Abstract

In this chapter, we consider the problem of scheduling time-constrained round-robin sports tournament problems, metaheuristics for its approximate solution, and their practical applications. This chapter uses graph theory as the fundamental tool. It presents a short introduction to its essential elements, definitions, and results relevant to the subject of this work. We also introduce the basic graph model used to represent single round-robin tournaments and the circle method for constructing timetables. We describe the different neighborhood structures that have been used in the literature of metaheuristics and local search procedures for scheduling time-constrained single round-robin sports tournaments: Home-Away Swap, Team Swap, Partial Team Swap, Round Swap, Partial Round Swap, and Generalized Partial Team Swap. They may be directly extended to double round-robin problems. We conclude by presenting a collection of applications of metaheuristics to sports scheduling problems.

Keywords

Round-robin tournaments · Time-constrained tournament · Circle method · Local search · Metaheuristics · Neighborhoods for round-robin problems · Applications of sports scheduling

Introduction

Metaheuristics are general high-level procedures that coordinate simple methods and rules to find high-quality (often optimal) approximate solutions to hard optimization problems. Among them, we find simulated annealing, tabu search, greedy randomized adaptive search procedures (GRASP), iterated local search (ILS), variable neighborhood search (VNS), genetic algorithms, and others. They have been applied to various academic and real-world problems, particularly sports scheduling.

A *round-robin tournament* (or *all-play-all tournament*) between an even number $2n$ of competitors is one in which each competitor plays precisely the same number of games with every other competitor in the tournament. The games are played in rounds in which each team plays exactly once. This definition implies that the tournament is time-constrained and excludes time-relaxed sports tournaments in which the number of available rounds is greater than the number of games each team must play. Although many sports tournaments are time-constrained, some are time-relaxed. An interesting application in the context of time-relaxed tournaments appeared in [12], where a heuristic is proposed to schedule the games of the National Hockey League in Canada and the United States.

Most professional sports leagues play either a single round-robin tournament (SRR), where each pair of teams meets once, or a double round-robin tournament (DRR), where each pair of teams meets twice. In general, each competitor plays against each other exactly m times. The number of rounds in a compact tournament (i.e., a tournament in which each competitor plays precisely once in each round) is equal to $m(2n - 1)$.

Double round-robin tournaments can be organized in different manners, such as unconstrained tournaments in which the games can be played in any arbitrary order; tournaments with constraints avoiding that the two games between the same pair of competitors be played in two consecutive rounds; tournaments organized in two separate phases, each of which is an SRR tournament itself (possibly with different timetables); and mirrored tournaments (in which both phases are SRRs with the same timetables, but the venues of the two games between each pair of competitors are interchanged from one phase to the other).

The remainder of this chapter is organized as follows. The next section overviews approximate optimization methods, from construction algorithms to local search and from local search to metaheuristics. Section "Elements of Graph Theory" presents the fundamental elements of graph theory used throughout this chapter. Section "Basic Graph Model for Single Round-Robin Tournaments: The Circle Method" presents the basic graph model for representing single round-robin tournaments and describes the basic circle method for constructing canonical schedules. Section "Local Search and Neighborhoods" examines neighborhoods, search spaces, and local search methods. Section "Fundamentals of Metaheuristics for Sports Scheduling" reviews some fundamental principles of metaheuristics and describes some of the most widely and successfully used metaheuristics in sports scheduling: simulated annealing, tabu search, greedy randomized adaptive search procedures, and iterated local search. Metaheuristics to sports scheduling problems use local search methods based on specially tailored neighborhoods. Section "Neighborhoods for Round-Robin Tournaments" shows different neighborhoods defined for round-robin tournament scheduling problems. The chapter concludes with the presentation of a non-exhaustive collection of applications of metaheuristics to problems in sports scheduling.

Exact and Approximate Optimization Methods

Combinatorial optimization, which includes sports scheduling problems as one of its application areas, consists in finding optimal solutions to problems defined over a discrete set of feasible solutions.

Any combinatorial optimization problem may be formulated as the constrained minimization (resp. maximization) of some function $f(S) : S \in F$. Here, E is a discrete ground set formed by the elements that form the problem solutions, $F \subseteq 2^E$ is the set of feasible solutions, and $f : 2^E \rightarrow \mathbb{R}$ is the objective function. Any solution S for this problem is formed by a subset of the elements of the ground set. We seek an *optimal solution* (or, simply, an *optimum*) $S^* \in F$ such that $f(S^*) \leq$

$f(S)$ (resp. $f(S^*) \geq f(S)$), for all $S \in F$. The ground set E, the objective function f, and the feasible set F are specific to each problem instance. Some scheduling problems are feasibility problems, that is, there is no objective function, and the problem is to find a solution that satisfies the restrictions imposed by F. In this case, one may relax a subset of the constraints that define F and consider the minimization of the number of violations of relaxed constraints as the objective function of the problem.

A method for solving an optimization problem is *exact* if it is guaranteed to produce, in finite time, a global optimum for this problem and a proof of its optimality, in the event that one exists or otherwise to show that no feasible solution exists. Globally optimal (or, simply, optimal) solutions are often referred to as exact solutions.

Efficient (i.e., running in polynomial time with respect to the instance size) exact algorithms are unknown (and are unlikely to exist) for a broad class of optimization problems classified as NP-hard. These problems are often referred to as *intractable*. Although the size of the problems that can be solved exactly to optimality has been continuously increasing due to algorithmic and technological developments, there are problems (or problem instances) that are not amenable to being solved by exact methods. Other approaches are needed based on different paradigms to tackle such challenging and large-size optimization problems.

Opposed to exact methods, *approximate methods* or *heuristics* provide feasible solutions that are not necessarily optimal. Approximate methods usually run faster than exact methods. They are capable of handling larger problem instances than exact methods.

Constructive heuristics build a feasible solution from scratch, like the circle method originally proposed by Kirkman [58] to construct a feasible round-robin schedule (see also Ribeiro et al. [104]) that constructs a canonical schedule for SRR tournaments or methods derived from the proof of Vizing's theorem [120] that are able to construct any schedule for SRR tournaments.

Local search methods start from a feasible solution and improve it by successive minor modifications until a solution that cannot be further improved is encountered. Although they often provide high-quality solutions whose values are close to those of the optimal solutions, they can become prematurely trapped in low-quality, locally optimal solutions in some situations.

Metaheuristics are based on distinct paradigms and offer different mechanisms to escape from locally optimal solutions (as opposed to greedy algorithms or local search methods). They are among the most effective solution strategies for solving challenging combinatorial optimization problems in practice. They often produce much better solutions than those obtained by the simple heuristics and rules they involve. The section "Fundamentals of Metaheuristics for Sports Scheduling" recalls the principles and templates of some of the metaheuristics used in sports scheduling, which have been instrumental and contributed to most developments and applications in the field.

Elements of Graph Theory

This section introduces the main graph theory definitions and results essential for understanding the models and neighborhoods presented in this chapter.

A graph $G = (V, E)$ consists of a set V of nodes and a set E of edges. Each edge $e = [u, v]$ is an unordered pair of distinct nodes. The nodes $u, v \in V$ are the endpoints of edge e. An edge $e = [u, v]$ may be given an orientation, say from u to v: in this case, it becomes an arc $a = (u, v)$.

A *simple graph* has neither loops (edges whose endpoints coincide) nor parallel edges (multiple edges between the same pair of endpoints).

The *degree* $d_G(v)$ of a node $v \in V$ in G is the number of edges having v as an endpoint (i.e., the number of edges adjacent to v). A graph $G = (V, E)$ is *complete* if there is an edge in E between every pair of nodes $u, v \in V$, with $u \neq v$. We denote by K_n the complete graph with $n = |V|$ nodes. The graph G is *d-regular* if $d_G(v) = d$ for every node $v \in V$. A *cycle* is a sequence of edges $[u_1, u_2], [u_2, u_3], \ldots, [u_{p-1}, u_p], [u_p, u_1]$, where $u_1, u_2, \ldots, u_{p-1}, u_p$ are nodes of V.

A graph $G = (V, E)$ is *bipartite* if its node set V may be partitioned into two subsets V_1 and V_2 such that no edge in E has both endpoints in V_1 or in V_2. If every possible edge between V_1 and V_2 exists in a bipartite graph G, then G is a *complete bipartite* graph. The complete bipartite graph with n nodes in one subset and m nodes in the other is denoted by $K_{n,m}$. A graph is bipartite if and only if it has no *odd cycle* (i.e., a cycle with an odd number of edges).

A subset $F \subseteq E$ *spans* the graph $G = (V, E)$ if every node $v \in V$ is the endpoint of at least one edge in F. In this case, F is called a *factor* of G. F is an ℓ-factor of G if every node $v \in V$ is an endpoint of exactly ℓ distinct edges in F.

A subset $F \subseteq E$ such that no two edges in F have a common node is called a *matching*. In a *perfect matching* F (also called a *1-regular matching*), each node $v \in V$ is adjacent to exactly one edge in F. We notice that a perfect matching is equivalent to a 1-factor.

A partition of the edge set E into matchings is an *edge coloring* of graph G. If all matchings in an edge coloring are perfect (i.e., 1-factors), then the edge coloring is a *1-factorization*.

The minimum number of matchings in an edge coloring of graph G is its *chromatic index* $\chi'(G)$. Clearly, $\chi'(G) \geq \Delta(G)$, where $\Delta(G)$ is the largest node degree in G.

