solution of each population to the neighboring populations every five iterations.

In the second scheme, a set of heterogeneous metaheuristics including GAs is executed in parallel. For example, Talbi and Bachelet [133] combine a GA, tabu search, and a local search procedure that communicate through an adaptive memory that contains the search history. Multiple independent tabu search tasks run in parallel without any direct cooperation. However, the adaptive memory maintains a history of the search performed by these tabu search tasks. This information is used

by the GA to generate individuals in unexplored regions. At the same time, elite solutions from the adaptive memory are improved with the local search procedure.

Collaborative Relay Hybrid GAs

In the *collaborative relay hybrid GAs*, a GA is executed, in a pipeline fashion, with another GA or other type of metaheuristic so that the output of each algorithm is used as input of the next one. Most instances of collaborative relay GAs follow the principle of favor exploration in the initial stages and exploitation later, inspired by the design of classical metaheuristics such as simulated annealing [90]. In this line, Chelouah and Siarry [18] presented a hybrid GA that combines a GA specialized for diversification and a local search process that improves the best individuals found by the GA, whereas García-Martínez et al. [45] proposed a collaborative relay hybrid GA where the local refinement of solutions is performed by a specialized GA. They run a global real-coded GA during a determinate percentage of the available evaluations, and then they perform the local real-coded GA. The initial population for the local algorithm includes the best individuals of the global one.

Integrative Teamwork Hybrid GAs

In the case of *integrative teamwork hybrid GAs*, we can find two different approaches: *memetic algorithms* [106] and *GAs with metaheuristic-based components*. The classic scheme of memetic algorithms applies a local search method to solutions obtained by the GA that is in charge of the global search. The idea behind memetic algorithms is to provide an effective and efficient optimization method by achieving a trade-off between global exploration of GAs and local exploitation of local search procedures [103]. However, memetic algorithms also include combinations of GAs with problem-dependent heuristics, approximate algorithms, truncated exact methods, specialized recombination operators, etc. [106].

Many different instantiations of *memetic algorithms* have been presented to deal with a wide variety of application domains. However, the additional fitness function evaluations required for the local search method can increase significantly the computational cost of memetic algorithms. In order to mitigate this drawback, Molina et al. [103] proposed a memetic algorithm with local search chains that aims at focusing the local search action on promising areas of the search space. This is addressed by retaking the local search from solutions obtained in a previous application of the local search method, adopting also the former final strategy parameter values as its initial values.

In this line, we can find memetic algorithms in which the refinement procedure is performed by another GA instead of the classical local search procedure. With

this idea, there have been presented several memetic algorithms that use GAs with a small population and short evolution or micro GAs (μGA) [78, 91, 108] (see also the section "Diversification Techniques for GAs") to locally improve solutions. μGA models provide some advantages over classical local search methods. Most local search techniques find difficulties in following the right path to the optimum in complex search spaces. However, it was observed that μGAs are capable of following ridges of arbitrary direction in the search space regardless of their direction, width, or even, discontinuities [78]. For example, the μGA presented in Kazarlis et al. [78] is a GA with five individuals that encode perturbations. Aptitude values of these individuals depend on a solution given by the master GA. This feature ensures that search is focused on the neighborhood of the given solution, whereas low-sized population promotes high selection pressure levels.

With regard to *GAs with metaheuristic-based components*, we can find in the literature several proposals where the selection mechanism, the crossover, and mutation operators of GAs have been replaced or extended by other classical metaheuristic. The approach proposed in Adler [1] combines simulated annealing with a GA by extending the mutation and crossover operators with simulated annealing. Mutated and recombined solutions are accepted according to the standard simulated annealing acceptance condition. Kurahashi and Terano [85] proposed a tabu-based GA where after evaluating individuals in each iteration, they store the best individual of the generation into both long-term and short-term tabu lists. Then, the GA selection refers to the tabu lists in order to select individuals with dissimilar genotypes and consequently avoid premature convergence to local optima.

Integrative Relay Hybrid GAs

Finally, we undertake the study of *integrative relay hybrid GAs*. In this scheme, usually, a GA is used to perform one or more functions in the master metaheuristic. García-Martínez et al. [46] presented a GA designed specifically to play the role of the simulated annealing neighborhood operator. In particular, a steady-state GA creates one single candidate solution at each iteration, by crossing over the current solution of the master simulated annealing and another one from the population. Afterward, the master simulated annealing applies an acceptance mechanism to decide which solution becomes the new current solution, either the candidate solution or the current one. The other solution is inserted into the population by a replacement strategy. Another approach following this scheme was presented in Lozano and García-Martínez [90]. In this work, the authors present an iterated local search with a perturbation operator based on a μCHC algorithm. CHC provides high diversity by means of high selective pressure, allowing diverse and promising solutions to be maintained. This behavior is desirable for a GA assuming the work of a perturbation operator.

GA Applications

GAs have had a great measure of success in search and optimization problems. The reason for a great part of their success is their ability to exploit the information accumulated about an initially unknown search space in order to bias subsequent searches into useful subspaces, i.e., their adaptation. This is their key feature, particularly in large, complex, and poorly understood search spaces, where classical search tools (enumerative, heuristic, etc.) are inappropriate, offering a valid approach to problems requiring efficient and effective search techniques.

With the aim of showing the broad variety of GA applications, we have searched for papers from Scopus with the keyword "genetic algorithm." (The query was submitted in April 2024.) Table 6 outlines the number of documents with "genetic

algorithm" in the title, abstract, or keywords, according to their subject areas. The huge amount of papers (71,147 and 264,139) and the wide spectrum of subject areas with GA applications allow us to say that the research on GAs has reached a stage of great maturity, and there is an active and vibrant worldwide community of researchers working on these algorithms, as it may be confirmed in Fig. 3, which illustrates the number of publications appeared in each year in the period 1970–2023. Specifically, we may see that from approximately the last 15 years, GAs involved more than 3500 publications, with the term in their titles, per year.

An additional remark from Table 6 concerns the outstanding activity coming from the engineering field, where challenging hard optimization problems arise, which are characterized by having multiple objectives, by being dynamic problems, by the high number of implied decision variables and the complex relationships among them, and, in many cases, by the strict feasibility constraints. To effectively face problems with such a diverse nature, the original GA scheme was extended in different ways:

- *Multiobjective GAs*. Multiobjective optimization problems require the simultaneous optimization (maximization or minimization) of several objectives that cannot be compared easily with each other. The goal of solving these problems is not to find an optimal solution, rather to find a set of nondominated solutions, the so-called Pareto set. Since the 1980s, the application of GAs in solving multiobjective optimization problems has been receiving a growing interest, and they are still one of the hottest research areas in the field of evolutionary computation [21, 30]. By evolving a population of solutions, these GA approaches are able to capture a set of nondominated solutions in a single run of the algorithm [31].
- *Evolutionary Multitasking* The work [58] stands out as a burgeoning subject within evolutionary computation. The objective is to tackle the solution of several optimization problems simultaneously by taking advantage of knowledge sharing between problems. The evolutionary paradigm is ideally suited for this

purpose given its intrinsically parallel nature through the concept of population of solutions. Within the field of multitask evolutionary algorithms, the most widely used are the *multifactorial evolutionary algorithms*. The latter facilitate the transfer of knowledge through crossover and mutation operators, leading to high-quality solutions in a more efficient manner compared to single-task evolutionary algorithms [89]. This paradigm has been successfully used for training reinforcement learning models [98] and permutation-based discrete optimization problems [113].

- *Constrained GAs*. In many science and engineering disciplines, it is common to encounter a large number of constrained optimization problems. Such problems involve an objective function that is subject to various equality and inequality constraints. The challenges in this optimization scenario arise from the various limits on the decision variables, the constraints involved, the interference among constraints, and the interrelationship between the constraints and the objective functions. Classical gradient-based optimization methods have difficulties in handling this kind of problems, as constrained optimization problems may usually lack an explicit mathematical formulation and have discrete definition domains. GAs are unconstrained search methods and lack of an explicit mechanism to bias the search in constrained search space. However, researchers have been able to tailor constraint handling techniques into GAs [22, 100, 143].
- *GAs for dynamic optimization problems*. In dynamic environments, the fitness landscape may change over time as a result of the changes of the optimization goal, problem instance, and/or some restrictions. Alternatives that were bad in the past can be good nowadays or vice versa; criteria that were important before become irrelevant now, etc., and moving in these dynamic scenarios is a challenge. For these cases, the goal of an optimization algorithm is no longer to find a satisfactory solution to a fixed problem, but to track the moving optimum in the search space as closely as possible. This poses great difficulties to standard GAs, because they cannot adapt well to the changing environment once converged. Over the past decade, an important number of GA approaches have been developed to face problems with these features, and readers are referred to Cruz et al. [24], Jin and Branke [74], Yang et al. [151] for a comprehensive overview.
- *Multimodal GAs*. Many real-world problems require an optimization algorithm that is able to explore multiple optima in their search space. However, given a problem with multiple solutions, a simple GA shall tend to converge to a single solution. As a result, various mechanisms have been proposed to stably maintain a diverse population throughout the search [87, 88, 152], thereby allowing GAs to identify multiple optima reliably in these multimodal function landscapes. Many of these methods work by encouraging artificial niche formation through sharing [53] and crowding [62, 124, 135] (see section "Strategies to Maintain Diversity").
- *Machine and Deep learning*. GAs have also been applied in a multitude of machine learning and data mining problems [144], such as feature and instance selection, rule-based classification, or frequent itemset analysis. In the realm of

deep learning neural networks, evolutionary algorithms have also been employed for tasks such as architecture search, hyperparameter optimization, and neural network optimization [2, 93, 155].

Finally, we remark that there are many open-source easy-to-use libraries for building GAs to solve real-world optimization problems. They are designed as general-purpose optimization libraries with the support of a wide range of parameters to give the user control over the GA life cycle. A variety of programming languages were employed to develop these libraries, such as *java* [137], *Python* [43], *R* [23, 125], and *C++* [102].

Conclusion

GAs have become a tool of choice since they offer practical advantages to researchers facing difficult optimization problems because they may locate high performance regions of vast and complex search spaces. Other advantages include the simplicity of the approach, their flexibility, and their robust response to changing circumstances. In the previous sections, we firstly provided a comprehensive guide for newcomers, revising the basic ingredients for designing a GA and presenting the classical GA approaches to solve three widely known optimization problems with very different characteristics. Then, we undertook the study of more complex GA instances through two fruitful research lines in this field such as the preservation of diversity in GAs and the hybridizations of GAs with other metaheuristics. With regard to the former, we analyzed the premature convergence problem in GAs and outlined different approaches that have been proposed to introduce new methods and operators that attempt to favor the diversity in GAs. Similarly, we described different schemes in the literature to hybridize GAs with other metaheuristics and presented different instantiations of these schemes that have been successfully applied. Finally, we reviewed the current activity in the GA field in terms of a number of publications and areas of interest, which shows the high level of interest in the field of GAs and predicts a promising evolution of this research area.

Abstract

GRASP (greedy randomized adaptive search procedures) is a multi-start metaheuristic designed to find high-quality solutions for combinatorial optimization problems. Each iteration of GRASP typically consists of two phases: a construction phase, where a feasible solution is built, and a local search phase, which begins from the constructed solution and performs iterative improvements until a locally optimal solution is achieved. While the construction phase is

Introduction

In a combinatorial optimization problem, given a finite (or countably infinite) solution set X and a real-valued objective function $f : X \to \mathbb{R}$, the goal is to find a solution $x^* \in X$ such that $f(x^*) \leq f(x)$ for all $x \in X$. While some of these problems can be solved in polynomial time, many are computationally intractable, as no exact polynomial-time algorithms are currently known to solve them [72]. Moreover, most real-world problems are either inherently computationally intractable or too large for exact algorithms to be practical. In these cases, metaheuristic methods are commonly used to find good, though not necessarily optimal, solutions. These methods typically alternate between phases of intensification and diversification. Intensification refers to focusing the search in a promising area of the solution space to refine and improve the current solution, often by applying more thorough local search techniques. On the other hand, diversification aims to explore new and potentially unexplored regions of the solution space, preventing the search from becoming stuck in local optima. Over time, various heuristic search techniques have been developed that effectively balance these two phases, significantly improving our ability to find high-quality solutions to complex combinatorial optimization problems. These techniques include simulated annealing [119], tabu search [73], genetic algorithms [101], biased random-key genetic algorithms [104], variable neighborhood search [85], adaptive large neighborhood search [151], and GRASP (greedy randomized adaptive search procedures) [52, 53].

GRASP is a multi-start metaheuristic designed to find good-quality solutions for combinatorial optimization problems. Each iteration consists of a construction phase, where a solution (which can be feasible or infeasible) is built, followed by a local search phase. The local search begins at the constructed solution and iteratively improves it until a locally optimal solution is reached. Although the construction phase is typically based on a randomized greedy algorithm, other construction procedures have been proposed. Repeated applications of the construction procedure generate diverse starting solutions for the local search, and the best local optimum found across all iterations is returned as the final solution.

This chapter overviews GRASP by describing its basic components along with some among the most fruitful proposed enhancements, including reactive GRASP,

intensification strategies, and hybridization with other metaheuristics. The chapter is organized as follows. Basic components, alternative construction mechanisms, and local search characteristics are described in the next section. Enhancements to the basic procedure, including reactive GRASP and intensification strategies, are discussed in section "**Enhancements**." Section "**Hybridizations**" describes several state-of-the-art hybridizations of GRASP with other metaheuristics, while section "**Continuous GRASP**" describes how GRASP has been extended to continuous optimization problems. Tables 1 and 2 report a number of GRASP implementations that have appeared in the literature, covering a wide range of applications in several and heterogenous fields. Moreover, the reader can refer to [66, 67, 134].

Basic Components

Given a finite solution set X and a real-valued objective function $f : X \to R$ to be minimized, a basic GRASP metaheuristic [52, 53] is a multi-start or iterative method, in which each iteration consists of two phases: construction of a solution and local search.

The construction phase builds a solution x, usually feasible, but optionally also infeasible. If x is not feasible, a repair procedure may be invoked to obtain feasibility. Once a solution x is obtained, its neighborhood is investigated by the

```
algorithm GRASP(f(·), g(·), MaxIterations, Seed)
1    x_best:=∅; f(x_best):=+∞;
2    for k = 1, 2, ...,MaxIterations→
3       x:=ConstructGreedyRandomizedSolution(Seed, g(·));
4       if (x not feasible) then
5          x:=repair(x);
6       endif
7       x:=LocalSearch(x, f(·));
8       if (f(x) < f(x_best)) then
9          x_best:=x;
10      endif
11   endfor;
12   return(x_best);
end GRASP
```

Fig. 1 Pseudo-code of a basic GRASP for a minimization problem

local search until a local minimum is found. The best overall solution is kept as the result. The pseudo-code in Fig. 1 illustrates the main blocks of a GRASP procedure for minimization, in which `MaxIterations` iterations are performed and `Seed` is used as the initial seed for the pseudorandom number generator.

Construction Phase

Starting from an empty solution, a complete solution is iteratively constructed in the construction phase, one element at a time (see Fig. 2). At each construction iteration, the choice of the next element to be added is determined by ordering all candidate elements (i.e., those that can be added to the solution) in a candidate list C with respect to a greedy function $g : C \rightarrow R$. This function measures the (myopic) benefit of selecting each element. The heuristic is adaptive because the benefits associated with every element are updated at each iteration of the construction phase to reflect the changes brought on by the selection of the previous element. The probabilistic component of a GRASP is characterized by randomly choosing one of the best candidates in the list, but not necessarily the top candidate. The

```
procedure ConstructGreedyRandomizedSolution(Seed, g(·))
1    x:=∅;
2    Sort the candidate elements i according to their incremental costs g(i);
3    while (x is not a complete solution)→
4       RCL:=MakeRCL();
5       v:=SelectIndex(RCL, Seed);
6       x := x ∪ {v};
7       Resort remaining candidate elements j according to g(j);
8    endwhile;
9    return(x);
end ConstructGreedyRandomizedSolution;
```

Fig. 2 Basic GRASP construction phase pseudo-code

list of best candidates is called the *restricted candidate list* (RCL). This choice technique allows for different solutions to be obtained at each GRASP iteration but does not necessarily compromise the power of the adaptive greedy component of the method.

The most used technique to build the RCL applies the min max–α percentage rules. At any GRASP iteration, let $g_{\min}$ and $g_{\max}$ be the smallest and largest incremental costs, respectively, i.e.,

$$g_{\min} = \min_{i \in C} g(i), \qquad g_{\max} = \max_{i \in C} g(i). \tag{1}$$

The RCL is made up of elements $i \in C$ with the best (i.e., the smallest) incremental costs $g(i)$. There are two main mechanisms to build this list: *cardinality-based* (CB) and *value-based* (VB) mechanisms. In the CB case, the RCL is made up of the k elements with the best incremental costs, where k is a parameter. In the VB case, the RCL is associated with a parameter $\alpha \in [0, 1]$ and a threshold value $\mu = g_{\min} + \alpha(g_{\max} - g_{\min})$. All candidate elements i whose incremental cost $g(i)$ is no greater than the threshold value are inserted into the RCL, i.e., $g(i) \in [g_{\min}, \mu]$. Note that the case $\alpha = 0$ corresponds to a pure greedy algorithm, while $\alpha = 1$ is equivalent to a random construction. The pseudo-code in Fig. 3 is a refinement of the greedy randomized construction pseudo-code shown in Fig. 2.