Two 1-factorizations $\mathscr{F} = \{F_1, \ldots, F_k\}$ and $\mathscr{H} = \{H_1, \ldots, H_k\}$ of G are called *isomorphic* if there exists a bijective function φ from the node set V of G onto itself such that $\{F_1^{\varphi}, \ldots, F_k^{\varphi}\} = \{H_1, \ldots, H_k\}$. Here, F_i^{φ} denotes the set of all edges $[\varphi(x), \varphi(y)]$ where $[x, y]$ is an edge in F_i. The concept of isomorphic 1-factorizations can also be extended to *isomorphic edge colorings*.

A 1-factorization is said to be *perfect* when the edges in $F_i \cup F_j$ form a *Hamiltonian cycle* for each pair of distinct 1-factors F_i and F_j.

Remark 1. In a complete graph K_{2n}, any 1-factorization is equivalent to a minimum cardinality edge coloring. ■

This remark highlights that 1-factorizations are a particular case of edge colorings.

Remark 2. Formally, there is no order between the 1-factors of the 1-factorization $\mathcal{F} = \{F_1, \ldots, F_k\}$ (or between the colors of an edge coloring). In the context of this chapter, we refer to the *ordered 1-factorization* $\mathcal{F} = (F_1, \ldots, F_k)$ as an ordered sequence whenever the order in which the 1-factors (or colors) are taken is relevant. ■

This second remark and the notation defined therein are relevant because, in sports scheduling, the order of the factors of a 1-factorization matters. By analogy, we could also refer to an ordered edge coloring.

Basic Graph Model for Single Round-Robin Tournaments: The Circle Method

We consider a round-robin tournament between $2n$ teams. It is quite natural to associate the $2n$ teams, numbered $1, \ldots, 2n$, with the nodes of a graph. Each game to be played by teams i and j will be represented by an edge $[i, j]$.

There is a one-to-one correspondence between ordered 1-factorizations and single round-robin timetables. If we have to construct a timetable for the games of a single round-robin tournament, we seek an edge coloring of the edges of a complete graph K_{2n} with $2n$ nodes. Since K_{2n} is $(2n-1)$-regular, any timetable will require at least $2n - 1$ rounds, assuming each team plays at most one game in each round. Indeed, one can always construct a timetable using exactly $2n-1$ rounds (i.e., $\chi'(K_{2n}) = 2n-1$). Let $\mathcal{F} = (F_1, \ldots, F_{2n-1})$ be such an edge coloring where F_i is the 1-factor whose edges correspond to the games played in round $i = 1, \ldots, 2n-1$. $\mathcal{F}$ is indeed a 1-factorization of K_{2n} since each team has to play exactly one of its $2n - 1$ games during each one of the $2n - 1$ rounds of the timetable.

The *circle method* (or *polygon method*) provides a simple construction for the so-called *canonical 1-factorization* $\mathcal{F} = (F_1, \ldots, F_{2n-1})$ of K_{2n}.

We give in Fig. 1 a graphical interpretation of the circle method. We first position the teams 1 to $2n - 1$ in the vertices of a regular polygon. For round 1, we first match the highest team of the polygon (team 1) with that in the center (team $2n$). Next, we pair each team on the left side of the polygon with that on the right side at the same height. This perfect matching defines the games of round 1. We repeat this procedure for rounds $2, 3, \ldots, 2n - 1$, by rotating the teams in the polygon's vertices counterclockwise at each step (or round).

The chronological sequence of the rounds in which the games are scheduled in the 1-factorization $\mathcal{F} = (F_1, \ldots, F_{2n-1})$ induces an order on $F_1, \ldots, F_{2n-1}$.

(a) K_4 (b) F_1 (c) F_2 (d) F_3

Fig. 2 Canonical 1-factorization of K_4. (**a**) K_4. (**b**) F_1. (**c**) F_2. (**d**) F_3

However, we shall refer to 1-factorizations without mentioning the order whenever no confusion may arise.

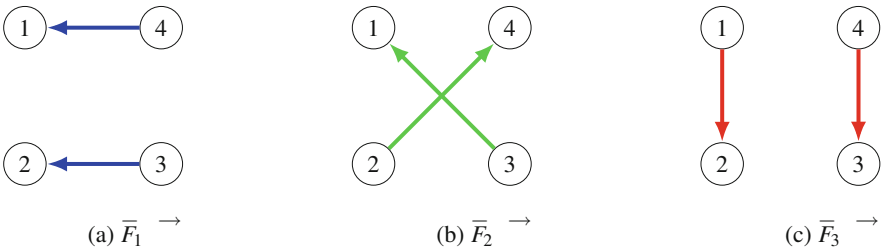
The circle method is frequently used to provide initial solutions to local search-based heuristics. Figure 2 shows a canonical 1-factorization $\mathscr{F} = (F_1, F_2, F_3)$ of K_4. In the first round, team 4 plays a game with team 1, while team 2 plays against team 3; then $F_1 = \{[4, 1], [2, 3]\}$. Similarly, $F_2 = \{[4, 2], [3, 1]\}$, and $F_3 = \{[4, 3], [1, 2]\}$.

Table 1 represents the timetable corresponding to the canonical 1-factorization of Fig. 2.

It is often the case that each team has its venue (or stadium) and each game between teams i and j is played either in the venue of team i or the venue of team j. In the first case, we say that team i plays a *home game* and that team j plays an *away game*. It is convenient to represent this game by an arc (j, i) oriented from j to i.

Table 1 Timetable corresponding to the canonical 1-factorization of Fig. 2

Rounds		
1	2	3
[4, 1]	[4, 2]	[4, 3]
[2, 3]	[3, 1]	[1, 2]



(a) $\overrightarrow{F}_1$ (b) $\overrightarrow{F}_2$ (c) $\overrightarrow{F}_3$

Fig. 3 Oriented edge coloring for the edge coloring of Fig. 2. (**a**) $\overrightarrow{F}_1$. (**b**) $\overrightarrow{F}_2$. (**c**) $\overrightarrow{F}_3$

In the second case, if the game between teams i and j is played in the home city of team j, we have an arc (i, j) oriented from i to j.

If every game in a single round-robin tournament is assigned to a venue, then each edge of K_{2n} receives an orientation and becomes an arc. Instead of an edge coloring, we now have an *oriented edge coloring*, denoted by $\overrightarrow{\mathscr{F}} = (\overrightarrow{F}_1, \ldots, \overrightarrow{F}_{2n-1})$. For the timetable associated with K_4 in Table 1, the edges may be oriented, e.g., as

$$\overrightarrow{F}_1 = \{(4, 1), (3, 2)\},\ \overrightarrow{F}_2 = \{(2, 4), (3, 1)\},\ \text{and}\ \overrightarrow{F}_3 = \{(4, 3), (1, 2)\},$$

as represented in Fig. 3.

Local Search and Neighborhoods

A feasible solution satisfies all constraints of the problem at hand. We recall that F is the set of feasible solutions for the combinatorial optimization problem. We denote by $\hat{F} = 2^E$ the set formed by all subsets of the ground set, which includes all feasible and infeasible solutions.

A local search heuristic starts from any feasible solution and improves it by successive minor modifications that visit other (feasible or infeasible) solutions until a solution that cannot be further improved is encountered. Local improvements are evaluated concerning neighbor solutions that can be obtained by slight modifications applied to the current solution.

A *neighborhood* of a solution $S \in F$ can be defined as any subset of F. More formally, a neighborhood is a mapping that associates each feasible solution $S \in F$ with a subset $N(S) = \{S_1, \ldots, S_p\} \subseteq F$ of feasible solutions.

Each solution $S' \in N(S)$ can be reached from S by an operator called a *move*. Typically, two neighboring solutions S and $S' \in N(S)$ differ only by a few elements

of the ground set, and a move from S to S' consists simply of the modification in one or more elements in S. Usually, $S \in N(S')$ if only if $S' \in N(S)$.

The *search space* (or *solution space* or *search graph*) of a given problem for some neighborhood N may be seen as a graph $\mathscr{G} = (F, M)$ whose node set corresponds to its set F of feasible solutions. Its edge-set M is such that there is an edge $(S, S') \in M$ between two solutions $S, S' \in F$ if and only if $S' \in N(S)$ and $S \in N(S')$. An extended search graph may be similarly defined, encompassing not only the set of feasible solutions F but, instead, the whole set $\hat{F} = 2^E$ formed by all subsets of elements of the ground set (feasible or infeasible).

Different neighborhoods can be defined and used to implement a local search method. Depending on the neighborhood used, the search space may be disconnected. This situation can lead to implementation difficulties and can even make it impossible for the search procedure to find reasonable solutions located in the part of the search space graph that cannot be reached from the initial solution. From another point of view, the larger the neighborhood, the denser the search space and the shorter the paths connecting any two solutions. On the other hand, larger neighborhoods require the evaluation of more neighboring solutions, leading to higher computation times.

It is noticeable that the search space does not need to be formed exclusively by feasible solutions in F. It can be enlarged to contain also infeasible solutions. In this situation, a path in the search space can visit feasible and infeasible solutions, but, in any case, it must terminate in a feasible solution.

Finding an appropriate neighborhood and the best way to explore it is a crucial step toward implementing effective and efficient local search methods and metaheuristics. Neighborhoods for round-robin scheduling problems will be described and compared in detail in the section "Neighborhoods for Round-Robin Tournaments."

Yagiura and Ibaraki [129] traced the history of local search since the work of [17]. Hoos and Stützle [50] developed a thorough study of the foundations and applications of stochastic local search, methods based on local search that use randomization to generate or select candidate solutions for combinatorial optimization problems. In their seminal work, Lin and Kernighan [70] developed a local search heuristic based on 2-opt and 3-opt exchanges for approximately solving the symmetric traveling salesman problem, which is one of the best approaches for the problem. Michiels et al. [77] discussed theoretical aspects of local search. Chapter 4 of the book by Resende and Ribeiro [95] describes enhancements in the implementation of local search methods, such as candidate lists in best-improving strategies and circular search in first-improving strategies; see also [36].