Prais and Ribeiro in [126,127] analyzed GRASP with different RCL construction mechanisms, varying the parameter α in three ways:

```
procedure ConstructGreedyRandomizedSolution(Seed, α, k, g(·))
1    x:=∅;
2    Initialize the candidate set C by all elements;
3    Evaluate the incremental cost g(i) for all i ∈ C;
4    while (|C| > 0)→
5        g_min := min_{i∈C} g(i); g_max := max_{i∈C} g(i);
6        if (CB RCL is used) then
7            Sort candidate elements i ∈ C according to g(i);
8            RCL:=C[1 ··· k];
9        else RCL:={i ∈ C | g(i) ≤ g_min + α(g_max − g_min)};
10       endif;
11       v:=SelectIndex(RCL, Seed);
12       x := x ∪ {v};
13       Update the candidate set C;
14       Reevaluate the incremental costs g(i) for all i ∈ C;
15   endwhile;
16   return(x);
end ConstructGreedyRandomizedSolution;
```

Fig. 3 Refined pseudo-code of the GRASP construction phase

(a) α randomly chosen from a uniform distribution
(b) α randomly chosen from a decreasing nonuniform distribution
(c) Fixed α, close to the greedy choice

They applied these strategies to four optimization problems, and they found that strategy (c) had the shortest computation times and less variability, while strategy (a) achieved more frequent hits, showing the effectiveness of varying α.

Additionally, they tested a self-adjusting version of GRASP, where α is modified based on solution quality. This extension is known as Reactive GRASP and will be discussed further in the next section.

Local Search Phase

As is the case for many deterministic methods, the solutions generated by a GRASP construction are not guaranteed to be locally optimal with respect to simple neighborhood definitions. Hence, it is almost always beneficial to apply a local search to attempt to improve each constructed solution. A local search algorithm works in an iterative fashion by successively replacing the current solution by a better solution in the neighborhood of the current solution. It terminates when no better solution is found in the neighborhood. The *neighborhood structure* N for a problem relates a solution s of the problem to a subset of solutions $N(s)$. A solution s is said to be *locally optimal* if there is no better solution in $N(s)$ with respect to the objective function value. The key to success for a local search algorithm consists of the suitable choice of a neighborhood structure, efficient neighborhood search techniques, and the starting solution. Figure 4 illustrates the pseudo-code of a generic local search procedure for a minimization problem.

In a GRASP framework, a local search starts from an initial solution $x_0 \in X$ and iteratively generates a sequence of improving solutions $x_1, \ldots, x_M$, where $M =$ `MaxIterations`. At the k-th iteration, $k = 1, \ldots, M$, x_k is locally optimal with respect to the neighborhood $N(x_{k-1})$ since $N(x_{k-1})$ is searched for an improving solution x_k such that $f(x_k) < f(x_{k-1})$. If such a solution is found, it is made the current solution. Otherwise, the search ends with x_{k-1} as a local optimum.

The effectiveness of local search depends on several factors, such as the neighborhood structure, the function to be minimized, and the starting solution. It has been experimentally shown that randomly generated solutions are of poor quality on average. On the other hand, greedy algorithms usually produce solutions of better quality than those of randomly generated solutions. Therefore, using

```
procedure LocalSearch(x, f(·))
1    Let N(x) be the neighborhood of x;
2    H:={y ∈ N(x) | f(y) < f(x)};
3    while (|H| > 0)→
4        x:=Select(H);
5        H:={y ∈ N(x) | f(y) < f(x)};
6    endwhile
7    return(x);
end LocalSearch
```

Fig. 4 Pseudo-code of a generic local search procedure

greedy solutions as starting points for local search in a multi-start procedure will usually lead to good, though, most often, suboptimal solutions. This is because the amount of variability in greedy solutions is small, and it is less likely that a greedy starting solution will be in the basin of attraction of a global optimum than a random solution. A greedy randomized construction as the one embedded in GRASP adds variability to the greedy algorithm.

Enhancements

To improve the performance of the basic GRASP framework, most efforts have focused on construction mechanisms. Since Mockus et al. [114] pointed out that GRASP with a fixed nonzero RCL parameter α is not asymptotically convergent to a global optimum (During construction, a fixed RCL parameter may rule out a candidate that is present in all optimal solutions.), several remedies have been proposed to get around this problem. They include reactive GRASP, cost perturbations in place of randomized selection, bias functions, memory and learning, and local search on partially constructed solutions.

Reactive GRASP

The results of the study conducted in [126, 128] involving variation of the value of the RCL parameter α motivated the proposal of the extension of the basic GRASP called reactive GRASP. Prais and Ribeiro in [128] have shown that using a single fixed value for the value of RCL parameter α very often hinders finding a high-quality solution, which eventually could be found if another value was used. Moreover, one drawback of the basic GRASP is the lack of *learning* from the history of solutions found in previous iterations. The basic algorithm discards information about any solution encountered that does not improve the incumbent. Instead, it is worth to use information gathered from good solutions leading to *memory-based* procedures. Information about the quality of previously generated solutions can influence the construction phase, by modifying the selection probabilities associated with each element of the RCL.

In this paragraph, we describe reactive GRASP, the first enhancement that incorporates a learning mechanism in the memoryless construction phase of the basic GRASP. In reactive GRASP, the value of the RCL parameter α is selected in each iteration from a discrete set of possible values with a probability that depends on the solution values found along the previous iterations. One way to accomplish this is to use the rule proposed in [128]. Let $\mathcal{A} = \{\alpha_1, \alpha_2, \ldots, \alpha_m\}$ be the set of possible values for α. At the first GRASP iteration, all m values have the same probability to be selected, i.e.,

$$p_i = \frac{1}{m}, \qquad i = 1, 2, \ldots, m. \tag{2}$$

At any subsequent iteration, let $\hat{z}$ be the incumbent solution and let A_i be the average value of all solutions found using $\alpha = \alpha_i$, $i = 1, \ldots, m$. The selection probabilities are periodically reevaluated as follows:

$$p_i = \frac{q_i}{\sum_{j=1}^{m} q_j}, \tag{3}$$

where $q_i = \hat{z}/A_i$, $i = 1, \ldots, m$. If values of $\alpha = \alpha_i$ ($i \in \{1, \ldots, m\}$) lead to the best solutions on average, then the value of q_i is increased and larger values of q_i correspond to more suitable values for α. The probabilities associated with these more appropriate values will then increase when they are reevaluated.

Due to greater diversification and less reliance on parameter tuning, reactive GRASP has been successfully applied to several problems and has led to improvements over the basic GRASP in terms of robustness and solution quality [8,26,146].

Cost Perturbations

Another step toward an improved and alternative solution construction mechanism is to allow *cost perturbations*. The idea is to introduce some "noise" in the original costs in a fashion that resembles the noising method of Charon and Hudry [38, 39]. Cost perturbations are effective in all cases when the construction algorithm is not very sensitive to randomization, as, for example, in the case of the Steiner problem in graphs [62].

Another situation where cost perturbations can be effective is when there is no greedy algorithm available for the problem to be solved, as, for example, in the case of the prize-collecting Steiner tree problem. To solve this problem, the hybrid GRASP procedure proposed by Canuto et al. in [34] used the primal-dual algorithm of Goemans and Williamson [80] to build initial solutions using perturbed costs. More in detail, in [34], at each iteration a new solution for the prize-collecting Steiner tree problem is built using node prizes updated by a perturbation function, according to the structure of the current solution. Two different prize perturbation schemes are used to enforce search diversification, as described in the following.

Perturbation by eliminations: The primal-dual algorithm used in the construction phase is driven to build a new solution without some of the nodes appearing in the solution constructed in the previous iteration. This is done by changing to zero the prizes of some persistent nodes, which appeared in the last solution built and remained at the end of the local search. A parameter μ controls the fraction of the persistent nodes whose prizes are temporarily set to zero.

Perturbation by prize changes: Similarly to the noising method of Charon and Hudry [38, 39], some noise is introduced into the node prizes, resulting in a change of the objective function as well. For each node i, a perturbation factor $\beta(i)$ is randomly generated in the interval $[1 - a, 1 + a]$, where a is

an implementation parameter. The original prize $\pi(i)$ associated with node i is temporarily changed to $\pi(i) = \pi(i) \cdot \beta(i)$.

Experimental results have shown that embedding a strategy of costs perturbation into a GRASP framework improves the best overall results. The hybrid GRASP proposed for the Steiner problem in graphs by Ribeiro et al. in [141] uses this cost perturbation strategy and is effective.

Bias Functions

Another construction mechanism was proposed by Bresina [31]. Once built the RCL, instead of choosing with equal probability one candidate among the RCL elements, Bresina introduced a family of probability distributions to bias the selection toward some particular candidates. A bias function is based on a rank $r(x)$ assigned to each candidate x according to its greedy function value and is evaluated only for the elements in RCL. Several different bias functions were introduced:

i. Random bias: $\text{bias}(r(x)) = 1$
ii. Linear bias: $\text{bias}(r(x)) = 1/r(x)$
iii. Log bias: $\text{bias}(r(x)) = \log^{-1}[r(x) + 1]$
iv. Exponential bias: $\text{bias}(r(x)) = e^{-r}$
v. Polynomial bias of order n: $\text{bias}(r(x)) = r^{-n}$

Let $\text{bias}(r(x))$ be one of the bias functions defined above. Once these values have been evaluated for all elements of the RCL, the probability p_x of selecting element x is

$$p_x = \frac{\text{bias}(r(x))}{\sum_{y \in \text{RCL}} \text{bias}(r(y))}. \tag{4}$$

A successful application of Bresina's bias function can be found in [29], where experimental results show that, although valid on all candidates, the evaluation of bias functions may be restricted only to the elements of the RCL.

Biased randomized GRASP (BR-GRASP) is a similar approach proposed in [61]. It applies a nonuniform, skewed probability distribution to the element selection process during the solution construction phase, but respect to Bresina [31], BR-GRASP allows all potential elements to be considered, with biased probabilities assigned to them. This change helps the algorithm converge more quickly to high-quality solutions, while keeping computational effort and the need for additional parameters minimal. Usually, the bias is given by a geometric distribution with a parameter that skews the probabilities.

Reactive GRASP has been the first and very simple attempt to enhance the basic GRASP in order to save and use history from previous iterations. Another very simple attempt is due to Fleurent and Glover [71] who proposed improved

constructive multi-start strategies that besides defining a special bias function also maintain a pool of *elite solutions* to be used in the construction phase. To become an elite solution, a solution must be either better than the best member of the pool, or better than its worst member and sufficiently different from the other solutions in the pool, in order to preserve not only solution quality but also the diversity of solutions. Fleurent and Glover defined: (1) a *strongly determined variable* as one that cannot be changed without eroding the objective or changing significantly other variables; (2) a *consistent variable* as one that receives a particular value in a large portion of the elite solution set, and (3) for each solution component i, a measure $I(i)$ of its strongly determined and consistent features that becomes larger as i appears more often in the pool of elite solutions. The intensity function $I(i)$ is used in the construction phase as follows. Recall that $g(i)$ is the greedy function, i.e., the incremental cost associated with the insertion of element i into the solution under construction. Let $K(i) = F(g(i), I(i))$ be a function of the greedy and the intensification functions. The idea of Fleurent and Glover is to define a special bias function that depends on $K(\cdot)$. In fact, the intensification scheme biases selection from the RCL to those elements i with a high value of $K(i)$ by setting its selection probability to be

$$p_i = \frac{K(i)}{\sum_{y \in \text{RCL}} K(y)}. \tag{5}$$

They suggested $K(i) = \lambda g(i) + I(i)$, with $K(i)$ varying with time by changing the value of λ, e.g., initially λ may be set to a large value that is decreased when diversification is called for. Rules and procedures for changing the value of λ are given by Fleurent and Glover [71] and Binato et al. [29].

Hybridizations

As enhancements to its basic framework, different hybridizations of GRASP with several other metaheuristics have been studied and proposed in the literature. In this section, some of them are surveyed and briefly described.

Laguna and Gonzalez-Velarde in 1991 [96] have first studied hybridization of GRASP with tabu search. Recently, in [131], GRASP is hybridized with tabu search to solve a variant of the multi-compartment vehicle routing problem (MCVRP). The hybrid approach uses GRASP to construct an initial solution and improves it by the tabu search algorithm, which intensifies the search by exploring the solution space more thoroughly. This combination enables the algorithm to balance exploration and exploitation, improving the overall solution quality by refining the initial GRASP solution while avoiding cycles and enhancing diversification. The proposed hybrid GRASP/TS method outperforms other heuristics in terms of solution quality and computational efficiency for the MCVRP.

GRASP has been used also in conjunction with genetic algorithms. Basically, the feasible solution found by using a GRASP construction phase has been used as

initial population by a genetic algorithm, as, for example, in [18] and in [3], where a greedy genetic algorithm is proposed for the quadratic assignment problem.

Another interesting hybridization of GRASP involves VNS (variable neighborhood search) and variable neighborhood descent (VND) proposed by Hansen and Mladenović [84, 113]. Almost all randomization effort in the basic GRASP algorithm involves the construction phase, while local search stops at the first local optimum. On the other hand, strategies such as VNS and VND rely almost entirely on the randomization of the local search to escape from local optima. With respect to this issue, probabilistic strategies such as GRASP and VNS may be considered as complementary and potentially capable of leading to effective hybrid methods.

A first attempt in the direction of integrating VNS into GRASP was done by Martins et al. [110]. The construction phase of their hybrid heuristic for the Steiner problem in graphs follows the greedy randomized strategy of GRASP, while the local search phase makes use of two different neighborhood structures as a VND strategy. Their heuristic was later improved by Ribeiro, Uchoa, and Werneck [140], one of the key components of the new algorithm being another strategy for the exploration of different neighborhoods. Ribeiro and Souza [138] also combined GRASP with VND in a hybrid heuristic for the degree-constrained minimum spanning tree problem. Festa et al. [69] studied different variants and combinations of GRASP and VNS for the MAX-CUT problem, finding and improving some of the solutions that at the time were the best known solutions for some open instances from the literature. In [57], the authors studied several hybridization of GRASP, including VNS, for the far from most string problem. Recently, Di Puglia Pugliese et al. [46] proposed a hybridization of GRASP with VND to solve a vehicle routing problem with occasional drivers. The VND has been used as local search phase, after a biased randomized greedy construction procedure.

At last, we devote the remainder of this section to the combination of the basic GRASP with path relinking. Path relinking was originally proposed by Glover [75] as an intensification strategy exploring trajectories connecting elite solutions obtained by tabu search or scatter search [76–78]. It can be traced back to the pioneering work of Kernighan and Lin [92]. Starting from one or more elite solutions, paths in the solution space leading toward other guiding elite solutions are generated and explored in the search for better solutions. This is accomplished by selecting moves that introduce attributes contained in the guiding solutions. At each iteration, all moves that incorporate attributes of the guiding solution are analyzed, and the move that best improves (or least deteriorates) the initial solution is chosen.

The first proposal of a hybrid GRASP with path relinking was in 1999 due to Laguna and Martí [97]. It was followed by several extensions, improvements, and successful applications [37, 47, 48, 58, 111, 124, 129]. Path relinking is applied to a pair of solutions $\mathbf{x}$ and $\mathbf{y}$, where one can be the solution obtained from the current GRASP iteration, and the other is a solution from an elite set of solutions. $\mathbf{x}$ is called the *initial solution*, and $\mathbf{y}$ the *guiding solution*. The set $\mathcal{E}$ of elite solutions has usually a fixed size that does not exceed `MaxElite`. Given the pair $\mathbf{x}, \mathbf{y}$, the procedure starts by computing the symmetric difference $\Delta(\mathbf{x}, \mathbf{y})$ between the two solutions, i.e., the set of moves needed to reach $\mathbf{y}$ (target solution) from $\mathbf{x}$ (initial

solution). A path of solutions is generated linking **x** and **y**. The best solution x^* in this path is returned by the algorithm. Since there is no guarantee that x^* is locally optimal, often local search is applied, starting from x^*, and the resulting locally optimal solution is returned.