Fundamentals of Metaheuristics for Sports Scheduling

This section reviews the basic principles and ideas involved in the design of some of the main metaheuristics. We describe four widely and successfully used metaheuristics: simulated annealing, tabu search, greedy randomized adaptive

search procedures (GRASP), and iterated local search (ILS). The reader may check the broad and ever-evolving literature on the subject, in particular, the handbooks edited by Reeves [85], Glover and Kochenberger [35], Burke and Kendall [9, 10], and Gendreau and Potvin [30].

Simulated Annealing

The principle of simulated annealing lies in the analogy between the physical annealing process and the combinatorial optimization problem to be solved. In physics, annealing is a thermal process for obtaining the low-energy states of a solid in a heat bath. Solutions to the combinatorial problem are equivalent to states of the physical process, while the cost of each solution corresponds to the state's energy. Neighbor solutions correspond to states generated by a perturbation method. At each step of the simulated annealing, a new solution in the neighborhood of the current solution is randomly generated. The new solution replaces the current solution if it improves the latter or with a decreasing probability if it does not. The best-encountered solution is returned. It is a memoryless procedure that does not require a local search procedure.

The main advantage of simulated annealing is its simplicity of implementation because there is no local search. However, its convergence speed and solution quality depend on several parameter values and implementation choices that are not easy to tune. Furthermore, the algorithm is memoryless and does not use cost information about the entire neighborhood.

The work on optimization by simulated annealing was pioneered by Kirkpatrick et al. [59], with accounts of later developments and applications in textbooks [1,63]. Convergence and implementation strategies are also discussed in [2,45].

Tabu Search

Tabu search is a dynamic neighborhood method that uses memory to drive the search by escaping from local optima and avoiding cycling. Contrarily to memoryless heuristics such as simulated annealing, and to methods that use rigid memory structures such as branch-and-bound, tabu search makes use of flexible and adaptive memory designs.

For any solution S, in the case of tabu search, the neighborhood $N(S)$ is not a static set and can be modified according to the history of the search. At each local search iteration, tabu search looks for the neighbor solution that best improves the objective function (or, if none exists, for the one that least deteriorates the current solution). However, some moves to neighbors in $N(S)$ are forbidden and discarded. The set of forbidden (or *tabu*) moves is stored in a short-term memory, formed by the most recently performed moves, to prevent the search from returning to previously visited solutions. Contrary to simple local search procedures, tabu search chooses the move that least deteriorates the objective function value whenever there are no improving moves.

The basic tabu search scheme can be extended by incorporating more sophisticated strategies: aspiration criteria to override the tabu status of unvisited solutions, medium-term and long-term memories to implement intensification and diversification procedures, candidate list strategies to speed up the search, and hashing tables to accelerate and filter the search. These comprehensive strategies lead to much more powerful and effective implementations in terms of the quality of the solutions they obtain.

Tabu search is undoubtedly among the most effective approaches for solving hard combinatorial optimization problems. However, implementations of tabu search often involve setting many parameters, which have to be appropriately tuned for achieving good performance in practice.

The seminal papers of Glover [31, 32] established the fundamentals, extensions, and uses of tabu search. They provided solid foundations and originated most of the developments from where the field of metaheuristics flourished, as reported in the retrospective by Glover [34]. The reader is referred to the textbook of Glover and Laguna [36] for a thorough study of tabu search and related ideas. Glover et al. [37] gave an updated presentation of the fundamental ideas of tabu search with some hints for an efficient implementation. A variety of applications of tabu search with basic modeling suggestions were described by Hertz et al. [47].

Greedy Randomized Adaptive Search Procedures

A greedy randomized adaptive search procedure (GRASP) is a metaheuristic resulting from hybridizing a greedy randomized algorithm with a local search method embedded in a multi-start framework.

An especially appealing characteristic of GRASP is its ease of implementation. Few parameters must be set and tuned; therefore, development can focus on implementing efficient data structures to ensure fast computations in all iterations. Basic implementations of GRASP rely almost exclusively on two parameters. The first is the stopping criterion, often defined by the maximum number of iterations (or by the maximum number of iterations without improvement in the best solution found). The second is a parameter used to limit the size of the restricted candidate list within the greedy randomized algorithm used in the construction phase. GRASP is also amenable to efficient and straightforward parallel implementations (see, e.g., Ribeiro and Rosseti [98, 99]). Despite its simplicity and ease of implementation, GRASP is a very effective metaheuristic and produces the best known solutions for many problems.

GRASP was proposed by Feo and Resende [25] (see also [26]). Reviews and tutorials appeared in Ribeiro [97] and Resende and Ribeiro [90, 91, 92, 93]. Festa and Resende [27, 28] presented reviews of applications of GRASP. The book by Resende and Ribeiro [95] consolidated the fundamentals, advances, and extensions of optimization by GRASP.

GRASP, as initially proposed, is a memoryless procedure in which each iteration does not use information gathered in previous iterations. In other words, all its iterations are independent. Path relinking enhances the basic GRASP significantly,

adding a long-term memory mechanism to GRASP heuristics. GRASP with path relinking implements long-term memory using an elite set of diverse and high-quality solutions previously found during the search. In its most basic implementation, path relinking is applied at each iteration between the solution found at the end of the local search phase and any randomly selected solution from the elite set. The solution resulting from path relinking is a candidate for inclusion in the elite set. The hybridization of GRASP with path relinking can significantly improve solution time and quality.

Path relinking was initially proposed by Glover [33] as an intensification strategy exploring trajectories connecting elite solutions obtained by tabu search or scatter search. The use of path relinking embedded in a GRASP procedure as an intensification strategy applied to each locally optimal solution was first proposed in [64]. Several strategies (backward, forward, backward-and-forward, mixed, truncated, randomized, evolutionary) have been considered and combined with extensions and improvements of path relinking in successful implementations hybridized with tabu search, GRASP, and genetic algorithms (see, e.g., [11, 29, 75, 88–91, 96, 98, 101–103, 108]). Resende and Ribeiro [91] reviewed these strategies, showing that they involve trade-offs between computation time and solution quality. Chapters 8 and 9 of Resende and Ribeiro [95] reviewed path relinking strategies and hybridizations with GRASP in detail.

Iterated Local Search

Iterated local search (ILS) explores the solution space using a walk that moves from a locally optimal solution to a nearby one without the restriction of using exclusively moves in the neighborhood. Local search is applied to the initial solution. The main loop of the algorithm is performed until some stopping criterion is reached. Each iteration starts by applying a random perturbation to the current locally optimal solution, which results in an intermediate solution. Local search is again applied to the latter, resulting in a new local optimum. If this local optimum meets some acceptance criterion, it becomes the next solution of the solution trajectory. Otherwise, the algorithm remains in the same local optimum, and a new iteration resumes. A maximum number of perturbations is typically used as the stopping criterion.

Iterated local search was proposed in Martin et al. [74] and Martin and Otto [73] (see [72] for a review). Most of the work using ILS has been done with Markovian random walks, although some studies show that incorporating memory enhances its performance. ILS may also be hybridized with other metaheuristics such as GRASP.

Variable Neighborhood Search

Variable neighborhood search (VNS) is based on a systematic change in the neighborhood. It makes use of a finite set of $k_{\max}$ pre-selected neighborhood

structures identified as $N_1, \ldots, N_{k_{\max}}$ that may be induced by one or more metric functions introduced in the solution space. Let $N_k(S)$ denote the set of solutions in the k-th neighborhood of S.

At each VNS iteration, a solution is randomly sampled in the k-th neighborhood of the current solution S, and a local search is applied to the resulting solution. If the local minimum obtained does not improve the current solution, then the algorithm moves to the $(k+1)$-th neighborhood.

VNS is also a memoryless heuristic. It is easy to implement and relies on a few parameters: the stopping criterion and the number $k_{\max}$ of neighborhoods (and their definitions). It was originally proposed by Mladenovic and Hansen [78] (see [43,44] for reviews).

Genetic Algorithms

A genetic algorithm is a population-based method that uses selection, recombination, and mutation operators to generate new solutions in the search space, imitating the process of natural selection and evolution of species. Solutions are evaluated in terms of their fitness, which most often corresponds to the value of the objective function itself.

Contrary to the other metaheuristics reviewed in the previous sections, genetic algorithms explore a population of solutions that evolve along some generations, rather than a single trajectory emanating from a unique initial solution. The method starts from a population formed by a fixed number of feasible solutions that can be randomly generated or constructed by a more elaborate approach such as a greedy randomized algorithm. At each iteration (which is called a generation in this context), pairs of randomly selected solutions (parent solutions) are combined, and new solutions (offspring) are generated (crossover operator). Some randomly selected solutions go through small random modifications in their structure (mutation operator) to ensure diversification. The best-fitted solutions of the population are selected and passed to the new generation (selection operator), and a new iteration resumes.

Hybrid genetic algorithms, also called memetic algorithms, use specific knowledge available to solve the problem. Such strategies incorporate greedy randomized algorithms to create the initial population and the application of local search to some elements of the population of each generation. Genetic algorithms hybridized with optimization strategies usually perform much better than basic genetic algorithms.

Genetic algorithms were first presented in the book of Holland [48] (see also, e.g., Goldberg [39], Holland [49], Reeves and Rowe [87], and Michalewicz [76], among others). They are very appealing and easy to implement. However, many implementation choices exist for each of the above operators. Exemplary implementations require appropriate solution encodings as finite-length data strings and well-tuned strategies for the initial population generation, mate selection, crossover, mutation, and selection (see, e.g., [86]).