Figure 5 illustrates the pseudo-code of the path-relinking procedure applied to the pair of solutions **x** (starting solution) and **y** (target solution). In line 1, an initial solution **x** is selected at random among the elite set of elements, and usually, it differs sufficiently from the guiding solution **y**. The loop in lines 6 through 14 computes a path of solutions $\mathbf{x}_1, \mathbf{x}_2, \ldots, \mathbf{x}_{d(\mathbf{x},\mathbf{y})-2}$, local search is applied in line 15, and the solution x^* with the best objective function value is returned in line 16.

```
algorithm Path-relinking(f(·), x, E)
1   Choose, at random, a pool solution y ∈ E to relink with x;
2   Compute symmetric difference Δ(x, y);
3   f* := min{f(x), f(y)};
4   x* := arg min{f(x), f(y)};
5   x := x;
6   while (Δ(x, y) ≠ ∅) →
7       m* := arg min{f(x ⊕ m) | m ∈ Δ(x, y)};
8       Δ(x ⊕ m*, y) := Δ(x, y) \ {m*};
9       x := x ⊕ m*;
10      if (f(x) < f*) then
11          f* := f(x);
12          x* := x;
13      endif;
14  endwhile;
15  x* := LocalSearch(x*, f(·));
16  return (x*);
end Path-relinking
```

Fig. 5 Pseudo-code of a generic path relinking for a minimization problem

This is achieved by advancing one solution at a time in a greedy manner. At each iteration, the procedure examines all moves $m \in \Delta(x, \mathbf{y})$ from the current solution x and selects the one which results in the least cost solution (line 7), i.e., the one which minimizes $f(x \oplus m)$, where $x \oplus m$ is the solution resulting from applying move m to solution x. The best move m^* is made, producing solution $x \oplus m^*$ (line 9). The set of available moves is updated (line 8). If necessary, the best solution x^* is updated (lines 10–13). The procedure terminates when $\mathbf{y}$ is reached, i.e., when $\Delta(x, \mathbf{y}) = \emptyset$, returning the best solution found.

The procedure described above is the greedy PR, and it is just one way to apply path relinking. In the context of GRASP, path relinking (PR) has been applied in various forms, which enhance the search for better solutions. The main types of path relinking are greedy, random, and mixed. Randomized PR introduces a random element in selecting the moves, which helps explore diverse solutions and avoid local optima. Mixed PR combines both strategies, alternating between greedy and random moves during the path construction. This method aims to balance the exploration of the solution space and the exploitation of promising solutions. The choice between these strategies often depends on the specific problem and the desired balance between solution quality and computational effort.

Moreover, the concept of multiple parents introduces a novel strategy where several guiding solutions, rather than just one, are used to generate the path from the initiating solution. This approach creates a broader search trajectory, allowing the relinking process to combine attributes from multiple solutions, potentially leading to better solutions by exploring more diverse areas of the solution space. The path from the initiating solution to the guiding solutions is constructed by incorporating attributes from the guiding set based on their frequency of occurrence, which helps preserve beneficial solution characteristics. Additionally, interior and exterior PRs refer to different ways of managing the solutions during the relinking process. Interior PR focuses on incorporating attributes that are present in the guiding solution but not in the initiating solution, progressively modifying the initiating solution by adding the missing attributes. Exterior PR, in contrast, seeks to introduce elements that are not present in either the initiating or guiding solution, thereby creating more diversified intermediate solutions. This form of PR is particularly useful when diversification is required to avoid premature convergence to local optima. Both approaches aim to enrich the search either by focusing on attributes that are common in high-quality solutions or by exploring more distant solution spaces. Readers interested in further details can explore Laguna et al. [100].

Continuous GRASP

Continuous GRASP (C-GRASP) has been proposed in [86] and is an extension of the traditional GRASP algorithm, adapted for solving continuous global optimization problems. Unlike its discrete counterpart, which operates on combinatorial spaces, C-GRASP targets problems in continuous domains, specifically those constrained by box constraints. The algorithm follows a multi-start approach,

alternating between construction and local improvement phases, similar to the original GRASP method. During each iteration, C-GRASP constructs a solution using a greedy randomized approach, where each component of the solution is determined by evaluating the best possible outcome in its local search space. The local improvement phase refines the solution further by exploring the neighboring region for better solutions without relying on derivative information, making C-GRASP particularly useful for "black-box" problems where derivative-based optimization methods cannot be applied. C-GRASP's effectiveness lies in its ability to adapt the search resolution based on the progress of the solution, intensifying the search when improvements are slow. This makes it a robust and flexible tool for tackling complex global optimization problems in various fields.

In the construction phase, an initial solution is generated using a greedy randomized approach tailored for continuous optimization. The process begins by selecting a random point within the feasible region defined by the problem's constraints, such as the lower and upper bounds for each variable. Initially, all the coordinates of the solution are considered "unfixed," meaning that each dimension of the solution can vary. For each unfixed coordinate, a line search is conducted along that coordinate's direction while holding the other coordinates fixed. This line search aims to find the value that minimizes the objective function for that coordinate. After performing the line search for all unfixed coordinates, an RCL is created, which includes coordinates associated with the best objective function values. The RCL is determined by selecting those coordinates whose objective function values fall within a specific range, controlled by the parameter α. This parameter balances the level of greediness in the selection process, with higher values of α focusing more on the best options. Once the RCL is formed, a coordinate is randomly selected from it, ensuring some level of diversity in the generated solution. The selected coordinate is then fixed at the value determined from the line search. This process repeats for each coordinate until all dimensions of the solution are fixed, resulting in a complete solution.

The local search begins with the solution obtained from the construction phase. For a given solution, the algorithm explores possible moves by considering different directions from the current point in the solution space. These directions are formed by vectors with components set to values from the set $1, 0, -1$, indicating movement in the positive, zero, or negative direction along each dimension of the solution. To maintain tractability, a limit is set on the number of directions to explore. The number of directions is determined by a parameter, `MaxDirToTry`, which can either be fixed or based on the dimensionality of the problem. For each direction, the algorithm tests a new point by adjusting the current solution along that direction. If the new point improves the objective function (i.e., it yields a better solution), the search continues from this new point, and the process repeats with the updated solution. The local search continues iterating, modifying the solution along different directions, until no further improvements can be found in the selected directions. If a better solution is found, it becomes the new current best solution. If no improvements are possible after testing all allowed directions, the local search terminates, and the resulting solution is returned. This phase serves to fine-tune the

solution, progressively exploring the local neighborhood and refining the solution quality. The randomness in the direction selection helps avoid getting stuck in local minima by diversifying the search, while the use of multiple direction vectors increases the likelihood of discovering a better solution.

Hirsch et al. [90] proposed several techniques to speeding up C-GRASP, while de Araújo et al. [13] presented several direct search procedures that are used in a C-GRASP heuristic. Moreover, C-GRASP has been successfully applied to various problems, including solving nonlinear equations [89], matching projected 3D points and lines [91], economic dispatch of thermal units [117], and others [82, 88, 106].

An interesting variant of C-GRASP is the random-key GRASP (RK-GRASP) presented by Chaves et al. [40]. It integrates the random-key optimizer (RKO) paradigm to solve combinatorial optimization problems. In RK-GRASP, solutions are represented as vectors of random keys, which are real numbers in the interval [0, 1). The random-key vector encodes the solution, and a decoder is used to map this vector to a feasible solution in the problem space. The RK-GRASP procedure follows the typical two-phase structure of GRASP: the construction phase and the local search phase. In the construction phase, a semi-greedy approach is used to generate a solution. This phase starts by selecting a random-key vector, and then each key is perturbed using a line search technique, ensuring that the solutions evolve based on both greedy choices and some randomness. The algorithm builds the solution by iteratively selecting keys and updating the solution. The local search phase then refines the constructed solution by exploring its neighborhood. Three distinct local search strategies have been used: grid search, Nelder-Mead search, and random variable neighborhood descent (RVND). These strategies explore different neighborhoods of the solution space to improve the solution's quality. RK-GRASP is particularly attractive because it decouples the problem-specific components (the decoder) from the problem-independent solver, allowing for the application of the same algorithm to various combinatorial optimization problems by simply changing the decoder. This makes RK-GRASP a flexible and efficient approach for solving a wide range of optimization problems.

Conclusions

The goal of this chapter was to provide an overview of GRASP describing its basic components and enhancements to the basic procedure, including reactive GRASP, intensification strategies, and its hybridizations with different metaheuristics.

Abstract

This chapter presents a literature review of the main advances in the field of hyper-heuristics, since the publication of a survey paper in 2013. The chapter demonstrates the most recent advances in hyper-heuristic foundations, methodologies, theory, and application areas. In addition, a simple illustrative selection hyper-heuristic framework is developed as a case study. This is based on the well-known Iterated Local Search algorithm and is presented to provide a tutorial style introduction to some of the key basic issues. A brief discussion about the implementation process in addition to the decisions that had to be made during the implementation is presented. The framework implements an action selection model that operates on the perturbation stage of the Iterated Local Search algorithm to adaptively select among various low-level perturbation heuristics. The performance and efficiency of the developed framework is evaluated across six well-known real-world problem domains.

Keywords

Hyper-heuristics · Heuristics · Meta-heuristics · Evolutionary computation · Optimization · Search · Machine learning · Multi-objective optimization · Combinatorial optimization · Black box optimization · Dynamic optimization · Scheduling · Timetabling · Packing · Iterated local search

Introduction

Over the last 50 years or so, heuristic search methodologies have been successfully applied to address various real-world complex optimization problems. Computationally challenging optimization problems arise in various disciplines such as operational research, computer science, finance, bioinformatics, industrial informatics, engineering, and data sciences. Representative examples of optimization problems can be found in scheduling, timetabling, planning, resource and space allocation, cutting and packing, software design, hardware design, and engineering design problems. Such optimization problems can be addressed by exact or heuristic methodologies (or a hybridization). The main difficulty of solving such problems occurs from the often remarkably large and possibly heavily constrained search space. In such problems, or in noisy and dynamic real-world problem scenarios, finding optimal solutions by exact methods might be impossible. Therefore, in practice, heuristic search methodologies are often developed or applied that seek to find solutions of acceptable quality in reasonable time, but without having any guarantee of optimality.

Over the last few decades, a broad spectrum of different heuristics have been proposed and successfully applied to a wide variety of problems. However, heuristics are usually designed to solve specific optimization problems. Such heuristics are bespoke problem-specific methods that often demand significant time

to design and tune. They are also often expensive to implement and maintain. Hyper-heuristics have been motivated by the aim of raising the level of generality at which search algorithms can operate, as well as automating the design and tuning of heuristic algorithms [1–8]. The main characteristic of a hyper-heuristic method is that it operates on a space of heuristics rather than on a space of solutions. As such, a hyper-heuristic methodology attempts to find or generate the appropriate method or sequence of low-level heuristics instead of directly solving a particular problem. A hyper-heuristic can be characterized as a high-level methodology which automatically generates or combines low-level search components (heuristics) to effectively solve a given problem instance or class of problems.

The following definition has been provided in the literature:

> A hyper-heuristic is a search method or learning mechanism for selecting or generating heuristics to solve computational search problems [3, 4].

The use of the term of *hyper-heuristics* goes back to 2001 [9]. However, the idea of automating the design and/or selection of heuristics has existed in the literature for more than 50 years [10, 11]. It is possible to characterize hyper-heuristic methodologies by considering two dimensions [3]: the characteristics of the heuristics' search space and the feedback information from the search process. The heuristic search space can be further divided into heuristic selection and heuristic generation. The first category represents methodologies or models that select among a set of available heuristics, while the latter category covers methodologies that generate new heuristics from existing heuristic components. A further refinement in both categories can be made based on the characteristics of the utilized search heuristic, i.e., constructive and perturbative search paradigms [12].

Hyper-heuristics can be further distinguished by looking at how they handle feedback information from the search process. Two main categories can be currently observed: methodologies that learn from the feedback and the ones that do not learn from it. The first category can be further refined based on the source of learning: *online* or *off-line* learning. When considering online learning hyper-heuristics, the learning phase takes place during the search procedure. Thus, timely feedback information can be exploited by the learning mechanism to study the trends and behavior of the underlying components. In the case of off-line learning (off-line learning hyper-heuristics), all information about the process is known a priori. As such, the learning mechanism is able to gather knowledge and learn from a training set of problem instances and then apply its knowledge on a test set of unseen instances. The aim of such a procedure is to generalize from the training information to unseen problem instances in an expected way. Methodologies that do not learn from the feedback information usually simply discard it.

The aforementioned classification reflects the majority of the past and the current research trends that can be widely found in the literature. Nevertheless, interesting example methodologies can be found that represent an interplay between the categories of heuristics, i.e., combinations of selection and generation heuristic search procedures [13, 14].

Over the last few years, various introductory tutorials, review, and survey articles have been published on the area of hyper-heuristics. The first book chapter that appeared in 2003 [1] introduces the general idea of hyper-heuristics and provides a brief historical overview of the field at that time. In particular, the chapter focuses on one of the main objectives of hyper-heuristics, which is to increase the level of generality at which a search methodology can operate. The overview demonstrates the history as well as the developments and trends in the field at that time, through detailed descriptions of the representative applications and methodologies.

An introductory tutorial of the area was presented in [7] that effectively demonstrated the development process of a hyper-heuristic approach, through useful guidelines and characteristic examples. It additionally pinpoints potential application areas and discusses some issues and possible future research pointers in the area. A second-edition tutorial with enriched material and information was recently published in [8].

A classification of the field and a discussion of developments at that time were published in 2008 [5]. The chapter emphasizes the real-world applications that have been tackled by hyper-heuristic approaches and presents three criteria that characterize a hyper-heuristic methodology: operating at a higher level and managing low-level heuristics, searching the heuristic space rather than the solution space, and limited access to problem domain information, i.e., an increased level of generality. The authors identified the last criterion as a particularly important one for the general applicability and robustness of a hyper-heuristic approach.

An overview chapter was published in 2009 [2] that discusses hyper-heuristic methodologies that are able to generate new effective heuristics that are not known beforehand. The chapter addresses the concept of automatically designing heuristics and describes a methodology to generate new heuristics. Several representative case study examples are also provided. In addition, the presented methodology emphasizes the main algorithmic component of this class which is the genetic programming algorithm. Moreover, it briefly covers the related literature and discusses the characteristics and issues of this class of approaches.

A unified classification and definition of the field were presented in 2010 [3]. The chapter provides an overview of the previous categorizations of the area and determines a unified classification and definition of hyper-heuristics that captures the current and potential future directions of hyper-heuristics. Two main classes of hyper-heuristic approaches are recognized in the categorization, heuristic selection and generation approaches. Several characteristic examples are presented and discussed for both categories.

A recent survey of hyper-heuristics was published in 2013 [4]. The article presents the state of the art of the field up to 2012 by providing examples of the main and most representative methodologies and application areas. It also discusses the origins and intellectual roots of the field as well as provides a critical discussion of the literature. Various potential research trends are briefly discussed, and several future directions are highlighted. Finally, the most recent overview of hyper-heuristics was published in 2014 [6]. The article presents an overview

and critical analysis of hyper-heuristics specifically for educational timetabling problems.

Building upon the aforementioned overview articles that have been recently published, this chapter aims to provide a thorough literature review of the main very recent advances in the field of hyper-heuristics, since the publication of [4] in 2013. An additional objective is to provide a case study for the development process of a simple but highly efficient selection hyper-heuristic framework as a tutorial-style introduction to the field. The performance and efficiency of the developed framework is evaluated across six well-known real-world problem domains.

The remainder of the chapter is organized into three main parts. The first part will present a timely overview of the current developments in the field of hyper-heuristics (section "Recent Advances in the Field of Hyper-heuristics"). The second part presents the development of a simple selection hyper-heuristic framework as a case study (section "Case Study: A Selection Hyper-heuristic-Based Iterated Local Search"). The last part evaluates the generality and performance of the developed framework on six different problem domains (section "Computational Results"). The chapter concludes with a brief discussion that summarizes the presented work (section "Conclusions").

Recent Advances in the Field of Hyper-heuristics

This literature review covers and discusses the latest articles that have been published in the field. It aims to cover as many of the current advances and trends as possible, without presenting overlapping material with relatively recent overview and survey papers [1–8]. The main aim of this review is to cover the period since the publication of [4] in 2013.

The latest trends and directions regarding foundational and methodological aspects of hyper-heuristics are firstly presented in the literature review (section "Recent Advances on the Methodology of Hyper-heuristics"). Then it proceeds with discussion on the automatic design of algorithms (section "Automatic Design of Algorithms") and the latest theoretical works in the area (section "Recent Theoretical Results in Hyper-heuristics"). Hyper-heuristic developments in multi-objective and dynamic problem formulations are then reviewed (sections "Multi-objective Optimization" and "Hyper-heuristics in Dynamic and Uncertain Environments"). The intersection between machine learning and hyper-heuristic methodologies is studied in section "Machine Learning Methodologies", while section "Automated Parameter Control and Tuning" presents the recent advancements in hyper-heuristics for automatic parameter control. Finally, the most recent developments in application areas of hyper-heuristics are presented that include scheduling, timetabling, games, and various other areas (sections "Hyper-heuristics for Scheduling Problems", "Recent Educational Timetabling Applications of Hyper-heuristics", "Games and Education", and "Other Recent Developments").

Recent Advances on the Methodology of Hyper-heuristics

Starting from the foundations of hyper-heuristics and by studying the classifications of the area, the authors of [15] reformulate the mathematical definition of a hyper-heuristic. It is specifically exhibited that the new presented formulation naturally leads to a recursive definition of a hyper-heuristic. The authors draw parallels between the new hyper-heuristic formulation and a blackboard architecture from artificial intelligence, in which heuristics are able to annotate a shared workspace with information that can be exploited by other heuristics. In such a formulation, heuristics can share information at any level, which suggests that the domain barrier can be relaxed at any level required, without the loss of generality. A detailed description of the proposed formulation and its developments can be found in [15]. A concrete example application on the 3-SAT problem domain has been presented as a case study, which exhibits the improvements of the proposed idea over a wide set of problem instances. Other extensions of the existing formulations of hyper-heuristics have been proposed in [16]. This study advocates the need to reconsider the existing approaches to be able to produce self-organizing heuristics that will be able to automatically self-adapt to the environment when the underlying problem domain changes.

The need for more general and cross-domain efficient methodologies [4, 8, 17] has led to novel studies that try either to introduce unified representations or to embed common domain knowledge across various problem domains [18, 19].

In particular, the authors in [18] do not employ a high-level barrier across domains that are used in much of the hyper-heuristic literature. Instead, they propose an evolutionary memetic computing paradigm that is capable of embedding domain knowledge in memes across different but related problem domains. To improve search efficiency, the memetic paradigm is capable of learning and evolving knowledge memes on two different problem domains that can share a common representation, the capacitated vehicle and arc routing problems. Thorough analyses and experimental results show that the evolutionary search can benefit from different relevant problem domains. The knowledge that a meme has is crucial for the search procedure. It was observed that low discrepancy in the common feature space, between the problem domains, is able to enhance the evolutionary search procedure.

Furthermore, a general-purpose hyper-heuristic approach has been proposed that has the ability to solve combinatorial problems with minimal effort [19]. A unified representation and a set of domain-independent low-level heuristics are essentially proposed under a hyper-heuristic framework. To demonstrate the generality of the approach, the framework has been applied on different problem domains that share common characteristics but vastly differ as applications. An analysis reveals that the unified framework is very competitive in performance with state-of-the-art tailor-made heuristics for each problem domain.

The aforementioned studies suggest that both high and low levels of abstraction in the problem domain can enhance the search efficiency of hyper-heuristics. Such approaches demonstrate the real power of hyper-heuristic techniques. It is possible

to develop approaches that have enough generality and efficiency to enable them to produce competitive performance against tailor-made search algorithms for either a given problem class or across problem domains.

Various recent developments include novel hyper-heuristics that operate across the main categories of hyper-heuristics. Such an approach was introduced in [13]. It combines both heuristic selection and generation approaches. Specifically, it incorporates a dynamic multi-armed bandit with extreme credit values to online select the most appropriate low-level heuristic for the problem on hand. In parallel, instead of using a fixed acceptance criterion, it gradually generates new acceptance criteria for each problem instance through a gene expression programming framework. The effectiveness and generality of the approach are evaluated on exam timetabling instances from the 2007 International Timetabling Competition and on dynamic vehicle routing problem instances from the literature. Empirical results suggest that the introduced method shows competitive and general performance across both domains, compared with several state-of-the-art algorithms.

An automatic design framework was introduced in [20]. It automatically generates high-level heuristics for hyper-heuristic methodologies. The framework utilizes a gene expression programming algorithm to create high-level heuristics during the searching process. It captures information from the current state of the given problem and determines the low-level heuristic selection rule, as well as the solution acceptance criterion. As such, possibly new high-level rules can be produced for each problem instance. Experimental analyses on six problem domains exhibit its generality and competitive performance with state-of-the-art hyper-heuristic methodologies across all problem domains.

Techniques have been developed that are capable of learning and self-adapting their behavior based on the learned knowledge. More specifically, a hyper-heuristic system that embraces the concept of lifelong learning has been considered in [14, 21–23]. The system is based on a self-reliant network of interacting components inspired by artificial immune systems. It has the ability to continuously learn over time how to solve combinatorial optimization problems. It is capable of generating new heuristics continuously as well as sample problems from its environment. The core of the system is adaptable to its environment and has the intelligence to save and learn characteristic problem instances and heuristics from it. These characteristics result in an intelligent platform that exploits existing knowledge and quickly generates promising solutions of a given problem, as well as generalizing and adapting to new unseen problems with different properties. A rigorous experimental analysis on the bin packing domain demonstrates its excellent performance and generalization capabilities across a wide range of different problem instances. The dynamic and adaptive nature of the system makes it computationally efficient and scalable.

Various studies have been proposed that carefully investigate intrinsic characteristics of hyper-heuristics, such as diversity in the heuristic space, or understanding the behavior of the low-level heuristics. In particular, in [24], the impact and effect of a diverse set of available heuristic algorithms on the performance of a

selection hyper-heuristic is studied. The study firstly makes an attempt to define and measure the diversity of heuristic spaces and then proceeds to investigate the impact in performance of a hyper-heuristic that utilizes various strategies to manage the measured diversity. The diversity concept is studied with a hyper-heuristic that employs as low-level heuristic various black box optimization methods that operate on continuous spaces (see also [25]). The evaluation of the proposed method on a wide range of benchmark functions suggests that the heuristic space diversity significantly impacts upon the performance of the method.

The performance of low-level heuristics plays a crucial role in the performance of a hyper-heuristic methodology. In [26], the authors try to understand the performance efficiency of each low-level heuristic when it operates individually or in combination with other heuristics. As such, the concepts of competence and affinity (in terms of heuristics) have been defined and qualitatively estimated on a problem-specific hyper-heuristic approach. The resulting information from this process is exploited and used to improve the performance of problem-specific hyper-heuristics for the hybrid flow-shop scheduling problem. The tailor-made hyper-heuristics exhibit promising performance on the studied instances.

In parallel, novel search approaches have recently been incorporated within hyper-heuristic approaches. A novel diversification method is introduced in [27]. The method perturbs the problem instance under investigation to create justifiable new search directions. As such, various low-level heuristics that act upon this idea are proposed under a hyper-heuristic framework. The low-level heuristics are guided through an expressive grammar high-level strategy that has the ability to easily satisfy the problem constraints and thus easily produce feasible solutions. An experimental evaluation and analyses on the Ising spin glass and the p-median problem demonstrate its efficiency and its competitive performance.

When considering selection hyper-heuristics, each of the available search low-level heuristics (to be selected) is scored by a credit assignment mechanism. The credit assignment mechanism is responsible for assigning a reward, or credit value, to the applied heuristic, based on measurable feedback from the search procedure. The feedback may represent a measurement or qualitative characterization of the applied heuristic effects on the current state of the search process. The role of the credit value is crucial for the performance of the hyper-heuristic search algorithm, since it is the main information that guides the search procedure. Recently, different new types of feedback information have been introduced, based on landscape analysis techniques.

In [28], the evolvability of a search operator has been considered. The evolvability metric uses local characteristics of the fitness landscape to approximate the potential of a search component to generate improved solutions, from the current state of the search. An experimental study on benchmark problems reveals that evolvability feedback has significant potential to improve the performance of a hyper-heuristic, when compared against simple fitness improvement feedback.

Additionally, a novel selection hyper-heuristic methodology has been introduced in [29] to address the Capacitated Arc Routing problem. In the higher level, an online learning algorithm has been considered, the Dynamic Weighted Majority

method, to predict and determine the most appropriate search mechanism. The learning mechanism selects a crossover operator from an available set. Each of the available choices does not rely on its ability to improve the fitness of the generated solution. Instead, each operator can be scored based on four different fitness landscape analysis techniques. The analysis takes into account dispersion and neutrality as well as evolvability measures. Extensive comparisons on a set of benchmark problems verify the efficiency of the proposed methodology against state-of-the-art techniques.

Automatic Design of Algorithms

A comparison of the fields of meta-learning and hyper-heuristics has been recently proposed in [30]. The study draws parallels between methodologies and concepts from the two fields and advocates the common objective of automating the algorithm design process. A brief historical overview of automated algorithm design is presented along with a discussion on the similarities and differences between supervised machine learning and hyper-heuristics. Various issues are discussed, including the different levels of automation and generality, the problem and algorithm space, and various measures of performance.

The automatic design process was used to generate simple, general, modular, and efficient Iterated Local Search-based methodologies in [31, 32]. The generated methodologies are very competitive with the state-of-the-art methodologies in domain-independent meta-heuristic search [32]. Other hyper-heuristics based on Iterated Local Search that have been recently proposed include [33] in addition to the case study presented in the sections below. In parallel, a novel grammar representation has been introduced in [34] to be used for the automatic design of heuristic algorithms for hard combinatorial optimization problems. The proposed representation of the grammar includes a sequence of categorical, integer, and real-valued parameters and incorporates an off-line parameter configuration tool to search for algorithms for a given problem. Extensive experimentation on one-dimensional bin packing and on permutation flow-shop problems demonstrates the efficiency of both the grammar and the parameter configuration tools against an established grammatical evolution algorithm for automatic design. An extension of the methodology was able to build more complex algorithmic schemes from a composition of problem-dependent and problem-independent grammars [35].

A unified selection hyper-heuristic framework that handles one- and two-dimensional regular packing as well as two-dimensional irregular packing and cutting problems has been proposed in [36]. The framework utilizes several different stages to generate fast algorithms with competitive performance against the best problem-specific heuristic for a given problem. The framework generates different hyper-heuristic algorithms, by representing them as variable-length chromosomes of low-level heuristics that are being evolved by a messy genetic algorithm. A data mining-based feature selection procedure is used to determine the most relevant features in the problem-state representation, and an off-line analysis is employed to

discover the most representative set of well-performing heuristics. The framework has been evaluated on a large set of problem instances, and the experimental results show that it is able to generate very competitive hyper-heuristics for the given problem. In addition, the performance of the produced hyper-heuristics is comparable or even better than the application of the single low-level heuristics on their own. Moreover, an automatic design process has been proposed to efficiently solve two-dimensional rectangular blocks for packing [37].

Recently, the commonalities of certain areas of memetic computing and hyper-heuristics have been reviewed in [38]. This has led to the development of a new framework that combines a multi-meme approach with an adaptive operator selection hyper-heuristic to address continuous optimization problems. The framework rewards and adaptively selects the most suitable heuristics/memes during the search procedure. Although it has a simple structure, it exhibits high-performance gains against state-of-the-art search algorithms in a wide range of benchmark problems.

To avoid stagnation to local optima solutions, a multi-objective formulation has been proposed to formulate the single-objective two-dimensional packing problem [39]. A new memetic algorithm along with a parallel hyper-heuristic approach has been introduced to search the new formulation of the problem. The behaviors of the proposed methodologies are analyzed, and experimental results on two-dimensional packing problem instances suggest that the parallel hyper-heuristic is very competitive since it has found new best solutions for some problem instances.

The effectiveness and generality of a well-designed hyper-heuristic approach that outperforms human-designed problem-specific algorithms are demonstrated in [40]. Specifically, an Iterated Local Search-based hyper-heuristic methodology that learns from feedback of the problem at hand and dynamically selects among the available search operators is developed. An off-line learning approach is compared and contrasted with an online learning model on a large set of real-world problem instances from the first and second international timetabling competition. The online learning approach demonstrates superior performance over the off-line (static) model and is competitive with the state-of-the-art algorithms in the field.

Recent Theoretical Results in Hyper-heuristics

Although there is a significant growth of research in the field of hyper-heuristics, most studies are empirical. The theoretical foundations of hyper-heuristics are largely unexplored. Prominent examples of recent theoretical work in the field include mostly runtime analysis. A rigorous runtime analysis of hyper-heuristics has been presented in [41]. The analysis considers selection hyper-heuristics that operate on a predefined set of low-level heuristics. It reveals that the combination of heuristics can lead to exponentially faster search than deterministically chosen heuristics for a given problem. However, the analysis shows that an appropriate mixing distribution should be carefully selected.

A runtime analysis on some very common learning mechanisms has been performed in [42]. In particular, the analysis considers the simple random, random

gradient, greedy, and permutation learning mechanisms in the case of selection hyper-heuristics. The analysis shows that the learning mechanisms behave similarly, which suggests that they do not necessary improve the performance of the hyper-heuristics in the studied cases.

Multi-objective Optimization

A wide range of real-world problems require high-quality decisions for more than one objective. In general, an effective multi-objective algorithm should possess good search characteristics in terms of both solution diversity and convergence on the Pareto-front set. Several very effective multi-objective search algorithms have been proposed in the literature. They have different search dynamics, characteristics, advantages, and disadvantages. Hyper-heuristic approaches have also been explored within the context of multi-objective search (multi-objective hyper-heuristics).

The choice function approach has been used as a selection hyper-heuristic for a number of years. Interestingly, it still continues to be a promising and effective approach. The choice function along with the great deluge and late acceptance as nondeterministic move acceptance mechanisms has been investigated to address multi-objective optimization problems in [43]. The method utilizes the hyper-volume metric during the move acceptance process to effectively guide the search in promising areas and enhance both diversity and convergence characteristics of the method. The proposed method has been applied to traditional multi-objective benchmark problems in addition to the vehicle crashworthiness design problem [44]. Experimental analyses and results indicate that the proposed hyper-heuristic approach has the ability and potential to efficiently solve continuous multi-objective optimization problems.

Similarly, a hyper-heuristic method that combines the strengths of three well-known multi-objective algorithms has been introduced in [45]. The proposed approach implements an online learning choice function as a selection hyper-heuristic to combine the underlying algorithms. The choice function adaptively ranks the performance of the algorithms and determines which algorithm to apply at the next step. The introduced hyper-heuristic framework exhibits very effective performance on a wide range of multi-objective benchmark functions and on a real-world problem case, the vehicle crashworthiness design problem. The employed online learning mechanism greatly enhances the performance of the hyper-heuristic algorithm which is able to efficiently combine and exploit the advantages of the multiple low-level multi-objective algorithms.

In parallel, a multiple evolutionary algorithm portfolio has been developed in [46]. This approach utilizes simultaneously multiple algorithms for solving multi-objective optimization problems. The performance of each algorithm is evaluated by a score function, and the hyper-heuristic approach selects which to apply in the next step based on its score. The developed approach exhibits promising results. Another example of a recently proposed hyper-heuristic has been presented in [47]. This method includes diversity-based techniques to solve the patrol scheduling problem.

The concept of adaptive operator selection in multi-objective algorithms was introduced in [48]. This utilizes state-of-the-art models for adaptive operator selection to select the most suitable operator at each stage of the algorithm. The methodology extends the well-known MOEA/D algorithm, which decomposes the multi-objective problems to single-objective problems and optimizes them simultaneously. Thorough experimental analyses indicate that the proposed methodology is robust, its performance is significantly better than other state-of-the-art multi-objective algorithms, and the operator selection process works effectively. Likewise, a hyper-heuristic approach has been recently incorporated into the Multi-Objective Particle Swarm Optimization algorithm [49]. This is a particle swarm optimization variant for multi-objective problems. Its main characteristic is that it has to employ a leader selection strategy and an archiving mechanism.

In [50], a genetic programming-based hyper-heuristic is proposed to solve the bi-objective aspect of the water distribution network design problem. The goal here is to find the optimal pipe sizes required by a network to provide best service with minimal costs. The objective of the proposed hyper-heuristic methodology is to generate efficient search operators (mutation operators) for multi-objective algorithms applied to solve the bi-objective formulation of the problem. Interestingly, the generated mutation operators reveal useful information for the designer. For example, an evolved operator incorporates domain-specific knowledge (pipe smoothing), while others are able to reproduce well-known operators from the literature. The methodology exhibits significant potential on various problem instances, while the evolved operators are general and can be used as new algorithmic components for future multi-objective algorithms. A further analysis of the strengths of various search operators along with the features of the problem is provided in [51].

Hyper-heuristics in Dynamic and Uncertain Environments

In the last few years, hyper-heuristic methodologies have been employed to address applications that are inherently dynamic and uncertain. This poses a major challenge for the research community since the majority of the developed methodologies that operate on static environments cannot easily cope with the dynamic and uncertain aspects of some applications. Various recent hyper-heuristic methodologies embrace adaptivity and are able to cope with dynamically changing problem scenarios.

A hybrid hyper-heuristic has been introduced to consider dynamic optimization problems [52]. This combines a selection hyper-heuristic and a memory/search algorithm. The hyper-heuristic is able to select between the available low-level heuristics for the problem instance in hand. To evaluate its performance efficiency, the following two problems have been considered: the dynamic generalized assignment problem and the moving peaks benchmark. Experimental results indicate that the hyper-heuristic framework performs significantly better than the memory/search algorithm in the majority of the tested cases. From the considered selection heuristics, the choice function with the only improving acceptance criterion seems

to have the most promising performance, since it is able to track changes in the environment and it can rapidly react to different types of changes.