A significant difficulty with implementing genetic algorithms resides in the crossover operator. It occurs because, in most cases, the solutions obtained by crossover turn out to be infeasible and, therefore, unusable by the algorithm. Although some strategies have been proposed in the literature to handle infeasibilities (such as the use of penalties or repair operators), they are problem-specific and of complex generalized implementation in practice, with a limited number of successful cases.

A biased random-key genetic algorithm (BRKGA) encodes solutions as a vector of real numbers called random keys. A deterministic algorithm (called a decoder) takes a vector of random keys as the input and associates with it a feasible solution of the combinatorial optimization problem at hand, for which an objective value (or fitness function) can be computed. The crossover is said to be biased because one parent is always an elite (high-quality) solution, while the other is not. The elite parent still has a higher probability of passing its elements to the new generation. Biased random-key genetic algorithms can be implemented straightforwardly. The crossover is performed in the space of random keys, and the corresponding solutions are built by the decoder a posteriori. Therefore, the resulting solutions are always feasible. BRKGAs are particularly effective for scheduling problems or other problems whose solutions may be represented by permutation vectors (see Goncalves and Resende [40], Londe et al. [71], Noronha and Ribeiro [80], and Resende and Ribeiro [94] for reviews and [6–8, 81, 83] for some applications).

Neighborhoods for Round-Robin Tournaments

We noticed in section "Local Search and Neighborhoods" that different neighborhoods can be defined and imposed on the set of feasible solutions of a combinatorial optimization problem.

Local search is a common component to many metaheuristics. Local search methods embedded in metaheuristics may generate neighbors randomly, as in the case of simulated annealing. They may also explore solution neighborhoods using first-improving or best-improving strategies, as in the cases of tabu search or GRASP.

Solutions for single round-robin tournament scheduling problems will be represented by oriented ordered 1-factorizations of the complete graph K_{2n} for a league with $2n$ teams, as described in the section "Basic Graph Model for Single Round-Robin Tournaments: The Circle Method." This representation may also be used for problems associated with mirrored double round-robin scheduling tournaments. With this representation, each 1-factor is associated with a different color, which is used to color all edges of this 1-factor.

Different neighborhood structures have been used in the literature of local search procedures for scheduling time-constrained single round-robin sports tournaments, although sometimes they have been referred to by different names. We name them as *Home-Away Swap, Team Swap, Partial Team Swap, Round Swap, Partial Round Swap,* and *Generalized Partial Team Swap*. Edge orientations are disregarded for all

neighborhoods except Home-Away Swap. These neighborhoods may be extended to the case of double round-robin problems. They are described in the following sections, using the notation and definitions introduced in the section "Elements of Graph Theory."

Neighborhood "Home-Away Swap" (HAS)

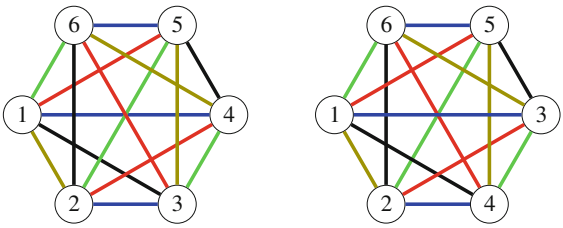
Moves in this neighborhood operate only on home-away patterns, leaving the timetable unchanged. The operator that defines the neighborhood consists of taking an arc of the oriented 1-factorization and reversing its orientation. In practice, it corresponds to exchanging the venue of the game between the two teams associated with the endpoints of this arc (see the representation illustrated in Fig. 3.).

Neighborhood "Team Swap" (TS)

Each move in this neighborhood is obtained by swapping two distinct nodes of the graph. After a TS move is applied to two nodes $v \neq w$, for every node $x \neq v$ and $x \neq w$, the arc between x and v gets the color previously used on the arc between x and w, and vice-versa. In practice, it corresponds to exchanging the opponents of the teams associated with nodes v and w in all tournament rounds. Figure 4 illustrates the application of a move in neighborhood TS to teams 3 and 4 for a schedule with six teams.

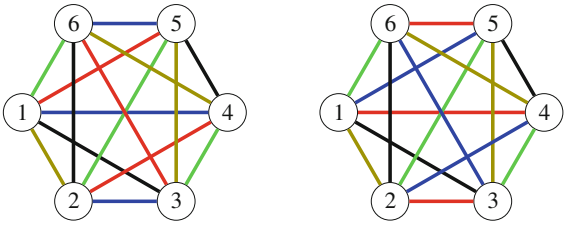
Neighborhood "Round Swap" (RS)

Moves in this neighborhood pick two distinct colors, j and k, and exchange them in all edges colored with any of these two colors. In other words, we swap the two 1-factors F_j and F_k associated with the colors j and k in the ordered 1-factorization.



(a) Current solution (b) Solution after move TS

Fig. 4 Graph on the left illustrates a 1-factorization of K_6. On the right, we see the 1-factorization obtained by a team swap move applied to teams (nodes) 3 and 4. (**a**) Current solution. (**b**) Solution after move TS



(a) Current solution (b) Solution after move RS

Fig. 5 Graph on the left illustrates a 1-factorization of K_6. On the right, we see the 1-factorization obtained by a round swap move applied to the colors red and blue. (**a**) Current solution. (**b**) Solution after move RS

In practice, it corresponds to swapping the two rounds j and k in the tournament sequence. Figure 5 illustrates the application of a move in neighborhood RS to the colors red and blue for a schedule with six teams.

Neighborhood "Partial Round Swap" (PRS)

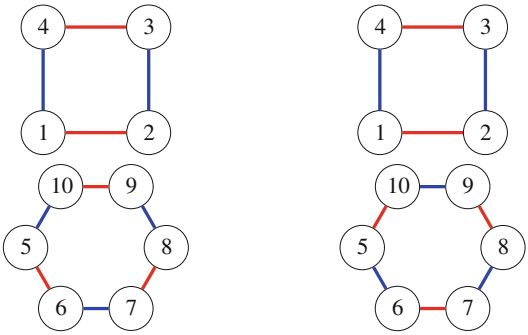
For moves in this neighborhood, we select two distinct colors and consider any cycle C in the subgraph formed by the edges colored with these colors. A neighbor is obtained by exchanging the colors in this cycle. If the edges of this cycle are incident to all vertices of the graph, i.e., if they form a Hamiltonian cycle, then this move is equivalent to a move in the RS neighborhood. Consequently, PRS and PS are equivalent in the case of perfect 1-factorizations. In practice, it corresponds to picking two rounds with a subset formed by an even number of teams that play exclusively among themselves in these two rounds. Figure 6 illustrates the application of a move in the PRS neighborhood.

A move in the neighborhood RS is equivalent to a sequence of moves in the neighborhood PRS.

Neighborhood "Partial Team Swap" (PTS)

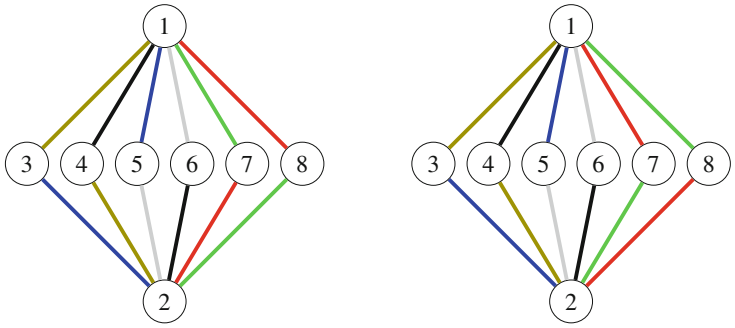
A move in this neighborhood takes two nodes v_1 and v_2 and a collection of chains $C = \{C_1, \ldots, C_p\}$ of length two between them. The set $\mathscr{S}$ of colors assigned to the edges of the chains in C adjacent to v_1 should be the same as the set of colors assigned to the edges of the chains in C adjacent to v_2. We choose $\mathscr{S}$ to be minimal, i.e., no proper subset of C satisfies this same condition. The edge-colored subgraph composed by v_1 and v_2 and the chains in C are called a *colorful chordless lantern*. Then, the two colors of each chain are exchanged.

If the number of colors occurring in these chains is always $2n - 2$ for any picked pair of nodes v_1 and v_2, then each PTS move is equivalent to a TS move. Such



(a) Current solution (b) Solution after move PRS

Fig. 6 Subgraph on the left is induced by edges with colors red and blue in a 1-factorization of K_{10}. On the right, we see the same subgraph after a partial round swap move has been applied by swapping the assignments of colors red and blue in the lower cycle. (**a**) Current solution. (**b**) Solution after move PRS



(a) Current solution (b) Solution after move PTS

Fig. 7 Subgraph on the left is obtained from a 1-factorization of K_8. On the right, we see the same subgraph after a partial team swap move with chains $C_1 =< v_1 = 1, 7, v_2 = 2 >$ and $C_2 =< v_1 = 1, 8, v_2 = 2 >$. (**a**) Current solution. (**b**) Solution after move PTS

1-factorizations have been named *L-blocking* in the literature because they block the possibility of obtaining a non-isomorphic 1-factorization by exchanging the colors of a colorful chordless lantern.

This move corresponds to picking the two teams corresponding to nodes v_1 and v_2 and a minimal subset of rounds in which both of them face the same opponents and then exchanging the opponents of v_1 and v_2 in each of these rounds. Figure 7 illustrates the application of a move in the PTS neighborhood with nodes $v_1 = 1$ and $v_2 = 2$.

A move in the neighborhood TS is equivalent to a sequence of moves in the neighborhood PTS.