An additional recent study on hyper-heuristics in dynamic environments includes [53]. This approach analyzes the performance of a hyper-heuristic methodology that utilizes specialized meta-heuristics across different types of dynamic environment. An interesting real-world problem with uncertainty has recently been efficiently addressed by a hyper-heuristic approach [54]. This is the online path planning for autonomous unmanned aerial vehicles. Online path planning is a challenging problem that includes problem scenarios in uncertain or unknown environments. A hyper-heuristic methodology has been implemented to navigate these unmanned vehicles using a 3-D online path planning model with sensing uncertainty. An experimental study on various terrains with different characteristics demonstrates the efficiency of the methodology to create efficient navigation path plans.

Machine Learning Methodologies

Machine learning methodologies play an important role in the field. Various methodologies have been incorporated mostly into the higher level of hyper-heuristics to learn the behavior of the underlying heuristics and to make effective decisions to guide the search procedure toward the most promising areas of the search space. In parallel, the automatic design concept in hyper-heuristics is widely applicable in the machine learning field to generate novel and more efficient machine learning methodologies for specific classes of problems or tasks. Recent advances include a wide range of methodologies.

A new machine learning approach based on tensor analysis was introduced in [55, 56]. It utilizes tensor analysis techniques and in particular tensor factorization to reveal latent relationships between the low-level heuristics and the hyper-heuristic. Intuitively, it models the history trace of the considered hyper-heuristic method and tries to identify the low-level heuristics that exhibit promising performance. Tensor analysis and factorization are employed to identify promising interactions and features between low-level heuristics as the search method operates, by observing feedback from the search history and performance. The method then exploits the knowledge learned to improve its overall search ability.

Inspired by Inverse Reinforcement Learning theory, the authors in [57, 58] explored apprenticeship learning for generalizing experts' behavior. Apprenticeship learning or imitation learning or learning by demonstration has been widely applied in control and robotic applications. The main goal of apprenticeship learning is to learn by observing experts while they are in action. Within the context of hyper-heuristics, apprenticeship learning has been applied to learn expert behavior in vehicle routing [57] and online bin packing problem domains [58]. The learning procedure has been trained with diverse experts on small problem instances, and it has been tested on larger instances with different characteristics to test its generalization ability. The learning procedure successfully captures experts' different actions and generalizes them on unseen problem instances. Experimental results

and analyses suggest that the novel learning mechanism demonstrates outstanding performance gains in both problem domains.

Monte Carlo Tree search has been used in [59] to search the space of low-level heuristics for various problem domains. In particular, it models sequences of low-level heuristics as trees and searches for optimal sequences to be applied at the corresponding state of the search procedure. Experimental results on six problem domains demonstrate the generality of the method as well as its competitive performance.

An automated design of classification algorithms tailored to deal with both balanced and imbalanced data has been proposed in [60]. This aims to automatically design decision-tree induction algorithms. A thorough analysis is firstly performed to determine the impact of different kinds of fitness functions on the performance of the proposed methodology for both balanced and imbalanced datasets. The best-performing fitness function is then used for the automatic design process. The evolved decision-tree induction algorithm is compared against traditional decision-tree induction algorithms on a wide selection of datasets. The experimental analysis suggests that the proposed method significantly outperforms the other methods.

A grammatical evolution-based hyper-heuristic has recently been introduced for designing automatically split criteria in decision trees for data classification tasks [61]. A hyper-heuristic evolutionary algorithm to automatically build Bayesian Network Classifiers tailored to a specific dataset [62] represents another recent addition to the literature.

Automated Parameter Control and Tuning

Automated parameter control represents one of the major applications of hyper-heuristics. A recent overview of the trends and future directions of the area can be found in [63].

Two interesting parameter control methods based on hyper-heuristics and fuzzy logic have been recently proposed in [64, 65]. They investigate the impact of solving single-objective optimization problems with multi-objective approaches. The utilized methodology is a bi-objective approach that uses diversity as a second objective. A probabilistic selection hyper-heuristic and a fuzzy logic method have been utilized to control the parameters of the bi-objective methodology. Experimental analysis on a wide range of problems reveals the efficiency of both parameter control methods against several static parameter settings and self-adaptive rules. Overall, the resulting method is computationally efficient and is able to outperform the single-objective scheme in most of the tested cases. A similar approach has been applied to address the frequency assignment problem [66]. Additionally, fuzzy system methods have been investigated as selection hyper-heuristics to control parameters [67]. Off-line parameter tuning has been employed to fine-tune and successfully generate efficient heuristics for online bin packing [68].

A reinforcement learning-based parameter controller has recently been published in [69] to dynamically adapt the control parameters of evolutionary algorithms. The

method is a generic and parameter-independent controller that can be easily adapted on any evolutionary algorithm. Experimental analysis that incorporates the proposed parameter control method on various state-of-the-art evolutionary algorithms, to address several continuous optimization problems, suggests that the method is capable of good performance. The controller is able to improve the quality of the solutions found by the algorithms with minimal effort and additional computational resources. Similar approaches include entropy-based controllers [70]. Furthermore, a recent study investigates the impact in performance of various feedback mechanisms that have been used for adaptive parameter control in evolutionary algorithms [71]. The study considers indicative feedback measures for both single- and multi-objective optimization problem formulations.

Time series prediction methodologies have recently been used [72] as parameter controllers to accurately predict suitable parameter values during the search process. In particular, various prediction methods have been utilized to predict future parameter values based on historical data from the search procedure. Evaluation of the considered methodologies on evolutionary algorithms suggests that the simple linear regression performs quite well, but without having a significant difference against the studied methods. The impact in performance of predictive parameter control methods is evident only when the performance data complies with the required assumptions of the prediction model, resulting in significant performance differences when compared against state-of-the-art parameter controllers. Otherwise, the prediction method does not exhibit any evident impact on the performance of the considered algorithm.

Hyper-heuristics for Scheduling Problems

As widely identified in previously published overview and survey articles [1–5, 7, 8], scheduling problems have played a major role in the development of hyper-heuristic approaches.

The automatic design of dispatching rules has been the subject of recent research attention because of the time-consuming process of manually designing such rules. An analysis of the representation of dispatching rules has been recently undertaken in [73]. The representation of dispatching rules essentially determines the search space and its complexity. As such, efficient representations highly impact upon the search process. Three different kinds of representations have been discussed in [73]: a linear combination of attributes, artificial neural networks, and a tree-based representation. Empirical analysis on the suitability of each representation in dynamic stochastic job-shop scenarios suggests that the tree representation, evolved with a hyper-heuristic genetic programming method, is the most efficient. Artificial neural network representations operate well mostly on processes with a small computational budget, while linear representations operate competitively only on quite small computational budgets.

Dispatching rules for semiconductor manufacturing have been also automatically generated with genetic programming [74]. Grammatical evolution has been suc-

cessfully applied as a hyper-heuristic methodology to address capacitated vehicle routing problems [75, 76]. Comparisons between adaptive and grammar-based hyper-heuristic approaches have been recently performed for various problem domains [77]. Moreover, a genetic programming-based hyper-heuristic has been considered in [78] to tackle order acceptance and scheduling problems in make-to-order manufacturing systems. This automatically generates dispatching rules that have stochastic behavior in order to improve the search procedure. The evolved rules exhibit high-performance gains compared to rules produced by either tailor-made heuristics or a simple version of the considered genetic programming method.

Several novel multi-objective genetic programming-based hyper-heuristics have recently been proposed that are able to generate scheduling policies in job-shop environments [79]. This paper proposes an automatic design approach to generate dispatching and due-date assignment rules for a dynamic version of the multi-objective job-shop scheduling problem. Having identified the complexity and the labor needed to manually design an effective scheduling policy, four multi-objective algorithms are developed to automate the process. All approaches are capable of handling multiple scheduling decisions in parallel. Thorough experiments and analyses demonstrate that the evolved Pareto sets represent effective scheduling policies that dominate policies from combinations of existing dispatching rules. These policies also have promising performance on unseen scenarios with various shop configurations. Generally all proposed methodologies exhibit not only effective but also very meaningful scheduling policies that help the decision-maker to understand their characteristics.

A two-phase search approach has been introduced in [80] to tackle the Workover Rigs Scheduling problem for maintenance services in onshore oil wells. The problem can be characterized as a parallel heterogeneous machine scheduling problem derived from the maintenance planning of heterogeneous wells. This problem is to find schedules for a small number of work-over rigs that minimize the production loss associated with the large number of wells waiting for service. The first phase of the proposed approach is a selection hyper-heuristic that searches for a promising initial solution to warm-start the second stage, which utilizes an exact branch, price, and cut approach. The considered hyper-heuristic uses learning mechanisms to learn from feedback during search and select the most effective low-level heuristic to apply in the next step. Having applied the abovementioned methodology to a variety of real-world problem instances from Petrobras, the Brazilian National Petroleum Corporation, the authors were able to identify classes of heuristics, which seem to be more efficient for solving the problem. In general, it was observed that the learning mechanisms were very effective and able to guide the search to promising areas of the solution space. It is worth noting that the hyper-heuristic approach generated solutions that were very near to the optimal solutions found by the exact algorithm.

An interesting analysis has been performed in [81] that investigates the performance impact of heuristics while solving a problem with routing and rostering characteristics. The implemented hyper-heuristics act as analysis tools on the heuristic behavior. The aim is to analyze the behavior of the available heuristics

and determine the requirements that a heuristic should consider to solve such problems. The following three different scheduling and routing problems have been considered: home care scheduling, routing and rostering of security guards, and maintenance personnel scheduling. The analysis revealed that some specific features of the problems under investigation significantly affect the performance of the heuristics. These features are the number of activities, the number of resources, and the planning horizon. The observed information of such analysis can be exploited and used in future search approaches to efficiently solve similar problems that share common characteristics. As such, hyper-heuristics can be employed as analysis tools for a particular problem class under investigation and may offer novel information on the characteristics of the problem class.

Nurse rostering is one of the applications where hyper-heuristics find wide applicability, with recent works including research in selection hyper-heuristics [82, 83]. A generic cooperative agent-based search framework has recently been introduced [84] that is able to incorporate the search strengths of various meta-heuristics to efficiently solve nurse rostering problems. The framework promotes the asynchronous cooperation of effective agents using pattern matching and reinforcement learning techniques. This enables the exploration of different fairness objectives across several real-world rostering problem instances. A thorough experimental analysis demonstrates the efficiency of such frameworks to generate high-performance rostering solutions in minimal time.

Several hyper-heuristic methodologies draw upon swarm intelligence techniques, such as particle swarm and ant colony optimization. A particle swarm optimization-based hyper-heuristic approach has been introduced to address the resource-constrained project scheduling problem [85]. This operates on the heuristic space by representing its particles as ordered sequences of heuristics to apply for the given problem. Subsequently, a feasible solution is constructed by a serial scheduling construction mechanism, while the generated solution is improved by double justification local search. Several problem instances from the well-known PSPLIB library have been used to test and compare the hyper-heuristic algorithm with other algorithms. Computational results verify its efficiency and competitive performance.

The problem of intercell scheduling with single-processing machines and batch-processing machines has been tackled in [86] with an ant colony optimization hyper-heuristic search method. Generally, intercell transfers in cellular manufacturing systems are essential to substantially reduce production costs. The formulation of this scheduling problem considers the following three subproblems in parallel: an assignment, a sequencing, and a batch subproblem. An ant colony hyper-heuristic has been adapted to search among different assignment heuristic rules for both parts and machines simultaneously. Subsequently, the discovered rules are applied to generate schedules. The efficiency of the proposed method is evaluated on randomly generated problem instances. The experimental results indicate that the method is significantly more efficient than CPLEX and genetic algorithms. Channel scheduling in multicell networks has also been addressed recently with hyper-heuristic methodologies [87].

A novel hyper-heuristic methodology has been proposed in [88] to solve task scheduling in cloud computing systems. Usually, rule-based scheduling algorithm is used for task scheduling in such systems. The method presented here is able to learn from the performance of several available scheduling algorithms and select the most suitable algorithm to apply. It incorporates a diversity and fitness detection strategies to efficiently balance the diversification and intensification behavior of the search procedure. This approach significantly outperforms several state-of-the-art scheduling algorithms on both simulation and real system scenarios. It produces solutions that have a significantly better makespan compared against other scheduling algorithms.

The problem of resource provisioning-based scheduling tasks in large-scale distributed environments, such as grids, has been addressed by exploring a hyper-heuristic scheduling method [89]. The main goal of this methodology is to efficiently schedule jobs on the available resources in order to simultaneously minimize execution time and increase security and reliability. The proposed hyper-heuristic algorithm is a particle swarm optimization-based algorithm that has been specifically developed to efficiently schedule jobs on available resources while addressing security requirements and constraints. A thorough experimental analysis reveals that the hyper-heuristic algorithm outperforms the state-of-the-art approaches, in terms of minimizing time, cost, and the makespan of the scheduling process.

Hyper-heuristics also have wide applicability in transportation scheduling. Motivated by a real railway-based disaster transportation relief scenario in the area of China, a selection hyper-heuristic search method [90] has been proposed to tackle emergency railway transportation problems. The evolutionary hyper-heuristic utilizes various search strategies as low-level heuristics and rewards each search strategy by assessing its ability to generate successful movements in the search space. The method has been compared with various state-of-the-art evolutionary algorithms on several problem instances, which have been created from disaster rescue operations data in China. Experimental results show high-performance gains across all instances against the considered evolutionary algorithms. The method has also been successfully applied on a real emergency during the 2013 Dingxi earthquake in China, producing a very satisfactory solution.

Another recent application of hyper-heuristic methodologies is the dial-a-ride transportation problem with time windows [91]. This is concerned with scheduling a set of available vehicles to pick up customers from an origin location and deliver them to a destination. It considers a range of constraints. The proposed hyper-heuristic methodologies are efficient and result in competitive performance against state-of-the-art approaches from the literature. Moreover, cooperative hyper-heuristics have been successfully applied to bus driver scheduling problems [92].

Recent Educational Timetabling Applications of Hyper-heuristics

A recent overview and critical analysis of the literature on the hyper-heuristic methodologies applied to educational timetabling problems have been published in

[6]. The article focuses on the hyper-heuristic research in three general educational timetabling problems, the university examination, the university course, and the school timetabling problems, as well as proposes several future research directions on the subject.

An estimation of distribution algorithm has recently been introduced [93] as a general hyper-heuristic approach to address exam timetabling problem instances. The objective was to develop a hyper-heuristic with increased generality over different problem instances. The hyper-heuristic operates on sequences of low-level exam-selection heuristics that construct a timetable, based only on non-domain-specific knowledge. The resulting algorithm is capable of guiding the search to very promising areas. It generates efficient sequences of timetabling heuristics. Experimental results on various real-world exam timetabling and graph coloring problem instances suggest that the hyper-heuristic is generic across all problem instances, with competitive performance against other hyper-heuristic approaches. In addition, the developed approach is capable of learning the most promising heuristic for the problem at hand.

A two-stage hybrid hyper-heuristic approach has recently been proposed to solve timetabling problems [94]. The two-stage hybrid approach utilizes a Kempe chain move heuristic and the time-slot swapping heuristic as search operators. Firstly, it generates and automatically analyzes random heuristic sequences. The analysis keeps the repeated heuristics of the best sequence and empties the remaining positions to be processed in the next stage. The second stage randomly assigns sequences if heuristics are in the empty positions in order to search for high-quality sequences of heuristics. The constructed ones are used for the given problem. The hybrid method is evaluated on two challenging sets of problems, the Toronto benchmark and the exam timetabling set of problems from the second International Timetabling Competition. The method exhibited competitive performance against the state-of-the-art methodologies for both problem sets.

New selection hyper-heuristic approaches that are based on simple stochastic search methods have exhibited outstanding performance in the recent high school timetabling competition [95]. Indeed, such approaches have provided exceptional results and new best solutions to very challenging problem instances. A hybrid hyper-heuristic which utilized sequences of low-level heuristics has also been applied recently in examination timetabling problems [96].

Games and Education

Hyper-heuristic methodologies have recently been proposed in the areas of games and education. A recent study focuses on solving the Jawbreaker puzzle [97]. The evolutionary process operates on the low-level heuristic space and produces sequences of low-level heuristics that can be applied to solve the given puzzle. The resulting methodology is able to efficiently solve instances of the puzzle with various sizes and levels of difficulty, including very difficult levels.

An educational game-based software tool has been introduced in [98] to teach the intrinsic operational characteristics of hyper-heuristics to engineering students. The tool is based on the Bubble Breaker puzzle, and it represents a strong synergy with the concept of selection hyper-heuristics. In addition, a hyper-heuristic method is used, under a context-aware ubiquitous learning environment, to maximize the learning efficacy of students [99]. The main goal of the search method is to locate quality learning paths for students by considering real-world context and constraints. The proposed approach is evaluated on real-world scenarios.

Other Recent Developments

The general character and the wide applicability of hyper-heuristics enable them to efficiently address a wide variety of applications. Here, the most recent developments in various scientific fields are presented, from linear algebra to aircraft structural design applications. A genetic programming-based hyper-heuristic is introduced in [100] to evolve the structure of the Sloan algorithm that aims to find a reduced envelope size of matrices. The envelope is the sum of the distances between each element of the matrix and its main diagonal. Its size has a major impact on the performance of large linear systems solvers. The best evolved algorithm (with the addition of a local search method) exhibits substantial performance gains and significantly outperforms state-of-the-art algorithms in the literature on classic problem sets.

The magic square problem has been efficiently tackled by a wide range of selection hyper-heuristic approaches [101] that utilize perturbative low-level heuristics.

A modified version of the well-known and widely used choice function has been successfully hybridized with a late acceptance strategy hyper-heuristic to tackle the multidimensional 0–1 knapsack problem [102]. In addition, a stochastic hyper-heuristic version of the choice function has been utilized to address the winner determination problem in [103, 104].

Another interesting application of hyper-heuristics is the real-world warehouse storage location assignment problem [105], in which a genetic programming methodology is employed to generate matching functions that guide the selection of subsets of items for a given problem. The methodology is able to locate high-quality solutions on the training problem cases. It is also able to perform well on unseen scenarios in the testing phase. This indicates that the evolved heuristics are reusable and can be directly applied to similar problem scenarios. Furthermore, aircraft structural design optimization problems have recently been efficiently addressed by hyper-heuristic methodologies [106, 107].

The problem of distributing resources among multiple threads in a processor has been studied in [108]. A learning hyper-heuristic that predicts the best-performing heuristic between a set of available heuristics has successfully been applied to the problem. On average, its performance is comparable or significantly better than the state-of-the-art techniques in the field.

Case Study: A Selection Hyper-heuristic-Based Iterated Local Search

In this section, a simple selection hyper-heuristic framework is demonstrated to provide a tutorial-style introduction to hyper-heuristic development. Specifically, a hyper-heuristic framework is developed that is based on the well-known Iterated Local Search algorithm. The development process and the decisions that had to be made during implementation are briefly discussed (section "Iterated Local Search with Adaptive Heuristic Selection"). The framework implements an action selection model that operates on the Iterated Local Search algorithm to adaptively select among various search low-level perturbation heuristics (section "Action Selection Models"). It is based on the HyFlex platform which can be used to easily implement prototypes of hyper-heuristic search methods without having to be concerned about the implementation of problem domain low-level heuristics (which are available from the HyFlex site) (section "The HyFlex Framework").

The HyFlex Framework

HyFlex is a Java-based software framework that enables the easy development and testing of cross-domain hyper-heuristic search methodologies. The framework implements a common software interface to provide all the essential ingredients for easily developing a general-purpose search algorithm, without having to implement specific problem domain knowledge.

The framework implements six different combinatorial optimization problems, namely, maximum satisfiability (Max-SAT), one-dimensional bin packing, personnel scheduling, permutation flow-shop scheduling, the traveling salesman problem, and the vehicle routing with time windows problem. For each problem domain, there are 10–12 available problem instances, including both challenging benchmark and real-world industrial problem instances. The framework additionally exposes the user to a broad set of state-of-the-art low-level heuristic search operators with different search dynamics and characteristics. For all problem domains and all instances, appropriate evaluation functions have been implemented to easily evaluate generated solutions.

HyFlex currently has two main versions, 1.0 and 1.1. The first version includes the main functionality described above, while the second version adopts the concept of batch-mode hyper-heuristics, i.e., allowing the developed hyper-heuristic methodology to operate on a whole set of instances for each run, instead of using a single instance. A description of the APIs and documentation for both versions can be found in [109, 110] and in [111–113]. The HyFlex framework has been utilized in two cross-domain search challenges, CHeSC 2011 [111] and CHeSC 2014 [112].

In this chapter, the first version of the framework has been adopted to develop the hyper-heuristic presented in the next section.

Iterated Local Search with Adaptive Heuristic Selection

This section discusses the motivation (and provides a detailed description) for designing a simple and general applicable hyper-heuristic search algorithm. However, the main purpose of this section is not to design a hyper-heuristic that has the best performance obtained in the literature so far. Instead, the goal of this section is to demonstrate how a simple search algorithm can be seen as a general hyper-heuristic approach. Moreover, it aims to show how the search algorithm can easily be applied to different problem domains without considering many unusual and made-to-measure design choices. The resulting approach can be easily fine-tuned on the application domains at hand and produce state-of-the-art performance gains [31, 32, 34].

The developed approach is based on a simple, general, and highly successful local search algorithm, the Iterated Local Search algorithm [12, 114, 115]. Iterated Local Search (ILS) is a single-point local search method that belongs to the wide category of stochastic local search methods [12]. The main idea behind its structure is to "iteratively create a sequence of potential solutions produced by a given heuristic search method, that leads to much better solution quality, than performing repeated random executions of it" [12, 114, 115]. In general, ILS includes four main stages in its structure. Firstly, ILS generates an initial solution for the problem at hand and then iteratively improves the current solution by applying a diversification (perturbation) and an intensification (local search) operation. Diversification is accomplished by applying a perturbation heuristic on the current solution, while intensification is achieved by employing a local search method on the perturbed solution. Having performed these two search operations, ILS determines whether the new solution is accepted to the next iteration, via an acceptance criterion. As such, in order to create an effective ILS variant, one should carefully determine the perturbation heuristic, the local search, and the acceptance criteria. A vast amount of available choices for various problem domains can be found in the literature [12, 114, 115].

Notice that the strength of perturbation heuristics varies among the available heuristics and greatly influences the behavior of the algorithm. For example, strong perturbations vastly increase the diversification of the search and might lead to a random restart-like behavior, i.e., there is a very low probability to find better solutions. In contrast, perturbations with small strength might lead to very similar solutions that will not help the local search procedure find a better solution. Instead, the local search might revisit its previous solutions. Similarly, acceptance criteria can influence the balance between the intensification and diversification search abilities of the algorithm. For example, the acceptance of improving solutions will increase the intensification behavior of the algorithm, while accepting worsening moves will increase diversification.

Naturally, several ILS variants adapt their search strategies as well as their properties during the search procedure to react on the respective stage of the search. Representative reactive search principles can be found in [12, 114, 116].

Arguably this is the essence of a hyper-heuristic methodology [1–8]. Motivated by these findings, this approach is adopted to develop a simple and general hyper-heuristic search framework and apply it to various problem domains. In particular, a simple framework of Iterated Local Search-based hyper-heuristic (HHILS) is implemented to exhibit the development process and the design choices that an interested researcher, or practitioner, might be faced with during the development phase of the hyper-heuristic search methodology.

In general, the HHILS framework follows the basic algorithmic structure of an Iterated Local Search methodology and enhances its reactive search ability with an action selection and a credit assignment module. The action selection module is devoted to efficiently predict and select the most suitable action to apply in the next step, while the credit assignment module is responsible for assigning a reward, or a credit value to the applied action, based on feedback from the search procedure. Arguably, the action selection module can be applied on any level or combination of levels within the search procedure, i.e., it can select among different perturbation heuristics, local search methodologies, and acceptance criteria, or any possible combination of them. This design choice is based on the level of adaptivity or reactivity that the researcher/practitioner is willing to incorporate in the search algorithm. In many cases, this decision will have a major impact on the performance of the resulting search methodology, since the adaptive procedure may rapidly change the dynamics of the search procedure, i.e., the diversification and intensification levels of the search. Here, a simple case is adopted in which the action selection module will operate only in the perturbation phase of the algorithm, i.e., it will be able to select from a set of available perturbation low-level heuristics.

The selected and applied action is scored based on the credit assignment module. The main role of the credit assignment module is to assign a reward, or credit value, to the applied action, based on feedback from the search procedure. The feedback can be seen as one or more measurements (or qualitative characterizations) of the applied action effects on the current state of the search process. The most common measurement for a search action is the quality improvement of its state (e.g., the difference in fitness value between the previous and the current state). However, various other qualitative different characterizations may be used, such as ranking successful movements [117], and evolvability [28, 29] of the search procedure. Such feedback is able to change the search characteristics of the algorithm and thus guide the search based upon different objectives. For example, the resulting algorithm will have more diversification characteristics or will avoid stagnating during the search procedure. Arguably, the quality of the feedback has a major impact on the performance and the success of the action selection model. As such, the literature includes various different attempts to investigate the impact of different feedback characterizations, like fitness improvement [117–120], successful movements [121], rank based improvements [117], and evolvability [28, 29]. The selected feedback for the HHILS framework is based on the mean improvement of the applied perturbation heuristics and will be explained in detail below.

Algorithm 1: Pseudo Code of the HHILS Framework of ILS Based Hyper-heuristics

1: Initialize the action selection, and the credit assignment module as well as create all data structures required by HHILS.
2: $s_{cur} \leftarrow$ GenerateInitialSolution() /* **Generate Initial Solution:** Initialize or construct a solution for the problem instance at hand. */
3: **while** termination criteria do not hold **do**
4: selected$_{llh} \leftarrow$ ActionSelection(str) /* **Action Selection:** Select a low-level heuristic with the str-th action selection model. */
5: $s_{tmp} \leftarrow$ ApplyAction(s_{cur}, selected$_{llh}$) /* **Perturbation:** Perturb the current solution (s_{cur}) with the selected low-level heuristic (selected$_{llh}$). */
6: $s_{tmp} \leftarrow$ ApplyLocalSearch(s_{tmp}) /* **Local Search:** Apply a local search procedure on the temporary solution s_{tmp}. */
7: $s_{cur} \leftarrow$ AcceptanceCriterion(s_{cur}, s_{tmp}) /* **Acceptance:** Accept which solution, between s_{cur}, and s_{tmp}, will survive to the next iteration based on an Acceptance criterion. */
8: CreditAssignment(selected$_{llh}$) /* **Credit Assignment:** Score the used action (selected$_{llh}$) based on feedback from the problem at hand. */
9: **end while**
10: **Return:** the best solution found so far s_{cur}.

A family of different HHILS variants can be easily produced by adopting new action selection models and different credit assignment feedback functions. Algorithm 1 presents the general structure of the HHILS framework. Although some design choices have been made based on specific details related to the HyFlex framework (which was used for the implementation of HHILS), the algorithmic structure of the HHILS framework is relatively general and can be easily adapted to any other available framework.

HHILS firstly initializes all the necessary modules and data structures that are required by the algorithm to run properly (line 1 of Algorithm 1). This procedure includes the initialization of the credit assignment module with an empty or zero initial reward as well as the initialization of the action selection module that sets all actions to have equal chances to be selected. Next, HHILS initializes a solution (s_{cur}) for the problem instance at hand (line 2). The initial solution can be either generated randomly or constructed with a constructive heuristic. This depends on the problem domain and the available method to initialize, or construct, a feasible solution. HyFlex provides such functionality for all problem domains which is convenient for easily constructing an initial solution independently of the problem domain.

Having found an initial solution, each iteration of HHILS performs the following five main steps. Let set $\mathcal{S}$ define the κ available perturbation low-level search heuristics $\mathcal{S} = \{llh_1, llh_2, \ldots, llh_\kappa\}$, for the problem domain in hand. In HyFlex, the

developer has the option to select between greedy and non-greedy heuristics. Here, all available non-greedy heuristics for the current domain have been considered, which correspond mainly to *mutation*- and *ruin-and-recreate*-type-based heuristics. HHILS employs an action selection method (`ActionSelection`(*str*), line 4) to predict and select the most appropriate perturbation low-level search heuristics to apply at the next step (selected$_{llh} \in \mathcal{S}$). The `ActionSelection` method might include various models, such as uniform selection and proportionate selection based on the reward values. The user is able to define which model to use with the *str* variable $str \in \mathcal{M}$, where $\mathcal{M}$ is the set of the available m action selection models, $\mathcal{M} = \{\mu_1, \mu_2, \ldots, \mu_m\}$. Section "Action Selection Models" briefly describes the models used in this chapter.

After selecting the selected$_{llh}$ perturbation low-level heuristic, HHILS proceeds with its application on the current solution s_{cur} to perturb its current position and create a new solution, s_{tmp} (line 5). The new position (s_{tmp}) is being immediately refined by the `ApplyLocalSearch`(s_{tmp}) procedure, which applies a greedy local search heuristic. In HyFlex, greedy local search heuristics belong in the *local search* category and have the property that they are not able to produce a worse solution than the given one. To avoid making a poor choice for the current problem instance, all of the available local search methods are applied in an iterative way [32]. More specifically, given a list $\mathscr{L}$ of the available λ local search heuristics, $\mathscr{L} = \{l_1, l_2, \ldots, l_\lambda\}$, at each iteration, a local search method is selected in a uniform random way and is applied to the current solution (s_{tmp}). If the application of the selected local search method does not lead to a better position (fitness improvement), it is excluded from the active list, until another local search heuristic finds an improved solution. If all the local search methods in the active list do not lead to an improved solution, then a local optimum has been reached. In this case, the iterative process will finish with the best solution found so far (s_{tmp}). The algorithmic scheme of the iterative local search procedure is illustrated in Algorithm 2.

Having applied the aforementioned transformations on s_{cur}, a new temporary solution s_{tmp} has been created. In the next step, HHILS employs an acceptance criterion `AcceptanceCriterion`(s_{cur}, s_{tmp}) (line 7 of Algorithm 1) procedure that is responsible to decide which of the two solutions will be accepted for the next iteration. In the literature, there are various choices available for the acceptance criterion [12], where the most common ones are to accept only improved solutions or to accept worsening solutions based on a probability distribution. These criteria will affect the diversification and intensification abilities of the current search method, for the given problem. Their impact depends on the landscape structure of the problem at hand. HHILS utilizes a Metropolis-based acceptance condition that accepts a worse solution based on a probability distribution. Intuitively, the greater the fitness improvement, the greater the probability, or the greater the worsening fitness, the smaller the likelihood to accept the worse solution. A representative example of such an acceptance condition is the simulating annealing method [122].

Algorithm 2: Pseudo Code for the HHILS `ApplyLocalSearch(`s_{tmp}`)` Method

1: $\mathcal{L}_{active} \leftarrow \mathcal{L}$
2: **while** $\mathcal{L}_{active}$ is not empty **do**
3: $i \leftarrow$ uniformly random select a local search from $\mathcal{L}_{active}$
4: $s_{ls} \leftarrow l_i(s_{tmp})$: Apply l_i local search on s_{tmp}
5: **if** $f(s_{ls}) < f(s_{tmp})$ **then**
6: $s_{tmp} \leftarrow s_{ls}$
7: **else**
8: $\mathcal{L}_{active} = \mathcal{L}_{active} \backslash \{i\}$
9: **end if**
10: **end while**
11: **Return:** the best solution found so far s_{tmp}.

Specifically, the probability density function of acceptance is defined as $p(f(s_{cur}), p\left(f\left(s_{cur}\right), f\left(s_{tmp}\right), T, \mu_i\right) = e^{\frac{f(s_{cur})-f\left(s_{tmp}\right)}{T \cdot \mu_i}}$, where $f(s_{cur})$ and $f(s_{tmp})$ are the objective value of the s_{cur} and s_{tmp} solutions, respectively, T is a constant temperature value with $T \in \mathbb{R}$, and μ_i is the mean improvement of the improving iterations [32]. The role of μ_i is to normalize the objective value difference by a quantity that does not depend on the problem at hand. Notice that the value of the temperature parameter is problem dependent and has to be fine-tuned for the considered problem in order to obtain optimal performance. Here, the temperature is fixed in all experiments to $T = 2$. A short and interesting study on the temperature behavior can be found in [32].

By this stage, HHILS has finished with the searching operations, and the applied low-level perturbation heuristic can be scored based on its search behavior. The final step of HHILS, before proceeding to the next iteration, is to employ the credit assignment module `CreditAssignment(`$selected_{llh}$`)` to score the selected perturbation heuristic, $selected_{llh}$ (line 8 of Algorithm 1). As such, HHILS defines the reward of an action as the improvement moves performed by the action, normalized by the total time it spends on them. Such a reward is a representative score for the improvement rate of each action over the time spend for each improvement. Specifically, let $\mathcal{A} = \{a_1, a_2, \ldots, a_\alpha\}$ be the available set of α actions (note that in HHILS $\mathcal{A} = \mathcal{S}$) and t_{α_i} be the time consumed by action α_i on searching the solution space (initially $t_{\alpha_i} = 0, \forall \alpha_i \in \mathcal{A}$). Then at each iteration, the time spent for the applied action, i, is calculated as $t_i = t_i + t_i^{spent}$, where t_i^{spent} is the time of action i spent on the current iteration. The reward value (r_i) of the applied action (i) can be calculated according to $r_i = \frac{1+improvement_i}{t_i}$, where $improvement_i = f(s_{cur}) - f(s_{tmp})$. In general, various different reward approaches can be used at this point, such as the instantaneous latest reward or the average or a ranked-based reward [117]. However, some of them tend to be unstable and noisy

estimations of credit due to the stochastic nature of the search process. To alleviate this drawback, the empirical quality of an action is estimated by utilizing the average value of a sliding window of its latest w rewards. More specifically, let W_i be a set of the latest w improvement rewards (r_i) achieved by the action a_i during the time step t of the hyper-heuristic. The final credit assignment value $r_{a_i}(t)$ is the average reward of the sliding window W_{a_i}, which can be determined by

$$r_{a_i}(t) = \frac{\sum_{j=1}^{|W_{a_i}|} W_{a_i}(j)}{|W_{a_i}|} \tag{1}$$

where $|W_{a_i}|$ indicates the cardinality of the set W_{a_i}.