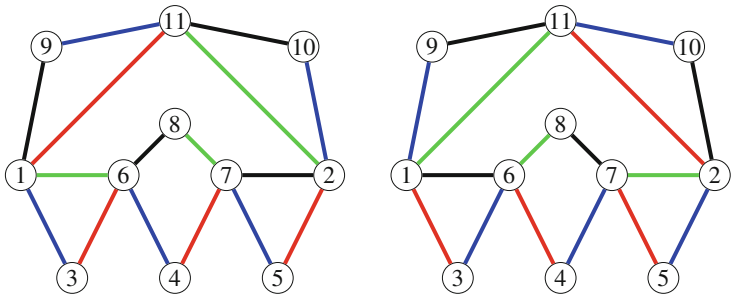
Neighborhood "Generalized Partial Team Swap" (GPTS)

This neighborhood involves two vertices v_1 and v_2 and a set of edge-disjoint alternating chains $\{C_1, \ldots, C_p\}$ of even length. We observe that GPTS generalizes both PRS and PTS. It generalizes PTS by allowing the chains to be longer than two. To see that it generalizes PRS, take v_1 and v_2 as two arbitrary nodes at even distance in the cycle C, and then the latter can be seen as two alternating chains of even length between v_1 and v_2. Figure 8 illustrates the application of a move in the GPTS neighborhood with nodes $v_1 = 1$ and $v_2 = 2$.

Considerations About the Neighborhoods

Several authors have used neighborhoods home-away swap (HAS), round swap (RS), team swap (TS), partial team swap (PTS), and partial round swap (PRS), although sometimes with different definitions, equivalent or not. Anagnostopoulos et al. [3] used moves in neighborhoods HAS, RS, TS, PRS, and PTS in their simulated annealing algorithm for the traveling tournament problem. Ribeiro and Urrutia [100] used moves in neighborhoods HAS, RS, and TS and in a restricted PRS in the local search of their hybrid heuristic for the mirrored traveling tournament problem. They also used ejection chain moves named game rotations as perturbations that are proved to be equivalent to PTS moves in Ribeiro et al. [104].

Guedes and Ribeiro [41] used moves in neighborhoods TS, RS, PRS, and PTS, as well as game rotation, row destruction, and column destruction perturbations in their hybrid ILS with multi-start heuristic for the minimum weighted carry-over problem. Costa et al. [14] used neighborhoods PRS and PTS in the local search of their ILS heuristic for the traveling tournament problem with fixed venues. They also showed that a move in the neighborhood TS (resp. RS) is equivalent to a sequence



(a) Current solution (b) Solution after move GPTS

Fig. 8 Subgraph on the left is obtained from a 1-factorization of K_{12}. On the right, we see the same subgraph after a generalized partial team swap move involving four alternating chains between nodes $v_1 = 1$ and $v_2 = 2$ (not all nodes of K_{12} appear in the figure). (**a**) Current solution. (**b**) Solution after move GPTS

of moves in the neighborhood PTS (resp. PRS). Di Gaspero and Schaerf [19] in their composite-neighborhood tabu search approach for the traveling tournament problem used neighborhoods HAS, TS, RS, PTS, and PRS. The last two are seen as repair chains, similar to ejection chains. Rosati et al. [105] also used neighborhoods TS, RS, PTS, and PRS in their multi-neighborhood simulated annealing for the International Timetabling Competition 2021 [115], together with an additional "partial swap teams phased" neighborhood. This neighborhood consists of the application of moves in the PTS neighborhood limited to one of the two SRR schedules of a double round-robin tournament organized in two separate phases (i.e., a phased DRR tournament).

Januario and Urrutia [51] used a neighborhood that can be seen as a particular case of GTPS, in which only one chain is allowed to have an arbitrary even length, while the others have length two. Januario et al. [52] unified the nomenclature by describing all the neighborhoods in terms of edge colorings of a graph.

Connectivity of the Tournament Space

Let $\mathscr{G} = (F, M)$ be the search space graph associated with some round-robin tournament scheduling problem. The node set F is formed by all ordered oriented 1-factorizations of K_{2n}, where $2n$ is the number of teams. Given a neighborhood structure $\mathscr{N}$, two nodes $u, v \in F$ are adjacent, i.e., $[u, v] \in M$, if and only if $u \in \mathscr{N}(v)$ and $v \in \mathscr{N}(u)$. The question arises to determine whether $\mathscr{G}$ is connected or not. If not, starting from some initial solution and applying a local search method, it might be impossible to reach some solutions because they are in different connected components of $\mathscr{G}$.

The size of the search space graph $\mathscr{G} = (F, M)$ of single round-robin tournament scheduling problems is huge even when compared with those of other classical combinatorial optimization problems, such as the traveling salesman problem. There is no known formula for the number of different 1-factorizations of K_{2n}. The number of non-isomorphic 1-factorizations of K_{2n} increases rapidly with $2n$. There are 526,915,620 non-isomorphic 1-factorizations of K_{12} [20] and 1,132,835,421,602,062,347 of K_{14} [56]. The number of single round-robin schedules is even much higher since for each of these non-isomorphic 1-factorizations, there are different round permutations, different home-away assignments for each game, and different teams' assignments to nodes.

In a perfect 1-factorization, the subgraph containing all vertices and edges belonging to the union of any two 1-factors is a Hamiltonian cycle. A perfect 1-factorization may not be desirable as the initial solution for local search algorithms for tournament scheduling problems because every move in the PRS neighborhood has the same effect as a move in the RS neighborhood, generating colorings that are isomorphic to the original one.

Kobayashi [61] showed that the values of $2n$ for which the canonical factorization is perfect are precisely the values of $p + 1$ for which $p > 2$ is prime. Januario et al. [53] showed that the values of $2n$ for which the canonical 1-factorization is

perfect and the PTS and TS neighborhoods coincide are the same for which a riffle permutation permutes all except the first and last of $2n$ distinct integers. Urrutia et al. [112] coined the term colorful chordless lantern and studied different properties of L-blocking 1-factorizations. They also investigated K-blocking 1-factorizations that do not contain an optimally colored even clique whose cardinality is smaller than the number of nodes.

The circle method is a simple strategy to obtain initial solutions for local search heuristics for single round-robin tournament scheduling problems. However, it generates only one type of 1-factorizations for K_{2n}, the canonical 1-factorization. It generates perfect 1-factorizations for every complete graph K_{2n} for which $2n = p + 1$, where p is a prime number. Therefore, whenever an initial solution is generated by the circle method, a move in the PRS neighborhood is equivalent to a move in the RS neighborhood. Consequently, these neighborhoods always lead to 1-factorizations that are isomorphic to the canonical one.

We may argue if the PTS neighborhood may be used to make the search escape from canonical 1-factorizations. In some cases, this neighborhood suffers from a similar drawback. PTS moves are equivalent to TS moves when there are $2n - 2$ chains of length two in the set $C = \{C_1, \ldots, C_p\}$ computed as explained in section "Neighborhoods for Round-Robin Tournaments." We could still ask if the neighborhoods PTS and TS are equivalent for some values of $2n$ for which the canonical 1-factorization is perfect. In order to provide an answer to this conjecture, we applied an exhaustive search procedure to check if that was the case for each value of $2n = p + 1 \leq 100$, where p is prime. We found that the PTS neighborhood is equivalent to the TS neighborhood for canonical 1-factorizations of K_{2n} for $2n =$ 4, 6, 12, 14, 20, 30, 38, 54, 60, 62, 68, and 84.

These results show that, for all the above values of $2n$, any local search heuristic using an initial solution constructed by the circle method will be trapped in a small portion of the search space formed by all 1-factorizations isomorphic to the canonical one.

In such cases, applying other constructive algorithms instead of the circle method, or using the GPTS neighborhood, might improve the effectiveness of the local search by exploring a broader portion of the search space.

An experiment using the circle method and the Vizing's algorithm [14] to build initial solutions for the traveling tournament problem with predefined venues was performed on instances with 18 and 20 teams. No significant improvements were observed for the instances with 18 teams when Vizing's algorithm was applied because, in this case, neighborhood PTS allows to escape from the canonical 1-factorization. However, for the instances with 20 teams, an improvement of almost 19% on average in the cost function was obtained when Vizing's algorithm replaced the circle method for constructing the initial solution. This experiment revealed that the coloring method based on Vizing's theorem could yield better results than canonical 1-factorizations.

It is not known whether neighborhood GPTS is connected or not. However, the example depicted in Tables 2 and 3 and Figs. 9 and 10 shows that the neighborhood GPTS can connect the canonical 1-factorization of K_{12} with a non-isomorphic

Table 2 Perfect 1-factorization of K_{12} for which neighborhoods PTS and TS are equivalent

K_{12} with a non-isomorphic 1-factorization that is not perfect. We recall that the canonical 1-factorization of K_{12} is one of the cases for which both TS and PTS are equivalent, as well as RS and PRS. Although this is not a proof of connectivity, it shows that neighborhood GPTS creates some connections in the search space graph $\mathscr{G} = (F, M)$ associated with the union of neighborhoods HAS, TS, RS, PTS, and PRS.

Concluding Remarks

Sports scheduling was the theme of the Fifth International Timetabling Competition (ITC2021). Its goal was to promote and provide insights into the development of more generally applicable sports timetabling solvers, considering that most works in the literature deal with particular sports scheduling problems applied to a specific context (in terms of the league, sport, and region).

The proposed problem asked for a schedule for a compact double round-robin tournament with 16, 18, or 20 teams. In some instances, the schedule must be phased, meaning that it should be composed of two consecutive single round-robin tournaments with an opposite home-away assignment.