Finally, the algorithm will iterate until one or more termination criteria hold. Here, the maximum allowed CPU wall clock time is used as termination criterion, $t_{allowed}$, which the algorithm may consume to solve the problem under investigation. It is worth noting that the HHILS framework does not consider whether the algorithm gets trapped in a particular position of the solution space for a long period of time. This is a very common situation in which either the algorithm is in a local optimum or the search operators are not able to find a better solution for a long period of time. In such cases, a restarting procedure is essential to help the searching capabilities of the algorithm to diversify the current solution. However, a restarting procedure requires specific design choices that for the sake of simplicity are overlooked in this tutorial demonstration.

Action Selection Models

As discussed previously, HHILS is a general framework that has the ability to adopt any action selection model. The literature includes various action selection models from different scientific fields such as statistics, filter theory, artificial intelligence, and machine learning. Each model has different advantages and disadvantages that depend on the properties of the underlying reward distribution that it is trying to predict. Representative examples of such models that have been used for this purpose include probability matching [123, 124], adaptive pursuit [123, 124], statistical-based models like the multinomial distribution with history forgetting [118, 121], evolutionary meta-learning methods [125–128], and reinforcement learning approaches [117, 129, 130].

In this chapter, five different models have been utilized: the uniform selection model, the proportional selection model, the probability matching [123, 124], the adaptive pursuit [123, 124], and the upper confidence-bound multi-armed bandit methodology [117, 130].

The first two models are very simple and act as baseline models for the HHILS framework. The uniform selection model simply selects between the available actions randomly by following a uniform distribution. In this case, the scores

assigned to each action do not have any impact on the selection process. This is the baseline methodology that will provide insights into the usefulness and impact of applying an action selection model on HHILS. Notice that several studies have identified the usefulness of random variation in either action or parameter spaces [63, 131, 132]. The second model performs proportional selection among the available actions based on their assigned scores from the credit assignment module. Intuitively, this model provides proportional chances to each action based on their reward scores during the optimization phase, i.e., the most successful will have more chances to be selected again in the next step. The proportional selection is performed by applying a simple roulette wheel selection [133].

Probability matching (PM) [117, 123, 124] is a simple probabilistic model that updates the selection probability of each action proportionally to its empirical quality with respect to the other actions. Specifically, given a set $\mathcal{A} = \{a_1, a_2, \ldots, a_\alpha\}$ of the available α actions (here $\mathcal{A} = \mathcal{S}$), let $P(t) = \left\{p_{a_1}(t), p_{a_2}(t), \ldots, p_{a_\alpha}(t)\right\}$ be the selection probability vector of all actions, where initially $p_{a_i} = 1/\alpha, \forall a_i \in \mathcal{A}$. After the application of the perturbation, the local search, and the acceptance criterion stages, a reward $(r_{a_i}(t))$ is measured from the credit assignment module. Notice that in the general case, the reactive procedure operates on a nonstationary environment where the estimation of the empirical quality of an action might be more accurate and reliable if the more recent rewards influence the empirical quality more than the past ones. Therefore, in such cases, it is a common practice by various action selection models to estimate the empirical quality $q_{a_i}(t)$ of each action (a_i) in accordance with the following relaxation mechanism:

$$q_{a_i}(t+1) = q_{a_i}(t) + \gamma \left(r_{a_i}(t) - q_{a_i}(t)\right). \tag{2}$$

where $\gamma \in (0, 1]$ is the adaptation rate (here γ is fixed to 0.1) [117, 123, 124]. Having calculated the empirical quality of each action (a_i), PM adapts its selection probability (p_{a_i}) using the following rule:

$$p_{a_i}(t+1) = p_{\min} + (1 - \alpha \cdot p_{\min}) \frac{q_{a_i}(t+1)}{\sum_{i=1}^{\alpha} q_{a_i}(t+1)} \tag{3}$$

where $p_{\min} \in [0, 1]$ is the minimum probability value of each action. $p_{\min}$ is responsible for ensuring that each action will always have a small probability (here $p_{\min} = 0.05$) [123, 124]. Having estimated the probabilities of each action, PM utilizes a stochastic proportional selection mechanism, based on these probabilities, to select which action will be applied in the next step.

Notice that PM allows the inefficient actions to have at least $p_{\min}$ selection probability. Thus, the best action will be selected with probability $p_{\max} = (1 - (\alpha - 1) \cdot p_{\min})$ However, this hinders the efficiency and performance of PM, since all inefficient actions keep being selected. Therefore, the adaptive pursuit (AP) strategy [123, 124] addressed this drawback by embracing a winner-takes-all strategy. In detail, AP, instead of updating proportionally the action probabilities, increases the probability of the corresponding best action $(a_{i^\star})$, while in parallel, it

decreases the probabilities of the other actions according to the following equations:

$$a_{i^\star} = \arg \max_{i=1,2,\ldots,\alpha} \left\{ q_{a_i}(t+1) \right\} \tag{4}$$

$$p_{a_i}(t+1) = \begin{cases} p_{a_i}(t) + \beta \left(p_{\max} - p_{a_i}(t) \right), \text{ if } a_i = a_{i^\star} \\ p_{a_i}(t) + \beta \left(p_{\min} - p_{a_i}(t) \right), \text{ otherwise} \end{cases} \tag{5}$$

where $\beta \in [0, 1]$ is a learning rate that manipulates the greediness of the winner-takes-all strategy (here $\beta = 0.8$). Intuitively, AP first finds the best action of the current step and then updates the probabilities by being in favor of the best action.

The last action selection model used in this chapter formulates the action selection model as a multi-armed bandit (MAB) problem and utilizes the upper confidence-bound (UCB) algorithm to solve it. The MAB problem considers κ one-arm slot machines and a player that has to decide which arm to pull, how many times to pull it, and in which order to choose between the available arms, having in mind that each machine provides a random reward. Intuitively, the MAB problem faces the well-known trade-off of *exploration* versus *exploitation*, where each time the player has to decide either to "exploit" its current knowledge, i.e., to pull the arm that gives the highest expected payoff, or to "explore" the available choices, i.e., to acquire more information about the expected payoff of the other arms.

More specifically, let us have κ arms (one-arm slot machines), where each arm (i-th) has a fixed unknown reward probability $p_i \in [0, 1], \forall i \in \{1, 2, \ldots, \kappa\}$. Assume that the arms are independent and that the associated rewards with each arm are independently and identically distributed. At each time step (t), the player selects an arm (j) and obtains a reward $r_t = 1$ with probability p_j or $r = 0$ otherwise. At any stage of the procedure, the performance of the MAB algorithm is estimated either by calculating the cumulative reward at the current stage or by employing a regret measure, i.e., the difference in performance between the current and the best arm. As such, the main objective of the selection algorithm at any stage is to either maximize the cumulative reward of the procedure or minimize its regret. In such a context, an "optimal" algorithm will have the best possible performance if at each time step it is able to select the best (unknown) arm, i.e., the arm with the maximum probability of obtaining a reward.

The upper confidence-bound (UCB) algorithm is implemented to solve the MAB problem [117, 129, 134]. It is worth mentioning that UCB achieves an optimal regret rate on the aforementioned formulation. Specifically, let $q_{a_i}(t)$ be an estimation of the empirical quality of action a_i on time step t, and let c_i be a confidence interval associated with the empirical quality of action a_i that depends on the amount of times $n_i(t)$ action i has been tried until the current step t. Then, at each time step, UCB deterministically selects the next action ($selected_{llh}$) with the optimal upper bound of the confidence interval c_i. The selection process can be calculated according to

$$selected_{llh} = \arg \max_{i=1,2,\ldots,\alpha} \left(q_{a_i}(t) + \mathbf{C} \cdot \sqrt{\frac{2 \log \sum_k n_k(t)}{n_i(t)}} \right). \tag{6}$$

$$n_i\,(t+1) = n_i(t) + 1 \tag{7}$$

$$q_{a_i}\,(t+1) = \frac{(n_i(t)-1) \cdot q_{a_i}(t) + r_{a_i}(t)}{n_i(t)} \tag{8}$$

where $\mathbf{C}$ is a user-defined scaling factor that balance the trade-off between exploitation and exploration ability of the model (here $\mathbf{C} = 0.8$). Intuitively, the first term of Eq. 6 favors the action with the best empirical quality (exploitation), while the second term benefits the trial of the other actions (exploration). UCB thus selects mostly the action that potentially provides the best reward, while giving the opportunity for infrequently tried actions to be applied regularly.

An analysis of the behavior and adaptability of the applied models should provide useful insights into the behavior of each model and its impact on the respective algorithm that incorporates it. However, this issue is beyond the scope of this tutorial chapter.

Computational Results

This section demonstrates a thorough analysis of the performance of the developed hyper-heuristics by evaluating them on a wide range of problem domains with different characteristics. The experimental protocol used in the experiments is firstly defined, and then two qualitative different analyses are presented. The first study provides comprehensive experimental results and statistical analyses of the developed hyper-heuristics on each of the considered problem domains separately, while the second study follows the experimental protocol used in the CHeSC 2011 [1] competition and compares the developed hyper-heuristics with the state-of-the-art approaches of the competition.

Experimental Protocol

Five different hyper-heuristic approaches have been developed that are based on the HHILS framework described previously in section "Iterated Local Search with Adaptive Heuristic Selection". The difference between the hyper-heuristics mostly lies in the action selection mechanism used to select among the available low-level perturbation heuristics. As such, comparisons between the following five hyper-heuristics are conducted:

- HHILS: The simplest HHILS variant that selects the available perturbation low-level heuristics randomly following a uniform distribution.
- HHILS-SA: An HHILS variant that proportionally selects which perturbation low-level heuristic to apply, based on their reward value.
- HHILS-PM: An HHILS variant that utilizes the probability matching selection method to select the perturbation low-level heuristics.
- HHILS-AP: An HHILS variant that utilizes the adaptive pursuit selection method to select the perturbation low-level heuristics.
- HHILS-MAB: An HHILS variant that utilizes the upper confidence-bound multi-armed bandit methodology to select the perturbation low-level heuristics.

All HHILS variants have been implemented in the Java programming language, based on the functionality provided by the HyFlex framework. Although their implementation details are specific for the HyFlex framework, their algorithmic design is general and can be easily adapted and developed in any other framework. To motivate the usage and further development of the HHILS variants, their source code is available at https://github.com/mikeagn/hhils.

To maintain a fair and reliable comparison, the same parameter configuration is used for the common parameters of all algorithms. In addition, for the different action selection models that have been incorporated in the HHILS variants, the default parameter settings are used as proposed in the literature. Specifically, all HHILS variants employ a temperature value of $T = 2.0$, while the action selection models employ the default values used in the literature as described in the previous section. Notice that it has not been performed any fine-tuning process to obtain high-quality parameter configurations. However, such parameter configuration values can be found by performing either manual or automatic tuning and sensitivity analyses. This tuning process might lead to superior performance gains; nevertheless, this is out of the scope of the current tutorial demonstration. Prominent examples of successful off-line automatic tuning tools among others are the `irace` [135], the `SPOT` [136], and the `SMAC` [137] tools.

Six different problem domains have been implemented within the HyFlex framework, namely, the Max-SAT (SAT), the bin packing (BP), the personnel scheduling (PS), the Flow Shop (FS), the traveling salesman problem (TSP), and the vehicle routing with time windows problem (VRP). For each problem domain, the HyFlex framework provides 10–12 problem instances. A problem instance corresponds to either a real-world realization or a well-known and challenging benchmark case of the considered problem domain. More information about the available instances can be found online in [138]. To evaluate the performance of an algorithm on a given problem instance, the best objective value achieved by the algorithm within a prespecified available time budget is used. Problem domains have been modeled as minimization problems. As such, the lower objective value indicates a better performance. The first part of the experimental analyses provides extensive experimental results for all available instances per problem domain.

For fair comparisons, a benchmarking program is provided on the CHeSC 2011 website [111]. This determines the allowed time limit ($t_{allowed}$) of each run under the

specific hardware architecture $t_{allowed}$ which corresponds to 10 min of CPU time on the machine used during the competition. All experiments in this study have been conducted on an AMD Opteron CPU of 2.2 GHz machine with 32 GB of RAM running GNU/Linux operating system. For this machine, the allowed time limit is 624 s ($t_{allowed} = 624$ s).

Finally, the second part of the analyses strictly follows the rules of the CHeSC 2011 competition in order to provide an easy and fair comparison between all hyper-heuristic search methodologies. A thorough description of the experimental setup used in section "Comparison to HyFlex State-of-the-Art Hyper-heuristics" can be found in [110].

Experimental Results

In this section, the HHILS variants are evaluated on the six available problem domains provided by the HyFlex framework. Specifically, the performances of the five developed HHILS variants are compared on all available instances per problem domain. Firstly the performance gains obtained by each algorithm are described separately, for each problem domain. Then, their overall performance is summarized, and the observed behavior is verified by statistical analysis.

Tables 1, 2, 3, 4, 5, and 6 show statistics on the performance of each algorithm per problem domain, in terms of the best objective value obtained over 31 independent runs. For each algorithm and each problem instance (I), the following statistics are provided: the best (min), the median (m), the mean objective value (μ), and the standard deviation (σ) from the mean objective value obtained by the algorithm at hand. The cases where either the best, the median, or the mean objective value is the smallest (i.e., best performance) across all algorithms for a problem instance in hand are highlighted with **boldface**. In general, it can be observed that, although each algorithm behaves differently across the various problem domains, some algorithms exhibit robust performance across the majority of the domains, such as the HHILS-AP and the HHILS-SA.

More specifically, it can be easily observed that HHILS-AP shows superior performance against the other algorithms in three different domains, BP, FS, and TSP. As presented in Tables 1, 2, and 5, for at least 60% of the problem instances, HHILS-AP shows superior mean and median performance, while it is able to find the best objective value against the other algorithms in 6, 8, and 7 instances for the BP, FS, and TSP, respectively. Regarding the VRP problem domain, although there are three instances where the observed median and mean value are the smallest, in the majority of the remaining cases, it is not able to show competitive performance against the first-ranking algorithms in the domain (HHILS-SA, HHILS-PM).

The next most promising hyper-heuristic is HHILS-SA, which is able to achieve best performance, in terms of both mean and median objective values, in three problem domains FS, PS, and VRP. HHILS-SA also demonstrates the best performance in several problem instances across the majority of problem domains, i.e., 11, 6,

4, 4, and 2 in SAT, VRP, FS, PS, and TSP, respectively. The remaining HHILS variants perform similarly for the majority of the considered domains. HHILS and HHILS-MAB do not exhibit observable performance differences for the majority of the studied cases, while HHILS-PM shows slight improvement gains against them for the BP, FS, and TSP domains (in terms of mean and median objective values). However, in general, the performance of HHILS-PM is more robust when compared with both HHILS and HHILS-MAB, since the mean objective values and their standard deviations are lower for the majority of the considered benchmarks.

It is worth noting that in the SAT problem domain, most of the HHILS variants behave equally well, since for the majority of the problem instances, they exhibit similar mean and median performance values. In addition, for most of the problem instances, they successfully reach the best objective value achieved in this study. Notice that observable performance gains have been shown mostly by HHILS-SA which reached the smallest (min) objective value for all problem instances.

To facilitate easy comparisons of the performance of each algorithm across all problem domains, instances, and independent runs, their objective values are normalized in a common range of values. As such, for a given problem instance, the obtained objective values of all algorithms defined on a range $O = [O_{\min}, O_{\max}]$ are transformed linearly to the normalized range $N = [N_{\min}, N_{\max}]$, where $O_{\min}$ and $O_{\max}$ are the smallest and the largest objective value observed by the considered algorithms, and $N_{\min}$ *and* $N_{\max}$ are the lower and upper bound of the new normalized range. Here, the normalized range $N = [0, 1]$ has been used to keep calculations simple. Strictly speaking, let $y \in O \subset \mathbb{R}$ be an objective value obtained by an algorithm for a given instance, and let $f: O \rightarrow N$ be a linear function that transforms its input according to $\xi = f(y) = (y - O_{\min})/(O_{\max} - O_{\min})$. As such, the performance of each algorithm now can be computed by the set $Y_{\text{Alg}} = \{\xi_1, \xi_2, \ldots, \xi_n\}$ that consists of the normalized objective values across all problem domains, problem instances, and independent execution runs, where n indicates the total number of sample values and is equal to the number of problem instances for each domain, times the number of independent runs, summed up over all problem domains. Notice that this normalization enables a summarizing comparison of the algorithms across all problem domains and instances. Intuitively, the smallest normalized objective values indicate better performance.

To graphically demonstrate the distributions of the performance for each algorithm per problem domain, a summarizing illustration is also provided in Fig. 1. This demonstrates box-plot graphs of the normalized performance for the developed hyper-heuristics across all domains. In each box-plot graph, the mean value of the underlying distribution is additionally marked with a diamond.

Notice that the previously described behavior is clearly captured by the summarizing box plots illustrated in Fig. 1. On the whole, it can be easily identified that HHILS-AP exhibits great performance gains in three problem domains (BP, FS, and TSP), while HHILS-SA in two problem domains (VRP and PS). The next best-performing algorithm seems to be HHILS-PM which exhibits competitive performance in BP, PS, SAT, and VRP. HHILS and HHILS-MAB behave quite similarly, and their performance gains cannot be distinguished by the graphical

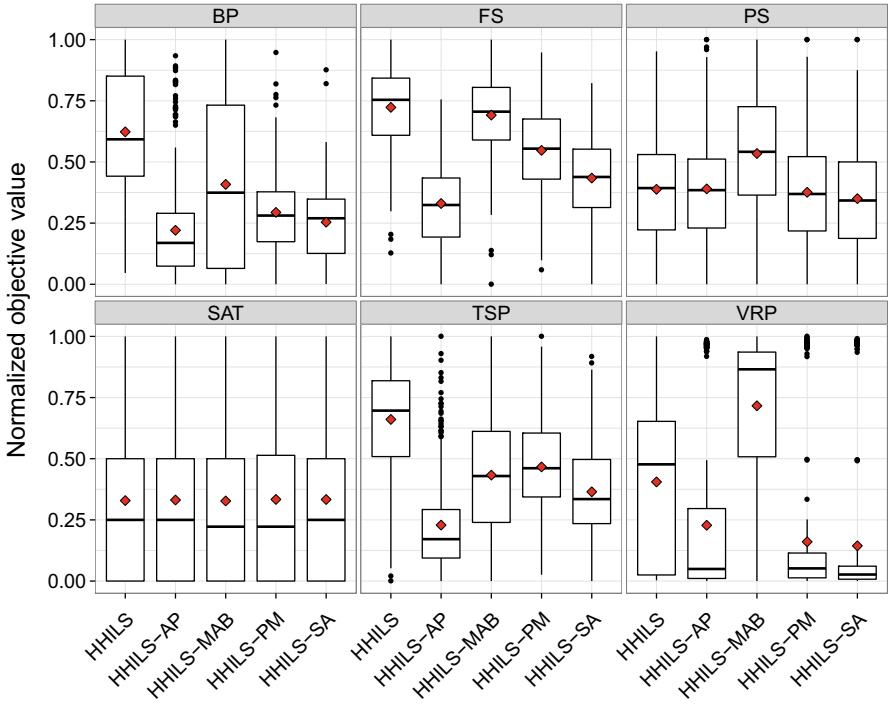

Fig. 1 Boxplot of the normalized objective values of all hyper-heuristics per problem domain

illustration. Interestingly, it can be additionally observed that the performance distribution of HHILS is the most robust against the remaining HHILS variants on the SAT domain.

To assess the existence of statistically significant differences, of the observed performance values, between at least two hyper-heuristics across all considered problem domains and instances, the Friedman rank sum test is applied [139]. For each algorithm, the distribution sample of its mean normalized performance per problem instance across all instances and all domains considered in this study is used. The null hypothesis of the Friedman test states that the distributions of all samples are the same, against the alternative hypothesis which states that at least two samples are not the same [139]. Given the existence of significant differences in performance, a post hoc analysis is employed to determine which two algorithms exhibit significant differences in performance. As such, pairwise comparisons are conducted, and for each comparison, the p-values (p_w) calculated by the nonparametric Wilcoxon-signed rank test are reported, since the underlying sample distributions do not follow a normal distribution (tested with the Shapiro-Wilk normality test [139]). Furthermore, to alleviate from the problem of having type I errors in multiple comparisons with a higher probability, the Bonferroni correction method is applied, and the adjusted p-values (p_{bonf}) are reported.

The Friedman test strongly suggests the existence of statistically significant differences in the performances between the studied hyper-heuristics ($p = 0.0000$, with $\chi^2 = 83.071$). Therefore, a post hoc statistical analysis is employed to determine which two algorithms significantly differ in performance. Table 7 presents summarizing statistics and p-values from pairwise statistical significance tests for all considered hyper-heuristics over all problem domains and instances. The left-hand side of Table 7 demonstrates the median (m_f), the mean (μ_f), and the standard deviation (σ_f) of the normalized objective values over all problem domains and instances, while the right-hand side presents the p-values obtained from the Wilcoxon-signed rank test (p_w) and the corresponding Bonferroni correction method (p_{bonf}). The presented statistics show that, on average, HHILS-SA and HHILS-AP are the most promising approaches. However, the statistical tests reveal that there are not statistically significant differences between their performances for the studied cases. Additionally, the pairwise comparisons indicate that HHILS and HHILS-MAB behave equally, while there exist statistically significant differences in performances for the remaining pairs of hyper-heuristics. This verifies the aforementioned reported performances observed in the analyses on each problem domain.

To further demonstrate the underlying performance distribution of the considered hyper-heuristics, Fig. 2 presents two graphical illustrations of their overall performances: a box-plot graph (left) and an empirical cumulative distribution function (ECDF) graph (right) on their normalized objective values over all the considered problem domains and instances. Such graphical illustrations are useful in displaying the characteristics of the distribution and the frequency of the observed performance values. Specifically, having measured a set of performance values (e.g., the normalized objective values) for an algorithm A, $M_A = \{\xi_1, \xi_2, \ldots, \xi_n\}$, the ECDF is defined as $F_n(\xi) = \frac{1}{n}\sum_{i=1}^{n} I_{(-\infty,\xi]}(\xi_i)$, where $I_{(-\infty,\xi]}(\cdot)$ is the indicator function which equals to one if $\xi_i \leq \xi$ and to zero otherwise. Intuitively, ECDF captures the empirical probability of observing a value that is less than or equal to ξ. The larger a ECDF value corresponding to a given value ξ, the higher is the empirical probability of observing ξ in Y_A.

The box-plot graph (on the left-hand side of Fig. 2) clearly illustrates the differences between the performance distributions of the considered algorithms. Based on the illustrated distributions as well as the previous mentioned results and statistical analyses, it can be safely concluded that HHILS-AP and HHILS-SA demonstrate the most promising performance across all domains. Although, from the analyses conducted per problem domain, HHILS-PM has not exhibited any superior performance gains, it can be observed that its average performance is very promising. Finally, the remaining two hyper-heuristics HHILS and HHILS-MAB perform on average quite similarly. Moreover, the ECDF graph interestingly reveals that almost all algorithms are able to reach best-performing results with quite similar frequency across all problem domains and instances. However, it has to be noticed that HHILS-AP, HHILS-SA, and HHILS-PM have more chance to locate a better solution for the problem under investigation. For example, HHILS-AP has a chance of more than 50% to achieve a quite competitive performance value

Table 7 Summarizing statistics of the normalized objective values of all hyper-heuristics over all problem domains and instances (left). Pairwise statistical significance tests of the normalized performances for all hyper-heuristics over all problem domains and instances (right)

across all studied problem domains, i.e., there is a 50% chance that the obtained performance value will be in the first quartile of the observed performance values of all algorithms across all studied problem domains.

Comparison to HyFlex State-of-the-Art Hyper-heuristics

In this section, the performance of the HHILS variants is studied and compared against several state-of-the-art hyper-heuristics that participated in the CHeSC 2011 competition. To this end, the same experimental setup has been implemented as provided and described in the website of the CHeSC 2011 competition [111]. Specifically, five problem instances have been chosen (three tests and two hidden instances) for each of the six problem domains, resulting in total 30 different problem instances. Each hyper-heuristic is applied to solve the problem instance at hand for an allowed time period. To calculate the performance of each hyper-heuristic, 31 independent runs are conducted for each problem instance. The median objective value obtained out of these independent runs corresponds to the score of the hyper-heuristic for the specific problem instance at hand. As such, the competition entries are ranked based on their median objective value according to a Formula 1 pointing system. A thorough description of the methodology used for the CHeSC 2011 competition can be found in [110].

Table 8 lists the total and the per-problem domain ranking scores of the CHeSC 2011 competition entries along with the HHILS variants. Specifically, the rows of the table are sorted based on the total score (*total*) of each hyper-heuristic and rank them (*rank*) based on a descending order of their overall score. The remaining columns represent the obtained score of each hyper-heuristic across the different problem domains (for clarity, abbreviations SAT, BP, PS, FS, TSP, and VRP stand for Max-SAT, bin packing, personnel scheduling, flow shop, traveling salesman problem, and vehicle routing with time windows problem domain, respectively).

The scores in Table 8 suggest that the most competitive hyper-heuristics developed in this study, HHILS-SA and HHILS-AP, exhibit very competitive performance compared against CHeSC 2011 entries. HHILS-SA and HHILS-AP hold the second and third position, respectively, on the leaderboard. Notice that the score difference between HHILS-SA/HHILS-AP and the first ranked approach (AdaptHH) is small (9–11 units difference), while there is a large gap between them and the fourth entry (ML), (35–38 units difference). AdaptHH algorithm produces the best performance in two out of the six problem domains (BP and TSP), and it performs really well on the instances used for the FS domain. HHILS-SA exhibits superior performance in the PS and the VRP problem domains and high-performance gains in the SAT problem domain. Similarly, HHILS-AP shows superior performance in the SAT problem domain, while it shows quite competitive scores for the PS, the FS, and the VRP cases.

HHILS-PM is able to exhibit promising performance only in the SAT domain and high scores in the PS and VRP cases, while its contribution to the other domains is minimal. Notice that almost all HHILS variants show superior performance in the SAT domain, with HHILS-AP and HHILS-PM to share the first position in the ranking for this specific domain. In general, it can be observed that the HHILS

Table 8 Total and per problem domain ranking scores of the developed hyper-heuristics as competitors on the CHeSC 2011 competition

variants were competitive entries for the SAT, PS, FS, and VRP domains. However, they were not successful in producing a competitive performance, against the other entries, in the BP and TSP cases.

It is worth noting that most of the CHeSC 2011 competitors have a very complex structure that demands a lot of time, effort, and experimentation in the development process, which is a natural process for participating in a competition. However, as suggested by the ranking scores, simple approaches, such as the tutorial demonstration hyper-heuristics in this chapter, might lead to quite efficient search methodologies with competitive performance gains. Notice that several approaches in the class of generation hyper-heuristics try to (semi-)automate the design algorithmic phase in order to alleviate the researcher from having to fine-tune the considered search methodology for a specific (or not) class of problems. Representative examples of automatic algorithmic design can be found in [2–4].

Conclusions

Hyper-heuristics range over a broad class of search methodologies. Many hyper-heuristic methods can be characterized by their general applicability and robustness across different application domains. The main feature of a hyper-heuristic is that it operates on a space of heuristics rather than on a solution space. Although there has been a significant level of research on hyper-heuristics during the last 15 years or so, several important and challenging research directions in the field are in their infancy and demand further exploration.

This chapter presents a timely and thorough literature review of the main advances in the field of hyper-heuristics since the publication of [4] in 2013. In addition, a simple hyper-heuristic framework has been developed and evaluated as a tutorial-style introduction to the field. The chapter has been divided into three parts. The first part reviews a wide spectrum of advances in the field of hyper-heuristics since 2012 and discusses the current trends and ideas that have been considered by the community. In particular, various studies have been identified that investigate the foundational ideas of the field, consider novel methodologies for automatic design of algorithms and parameter control, provide theoretical analysis, introduce novel hyper-heuristic methodologies and algorithms, develop hyper-heuristic frameworks in multi-objective and dynamic problem formulations, and successfully tackle real-world applications in various fields.

In the second and third parts, a simple but efficient selection hyper-heuristic framework is developed, as a tutorial-style introduction to the field, and evaluates its performance on six problem domains. The hyper-heuristic framework incorporates into the iterated local search algorithm an action selection model to adaptively choose the most promising perturbation heuristic based on feedback during the search process. Various state-of-the-art action selection models have been employed and evaluated. Experimental results and statistical analyses on six different problem domains verify its efficiency and performance. Comparisons with state-of-the-art hyper-heuristics in the field demonstrate its strength despite its relative simplicity.

The literature review highlights various interesting advances and limitations of the current state of the art, which can be summarized as follows.

The current formulation and classification of hyper-heuristics have stimulated the interest of the community. In particular, reformulations and extensions of the definition of hyper-heuristics have been proposed (see, e.g., [15]). A productive criticism on the level of the domain barrier revealed that both high and low levels of abstraction in the problem domain can enhance the search efficiency of hyper-heuristics. Problem domain information is sometimes able to strengthen the search dynamics of a hyper-heuristic without limiting its generality and robustness. Recent advances include unified representations as well as the embedding of mechanisms of common knowledge across different problem domains (see, e.g., [18, 19]).

From the methodological point of view, a variety of novel algorithms and frameworks have recently been published. Heuristic generation methodologies have been developed not only as hyper-visors to generate low-level heuristics but

also as mechanisms to generate high-level models [20]. Moreover, hyper-heuristic frameworks that are able to learn the feature space of a problem class and its representative search strategies have been proposed [14, 21–23]. These frameworks are capable of generating new search strategies and self-adapting their search characteristics based on new problem instances. Furthermore, various analyses have been published that study either the characteristics of the heuristic space, such as its diversity, or the feedback information that can be obtained through the search process (e.g., see [24–26, 28, 29]). It has also been identified that current developments in the field are mostly empirical, while the theoretical foundations and analyses of hyper-heuristics represent significant open research challenges. A few representative examples of recent theoretical work include the runtime analysis of hyper-heuristic algorithms [41, 42].

A comparison between the fields of meta-learning and hyper-heuristics has been performed that advocates their common objective of automating the algorithm design process [30]. Recent advances in the automatic design of algorithms include various simple, general, and efficient frameworks based on stochastic local search algorithms and novel gramma-based representations of heuristic algorithms among others (e.g., see [32, 35, 36]). Additionally, the commonalities in memetic computing and hyper-heuristics have been reviewed, and new frameworks that combine ideas from both fields have been presented [38]. Various other recent developments in the automated design of algorithms generate efficient algorithms for specific classes of problems, including (among others) packing and cutting problems [37, 39].

A significant number of real-world applications demand high-quality decisions. However, their formulations might include multiple objectives, uncertainty, or dynamically changing environments. Recent trends in the field promote research on both multi-objective and dynamic or uncertain problems. An effective multi-objective algorithm should possess good search characteristics in terms of both solution diversity and convergence on the Pareto-front set. Current developments include multi-objective hyper-heuristic approaches that operate on search strategies to efficiently guide search to diverse Pareto sets that converge to the Pareto front (e.g., see [43, 45, 46, 48–51]). Current methodologies mostly include selective mechanisms that combine the strengths of predefined search operators or algorithms, while heuristic generation approaches are in their infancy. Clearly, selection hyper-heuristics play a major role in this direction of research. However, the design of a multi-objective algorithm demands expert knowledge of the field, and it is a very demanding and time-consuming development process. Thus, automatic design processes that will efficiently address major issues will arguably have a tremendous impact on the multi-objective community. Hyper-heuristic methodologies for automatically designing and generating multi-objective algorithms are definitely a worthwhile (and growing) research direction.

Hyper-heuristic methodologies that employ adaptivity and cope with dynamically changing problem scenarios have been recently developed to address applications with uncertainty and dynamic changes in time. Most of the developed

approaches utilize heuristic selection mechanisms of specialized meta-heuristics that address dynamic problems across different types of dynamic environments [52–54]. Exploration of this area is only just beginning.

A major direction that draws upon the interdisciplinary scope of hyper-heuristics is the incorporation of machine learning methodologies to enhance hyper-heuristic efficiency and effectiveness. Machine learning methodologies have been incorporated mostly into the higher level of hyper-heuristics. The main aim of such methodologies is to learn the behavior of the underlying heuristics and be able to make effective decisions to guide the search toward the most promising areas of the search space. Recent advances include methodologies that consider tensor analysis, Inverse Reinforcement Learning theory, Monte Carlo Tree search, and grammatical evolution (among others, e.g., [55–62]). Moreover, hyper-heuristics and the automatic design of algorithms have influenced the machine learning community too. Various developed methodologies include the automatic design of classification algorithms, such as decision trees, to generate more general and robust methodologies for specific class of problems. Clearly, established methodologies in machine learning can potentially boost the strength of hyper-heuristic approaches. As foreseen in [3], it can be recognized that research at the interface of machine learning and hyper-heuristic methodologies has significant potential.

Hyper-heuristics have been successfully applied in a wide variety of diverse application areas. Complex applications that can be modeled as combinatorial optimization problems such as scheduling, timetabling, cutting, and packing problems represent the early adopted application areas of hyper-heuristic approaches. Recent developments not only continue to study these application domains but are also successfully applied to a wide variety of other applications, such as games, engineering, informatics, and parallel and/or distributed applications.

Hyper-heuristic research lies at the interface between operational research and computer science, and it has an impact on a broad spectrum of interdisciplinary application areas. The interdisciplinary character of the field promotes research that combines advanced knowledge from a variety of research areas with the common objective of successfully solving complex real-life optimization problems.