The constraints were grouped into soft and hard and divided into five categories. Capacity constraints force a team to play home or away in a given round, limit the number of games a team plays against a particular group of teams in a given period, set a limit on the number of consecutive home or away games, or enforce complementary patterns of home and away games. Game constraints enforce or forbid specific assignments of games to rounds. Fairness constraints impose that the maximum difference between the number of home games played by any pair of teams is at most two at any particular point in the tournament. Break constraints regulate the maximum number of home, away, and total breaks, as well as the set of rounds in which such breaks are allowed to happen. Finally, separation constraints impose lower and upper bounds on the number of rounds separating two games between the same teams.

Table 4 Applications of metaheuristics to sports scheduling problems

Metaheuristic	Problem	Reference
Simulated annealing	International Timetabling Competition 2021	Rosati et al. [105]
	Cricket scheduling (England)	Wright [128]

Ant colony optimization	Traveling tournament problem	Uthus et al. [114]
	Maximum value tournament scheduling	Uthus et al. [113]

To encompass as many real problems as possible, the soft and hard constraints varied from one instance to another. The objective function consisted in the minimization of penalties associated with the violation of the soft constraints, while the hard constraints must necessarily be met. Some algorithms proposed for the problem are described in Van Bulck et al. [118].

Table 4 concludes this chapter by presenting a non-exhaustive collection of applications of metaheuristics to sports scheduling problems. We include both time-constrained and time-relaxed sports scheduling applications. For each metaheuristic, we indicate the problems that motivated the applications and the corresponding references where they appeared. The base metaheuristic was sometimes hybridized with integer programming, constraint programming, or another metaheuristic. Although constraint programming is an efficient approach for scheduling problems in sports with intricate feasibility patterns [4, 46, 79, 109], entries to its specific applications are omitted from this table (see, e.g., Knust [60] for an extended list of references about sports scheduling methods and applications).

Competing Interest Declaration The author(s) has no competing interests to declare that are relevant to the content of this manuscript.

Abstract

Several real-world problems can be modeled as graph problems. Graph algorithms and theories that have evolved for decades can be applied to solve the problem on hand. Interestingly, many of these graph problems can be solved polynomially, while small changes in a problem definition turn the problem difficult. In this chapter, we explore this path from polynomial network problems to NP-hard ones. Along the chapter, we visit several problems, dedicating more extended discussions to two real-world problems: the weight setting problem,

originated from telecommunication networks, and the virtual network embedded problem, a recent stated optimization problem from the computer network area. For these two problems, we discuss their heuristic solution, since only small instances can be solved exactly within a reasonable amount of time.

Introduction

Many problems can be modeled as graphs. Once a problem can be modeled as a graph, all graph algorithms and theories that have evolved for decades can be applied to analyze and solve the problem at hand. It is the case, for example, of social networks or webgraphs. In webgraphs, nodes represent webpages and edges are hyperlinks, while in social networks nodes usually represent people, and arcs represent interaction among them. In these two types of networks basically, the graph topology is analyzed, which usually configures complex and massive networks. Google and Facebook base some of their algorithms on these graphs. On the other hand, in biological networks, nodes can be represented by genes, and the correlation between each pair of nodes is represented through edge weights in a complete graph. By analyzing these graphs, scientists discover genes related to diseases and can then propose new drugs and observe how they affect the edge weights of the graph. Health schools and computer science groups have made several joint efforts in this direction.

Another class consists of graphs originating from services, such as telecommunication and road networks. These service graphs naturally are represented as a set of elements that includes a topology, but also additional information about nodes and arcs such as capacity, distance, demand, and delay are considered in computations over the network. In this chapter, we focus on problems over service networks. We will also discuss strategies applied to network optimization problems. Initially, we introduce related polynomial problems, and then we discuss constraints that turn the problems difficult to solve. Among the hard problems, we put some emphasis on two NP-hard problems: the weight setting problem (WSP) and virtual network embedded problem (VNEP). WSP has its main applications in traffic engineering problems from transit and telecommunications, while VNEP is a computer network problem.

We present most of the problems by their definition and also by their mathematical formulation. We aim to make the reader familiar with the mathematical problem modeling since optimization can often exploit this feature when solving a problem. Moreover, by analyzing their mathematical formulations, we can also highlight how characteristics of the problem change its modeling and affect its algorithms and solution space.

Preliminaries

Graphs naturally model network problems. Let $G = (V, A)$ denote a directed graph (DAG), where V is the set of nodes and A is the set of arcs. In a directed graph, the set of outgoing arcs from u is represented by $N^+(u)$, and similarly $N^-(u)$ represents the set of incoming arcs to node u. We denote the size of these sets by $|V| = n$ and $|A| = m$. An arc (u, v) has u as the tail node and v as the head node. Throughout this chapter we consider problems in simple graphs, that is, graphs without self-loops or parallel edges. However, directed graphs can admit symmetric arcs (u, v) and (v, u). A path in a graph is a sequence of arcs that connect pairs of neighbor nodes. The path is simple if there are no loops. Along the text, link and arc are used as synonymous.

Basic Network Problems

Initially, we introduce three representative polynomial time network problems that are found independently or as part of the core of more complex optimization problems. From several problem candidates, the point-to-point shortest path problem, maximum flow problem, and minimum cost flow problem were chosen to be discussed. These are fundamental network problems that have several variants that embrace a large number of practical applications.

Point-to-Point Shortest Path Problem (PPSPP)

Given a directed graph $G = (V, A)$ with weights w associated to arcs $w : A \to \mathcal{R}^+$, and source s and target t nodes, the PPSP problem consists in finding the path of minimum cost between nodes s and t. If a variable $x_a \in \{0, 1\}$ is associated to each $a \in A$, representing whether arc a is part of the solution, the point-to-point shortest path problem can be mathematically formulated as:

$$\textbf{min} \quad \sum_{a \in A} w_a x_a \tag{1}$$

$$\textbf{s.a} \quad \sum_{a \in N^+(v)} x_a - \sum_{a \in N^-(v)} x_a = \begin{cases} 1, \text{for } v = s, \\ 0, \text{for } v \in V \setminus \{s, t\}, \\ -1, \text{for } v = t. \end{cases} \quad x_a \in \{0, 1\} \text{ for } a \in A. \tag{2}$$

The objective is to minimize the cost path (Eq. 1). The path constraints (2) guarantee to find a valid path between nodes s and t. If $w : A \to \mathcal{R}^{+*}$, i.e., w has only positive values, the path found is always simple, otherwise, the shortest

path can have cycles of zero cost. The weight function w associated to arcs can represent time, cost, distance, or other measures, depending on the application. A typical application of this problem is to find a route in a road network of a navigation system, as a GPS, where w represents distance or time or the result of a cost function involving these two measures.

This problem can be solved exactly in time $O(m \log n)$ using binary heaps by the Dijkstra's algorithm. If additional information is available (or possible to compute), such as estimated distances (it cannot be an overestimation) between each pair of nodes, an admissible heuristic function can be used as part of the evaluation function of the A^* algorithm, and its time performance can be sped up. Also, in some situations, heuristics can be used such that a sub-optimal solution is returned. It is the case of *anytime algorithms* [30], which a feasible solution is requested in a short time, and as more time is available, the solution can be improved to a given ϵ distance error or up to optimality. Another case where the algorithm performance can be sped up is when a large number of queries of a path between a pair of nodes are requested, considering a static input [22, 28, 29]. In this case, information can be pre-computed and stored to be used in multiple queries. Finally, if one or more arc weight values of the input graph change, a previously calculated shortest path can be updated, instead of recomputed [35] from scratch. This approach is efficient when the application requires successive changes and updates of the graph.

Next, we discuss two flow problems. We focus on the integer version of the problems, i.e., the flow traversing each arc is always an integer value. For an extensive study in network flow problems, we refer to [1] which addresses theoretical and practical aspects of several problems.

Maximum Flow Problem (MFP)

The maximum flow problem (MFP) is a fundamental problem in network optimization. Given a directed graph $G = (V, A)$ with arc capacities $l : A \to \mathcal{R}$ associated with arcs, and source s and target t nodes, the problem consists in sending the maximum amount of flow between s and t without surpassing the arc capacities. If variables $x_a \in \mathcal{N}$ represent the amount of load on each $a \in A$, where $d_s = F$, $d_t = -F$, and $d_u = 0$ for $u \in V \setminus \{s, t\}$, and F stands for the maximal amount of flow traversing the network, this problem can be mathematically formulated as:

$$\textbf{max} \quad F = \sum_{a \in N^+(s)} x_a \tag{3}$$

$$\textbf{s.a} \quad \sum_{a \in N^+(v)} x_a - \sum_{a \in N^-(v)} x_a = d_v, \text{for } v \in V, \tag{4}$$

$$x_a \leq l_a, \text{for } a \in A, \tag{5}$$

$$x_a \in \mathcal{N}, \text{for } a \in A. \tag{6}$$

The objective function (3) maximizes the flow outgoing node s and traversing the network directed to node t, while constraints (5) assure capacities are not surpassed. Constraints (4) guarantee flow conservation: the difference between the total flow emanating from v and entering node v is equal to its supply/demand.

The MFP problem can be solved polynomially. In 1956 the pseudo-polynomial algorithm of Ford-Fulkerson was proposed. It has a time complexity of $O(m^2 \log F)$, where F is the maximum flow traversing the network. In 1972 a specialization of the previous algorithm was proposed which led to the Edmonds-Karp algorithm, whose time complexity is $O(nm^2)$, the first polynomial algorithm for solving the problem. A few other polynomial algorithms were proposed over the years, with a remark to the $O(n^3)$ algorithm of Goldberg and Tarjan [21] (fastest in practice) and the recently proposed $O(mn)$ algorithm of Orlin [33].

Minimum Cost Flow Problem (MCFP)

If besides capacities we have also costs $w : A \to \mathcal{R}$ associated with arcs, each node u can supply or demand a flow $d_u \in \mathcal{N}$, we can then define the minimum cost flow problem. The problem consists in transporting the flow through the network, respecting capacity constraints, and minimizing the cost function. With $x_a \in \mathcal{N}$ being the flow amount on arc a, the objective function of the problem is

$$\textbf{min} \quad \sum_{a \in A} w_a x_a$$

while the constrains are the same (4), (5), and (6) from the MFP, with d_u positive for supply nodes and set to negative for demand nodes. Moreover, the sum of all supplies should be equal to the sum of all demands, otherwise, the problem has no solution. This problem and several variants can be solved by the algorithms for the MFC, with a simple modification of the input graph [27, Sect. 7.7].

The arc capacities naturally define upper bounds on the flow on arcs. A common variant of flow problems is to consider also a lower bound on arc capacities, forcing that a given minimum amount of flow circulates on certain arcs. If lower bounds are considered on the flow problems above, then the problem is still polynomial [27, Sect. 7.7].

Consider the set S of source nodes and a set T of target nodes. In case $S \cap T = \varnothing$, both MFP and MCFP remain polynomial due to the Hoffman-Kruskal theorem on totally unimodular matrices [24]. However, if $S \cap T \neq \varnothing$, these problems are not polynomial anymore, and we discuss some variants in the next subsection.

Multicommodity Flow Problems

The MCFP and MFP route a commodity per time. In multicommodity flow problems, not one, but several commodities are routed simultaneously on the network.

Let $K = \{(o(1), d(1)), (o(2), d(2)), \ldots, (o(|K|), t(|K|)\} \subseteq V \times V$ denote the set of commodities or origin-destination (OD) pairs, where $o(k)$ and $t(k)$ represent, respectively, the origination and destination nodes for $k = 1, \ldots, |K|$. Each commodity k has an associated demand of traffic flow $d_k = d_{o(k),t(k)}$, i.e., for each OD pair $(o(k), t(k))$, there is an associated flow d_k that emanates from node $o(k)$ and terminates in node $t(k)$. The total set of commodities defines a demand matrix whose each entry $[o(k)][t(k)]$ specifies the demand $d_k = d_{o(k),t(k)}$.

The MFP and MCFP problems can be easily extended to a multicommodity flow version. Given an arbitrary OD matrix, the multicommodity MCFP can be formulated as:

$$\textbf{min} \quad \sum_{a \in A} w_a \sum_{k \in K} x_a^k \tag{7}$$

$$\textbf{s.a} \quad \sum_{k \in K} \sum_{a \in N^+(v)} x_a^k - \sum_{k \in K} \sum_{a \in N^-(v)} x_a^k = d_v^k, \text{ for } v \in V \tag{8}$$

$$\sum_{k \in K} x_a^k \leq l_a, \text{ for } a \in A, x_a \in \mathcal{N}, \text{ for } a \in A. \tag{9}$$

The time complexity of different variants of the problem is classified as polynomial or not, depending on the problem definition. For both, direct and undirect graphs, the decision version of the multicommodity integer flow problem is NP-complete even if the number of commodities is two [16].

Heuristics are largely applied as the solution approach for NP-hard multicommodity network optimization problems. The reasons are diverse. There are cases solved by mathematical programming approaches when the instances are small. However, for most cases, an exact approach does not solve medium instances of the problem even if a long time is available for processing. It is common to happen that the model cannot even be uploaded by the solver due to its size. There are also situations in which the problem cannot be mathematically modeled by linear or nonlinear constraints, as, for example, some electrical network characteristics such as electrical impedance. More often the problem can be modeled, but it results in a nontrivial nonlinear problem model that cannot be efficiently solved in a reasonable amount of time. Finally, some problems take as input data sets composed of multiple data that are in many cases estimates or average values. An exact solution, in this case, many times does not represent the best solution for the problem. For all these applications, heuristics are largely applied, and in most cases, they are the only possible practical resolution approach for the problem.

Even when a problem is solved heuristically, modeling the problem and solving it exactly is always important to find out which size an exact approach can be used in practice and if there are subsets of instances that are easier to solve exactly.

The next two subsections detail two NP-hard problems that are found in service networks and which are solved through metaheuristics. Their solution approaches are also presented and discussed.

Weight Setting Problem (WSP)

The weight setting problem (WSP) is defined in a directed weighted capacitated network G = (V,A), with $w : A \rightarrow \mathcal{N}$ and $l : A \rightarrow \mathcal{R}^+$. The problem consists in attributing a weight on each arc of the network such that when each flow from a demand matrix is sent along the shortest paths, a cost function $\phi(l_a)$, which depends on the arc flow l_a, is minimized. Usually, ϕ is a congestion cost function, and it can be defined in different ways according to specific goals.

The WSP has its primary application in telecommunication networks. The Internet is divided into autonomous systems (AS). Each AS controls its interior routing by an interior gateway protocol. Common interior gateway protocols, for instance, open shortest path first (OSPF), allow the operator to define the routes by setting integer weights on the network links. For example, in the main application described in this chapter, weights are set in the range [1 : 20], and ϕ minimizes the network congestion.

Another application of the WSP is in road networks. A road network can be represented as a directed graph $G = (V, A)$ where V represents the set of nodes (street or road intersections or points of interest) and A the set of arcs (street or road segments). Each arc $a \in A$ has an associated capacity c_a, and a time t_a, called the *free flow time*, that represents the time spent when traversing the unloaded arc a. To calculate the congestion on each link, a potential function Φ_a is computed as a function of the load or flow ℓ_a on arc a, along with other arc-tuning parameters. The flow in an arc is computed taking into account that a driver takes the shortest path. The cost of a path is calculated as the sum of tolls allocated in the path or as a function of the time and tolls. The tollbooth problem [37] consists in attributing toll values on r arcs of a road network, such that when demand is sent along the shortest path between origin and destination, the network congestion is minimized. The weight w_a that the WSP problem defines on an arc a represents in the tollbooth problem the toll charged for each unit of flow traversing arc a. Note that in this case, at most r weights are allocated.

We detail in the rest of this section the WSP applied to telecommunication networks, revising the current approaches being used to solve the problem. We initiate this discussion describing the problem formally.

The WSP Applied to Telecommunication Networks

WSP receives as input a capacitated directed graph $G = (V, A)$ with a capacity of $l_a \in \mathcal{R}^+$ for each arc $a \in A$. Besides that, an OD demand matrix, with $d_k \in \mathrm{R}\ \forall k \in K$, where K is the set of commodities or OD pairs, is also given as input. The *OSPF weight setting problem* consists in determining weights to be assigned to the links so as to optimize a cost function, typically associated with a network congestion measure. Thus, the problem defines an integer weight $w_a \in [1 : 2^{16}]$ (most of the studies in the literature use $w_a \in [1 : 20]$) $\forall a \in A$. The flow is routed along the

shortest paths between $o(k)$ and $t(k)$ for each OD pair. The shortest paths are calculated according to the link weights w_a defined by the problem. If there is more than one shortest path to an OD pair, the flow is evenly split at each node among all outgoing arcs that belongs to the shortest path graph to the flow destination. The cost function takes into account the amount of load on each arc of the network. In [19] a piece-wise linear function $\Phi = \sum_{a \in A} \phi_{l_a}$ is used to calculate the cost function Φ. However, depending on the application, one can consider simpler cost functions such as the ratio between the load and the capacity on the arc $\frac{l_a}{c_a}$. A ratio on an arc larger than one means the arc is overloaded.

A mathematical model for the weight setting problem is given in eqs. (10), (11), (12), (13), (14), (15), (16), (17), (18), (19), and (20). The decision variables for this model determine the weight value of an arc a. Denote by $w_a \in \{W_{\min}, W_{\min}+1, \ldots, W_{\max}\}$ as the weight value attributed to arc $a \in A$, where $W_{\min} \in \mathcal{N}$ and $W_{\max} \in \mathcal{N}$ are the minimum and maximum values of weights, respectively. For convenience we specify $W_{\min} = 1$. Let Q be the set of all nodes that are a destination of at least one OD pair. The auxiliary binary variable y_a^q is set to one ($y_a^q = 1$) if arc $a \in A$ is part of a shortest path to destination node $q \in \mathcal{Q}$. Finally, auxiliary variable δ_v^q is the shortest path distance from node $v \in V$ to destination node $q \in \mathcal{Q}$, and the constants M_1, M_2 and M_3 are sufficiently larger numbers. Below the problem tackled in [8] is formulated inspired in constraints presented in [7].

$$\min \Phi = \sum_{a \in A} \phi\left(l_a\right) \tag{10}$$

Subject to :

$$\ell_a = \sum_{q \in \mathcal{Q}} x_a^q, \quad \forall a \in A, \tag{11}$$

$$\sum_{a \in N_v^+} x_a^q - \sum_{a \in N_v^-} x_a^q = d_{v,q}, \quad \forall v \in V \setminus \{q\}, \quad \forall q \in \mathcal{Q}, \tag{12}$$

$$w_a + \delta_{a_h}^q - \delta_{a_t}^q \geq 0, \quad \forall a \in A, \quad \forall q \in \mathcal{Q}, \tag{13}$$

$$\delta_q^q = 0, \quad \forall q \in \mathcal{Q}, \tag{14}$$

$$w_a + \delta_{a_h}^q - \delta_{a_t}^q \geq \left(1 - y_a^q\right)/M_1, \quad \forall a \in A, \quad \forall q \in \mathcal{Q}, \tag{15}$$

$$w_a + \delta_{a_h}^q - \delta_{a_t}^q \leq \left(1 - y_a^q\right) M_2, \quad \forall a \in A, \quad \forall q \in \mathcal{Q}, \tag{16}$$

$$y_a^q \geq x_a^q, \quad \forall a \in A, \quad \forall q \in \mathcal{Q}, \tag{17}$$

$$M_3 y_a^q + M_3 y_b^q \leq 2M_3 - x_a^q + x_b^q, \quad \forall a, b \in \mathrm{A}_{N_v^+}^2, \forall v \in V, \quad \forall q \in \mathcal{Q}, \tag{18}$$

$$W_{\min} \leq w_a \leq W_{\max}, \quad \forall a \in A, \tag{19}$$

$$x_a^q \in \mathcal{N}, y_a^q \in \{0, 1\}, w_a \geq 0, \delta_v^q \geq 0; \forall a \in A, \forall v \in V, \forall q \in \mathcal{Q}, \tag{20}$$

Objective function (10) minimizes average user travel time. Constraints (11) define the total flow on each arc $a \in A$, while constraints (12) impose flow conservation. The input data d_{uv} is the flow originated in u with destination in v. The following constraints impose the flow of each commodity to follow the shortest path between the corresponding OD pair. An arc a belongs to the shortest path to destination q if the distance $\delta_{a_h}^q - \delta_{a_t}^q$ is equal to the arc cost, which in this case is w_a. Thus, the constraints (13) define the shortest path distance for each node $v \in V$ and each destination $q \in \mathcal{Q}$. For consistency, constraints (14) require, for all $q \in \mathcal{Q}$, that the shortest distance from q to itself be zero. Constraints (15) and (16) together with (13) and (14) determine whether arc $a \in A$ belongs to the shortest path and thus determine the values of y_a^q, for $q \in \mathcal{Q}$. Constraints (15) require that an arc that does not belong to the shortest path has reduced cost $w_a + \delta_{a_h}^q - \delta_{a_t}^q > 0$. It also prevents flow from traversing zero-cost cycles. Constraints (16) assure that if the reduced cost of arc $a \in A$ and destination $q \in \mathcal{Q}$ is equal to zero, then arc a belongs to the shortest path to destination q, i.e., $y_a^q = 1$. Constraints (17) assure that flow is sent only on arcs belonging to a shortest path. Constraints (18) guarantee that flow is split evenly among all shortest paths (even-split constraints). In these constraints, $\mathsf{A}^2_{N_v^+}$ is the set of all ordered groups of two distinct elements of N_v^+. In [37] this constraint is also used and presented in detail. Constraints (19) limit the minimum and the maximum weight value. The last constraints define the domains of the variables.

Heuristic Approaches for the WSP

Fortz and Thorup showed that the weight setting problem for OSPF is NP-hard [19]. Several authors have proposed further heuristic solutions for solving variants of the problem applied in different contexts. Table 1 summarizes a literature review on solution approaches for solving the WSP. The first column of the table refers to the problem application. The problem is found in telecommunication and road networks. We mean by network operation the optimization on the use of available resources, while network design is related to the allocation of resources to attend minimal conditions for the network operation. Column $|V|/|A|/|OD|$ presents the measures (number of nodes, arcs, and OD pairs) of the largest network considered in the computational results for each reference indicated in the third column of the table. Finally, the last column presents the solution approach of each work indicated in the previous column. The methods used are tabu search (TS), genetic algorithms (GAs), simulated annealing (SA), memetic algorithm (MA), multi-objective optimization (MultiObj), heuristic based on mathematical programming (MIP), and biased random-key genetic algorithms (BRKGAs).

Table 1 Solution approaches for solving the WSP applied in different contexts

Application	$\|V\|$ / $\|A\|$ / $\|OD\|$	Reference	Solution approach
Telecommunications operation	100/403/–	[19, 20]	TS
Telecommunications operation	100/503/9,900	[15]	GA
Telecommunications operation	56/224/3,080	[34]	SA
Telecommunications operation	100/503/9,900	[8]	MA
Telecommunications design	30/148/–	[7]	MultiObj
Telecommunications design	71/350/4,960	[9]	MA
Telecommunication operation	50/88/662	[5]	MIP
Road network operation	974/2,153/9,505	[37]	BRKGA

In some of the works indicated in the third column of the table, the authors also presented results from optimal approaches, for comparison purposes. For example, in [37], which applies WSP to road networks, the largest network that CPLEX was able to solve optimally in less than 30 min has dimensions 9/26/68. If the instance sizes double, in about 50% of the runs, no feasible solution is found in 30 min. However, the BRKGA proposed in the paper presents results for real-world instances two orders of magnitude larger, within the same 30 min.

Construction Heuristics for the WSP

For all telecommunication operation problems from Table 1, a solution can be simply represented as a vector w of m weights, one for each arc. Once the weight vector is generated, the solution cost can be calculated according to Fig. 1.

In order to update the new arc loads, the shortest paths are computed to all destination nodes $t \in T$ and arrive at a graph $g^t = (V, A^t)$, $\forall\ t \in T$ (Line 2). This is achieved using Dijkstra's well-known shortest path algorithm. Since shortest paths are computed to all destination nodes, the directions of all arcs are reversed in G, and the distances $\pi_u^t,\ \ \forall\ u \in V$ to a destination in T are computed. Given the shortest paths to each destination, auxiliar vectors g^t (Line 3) and δ^t (Line 4) are computed considering each destination t. Each position $g_a^t \in \{0, 1\}$ indicates if arc a belongs to at least one shortest path with destination in t. On the nodes side, each position δ_v^t stores the number of outgoing arcs of node v that belongs to at least one shortest path with destination in t. The flows L^t (Line 5) from all OD demand pairs with destination t are then routed. Finally, the total flows $l_a\ \forall a \in A$ (Line 7). The cost of a solution is computed according to an evaluation function.

Any solution composed of integer weights generated within the range $[1{:}2^{16}]$ is a feasible solution in all telecommunication operation studies from Table 1. In fact, the interval [1:20] is adopted by most of the methods, since values are still within the range accepted by OSPF protocol and it was observed that with a larger range the results do not improve [15, 19]. If one or more arcs have their capacities surpassed, the solution evaluation will reflect this in a high objective function cost. In practice, in telecommunication networks a link overload means retransmission.

```
procedure EvaluateSolution(w)
1   forall t ∈ T do
2       π^t ← ReverseDijkstra(w);
3       g^t ← ComputeSPG(w, π^t);
4       δ^t ← ComputeDelta(g^t);
5       L^t ← ComputePartialLoads(μ, δ, π, g^t);
6   end forall
7   l ← ComputeTotalLoads(L);
8   Φ ← Σ_{a∈A} φ_a;
9   return(Φ);
end procedure
```

Fig. 1 Pseudo-code for a WSP solution evaluation procedure

In road networks, a link overload means high traffic. Thus, the problem allows the overload imposing a high cost in the objective function.

Even if any random solution is a feasible solution, it is hard to design a high-quality initial solution for this problem. Thus, most of the approaches use initial random solutions. However, two solution approaches were adopted in [9] that usually provides good initial solutions. One defines weights for each arc a proportional to the inverse of the arc capacity $1/c_a$. A second approach solves a relaxation of the problem considering the model with constraints (13), (14), (15), (16), (17), and (18), i.e., constraints that force the flow to take the shortest paths are not considered. The relaxation returns a set of fractional weights, which are rounded to the closest integer.

Local Search Heuristics for the WSP

The neighborhood used by most of the methods changes the weight of a single arc per time. In [19] an arc is chosen at random, and its weight is changed by a value selected at random in the interval [1:20]. Every time a weight value of an arc changes, the solution is reevaluated. To avoid recomputing solutions that were already evaluated, a hash function is used to detect when a solution was previously evaluated.

In [8] the local search also changes one arc weight per time but in a different fashion. Only the arcs with higher traffic have their weight changed. The initial step of the local search is to evaluate the current solution, given its weight vector. Then, the arcs with the higher traffic calculated according to ϕ_a have their weights changed, one arc at a time. However, the weight can only increase, one unit per time, while the solution is improving, or up to a specific weight defined by the algorithm. Instead of recomputing the whole shortest path graph from scratch, the graph and flow are only updated, to reflect the change. Moreover, unit changes are faster to compute than random changes [10]. Updating the graph is about 15 times faster than recomputing from scratch, as reported by the authors.

Virtual Network Embedded Problem (VNEP)

In the last few years, the amount of data routed through telecommunication networks has increased considerably. To attend the increasing demand, while maintaining a high quality of service for low prices, new enabling technologies are being deployed. One of them employs virtualizing environments which allow for multiple networks to simultaneously and transparently share the same physical structure. Likewise, service providers can offer customized services or co-location for expanded network presence [18]. Virtualization is a growing trend in the implementation of cloud computing architectures.

The virtual network embedding problem (VNEP) is central to achieve network virtualization. It consists of mapping virtual networks with heterogeneous architectures on physical infrastructures. Virtual nodes are mapped into physical substrate nodes, and virtual links are mapped into paths in the physical substrate network. Additionally, physical resources are finite and must be used judiciously: nodes have a processing capacity, and links have a bandwidth limit. The main objective of the VNEP is to minimize the use of the underlying resources such as bandwidth while respecting the mapping constraints. VNEP is a multicommodity flow problem since each virtual link corresponds to an OD pair since it consumes capacity of the substrate networks.

Several variants of VNEP have been proposed in the literature. For example, one virtual network can be mapped at a time [12], or several virtual networks are mapped simultaneously [23, 25]. Physical nodes and links can be restricted to host a limited number of virtual nodes and links, or specific virtual links can have a location restriction. Some applications have security restrictions which limit the subset of physical nodes and links that can be used for mapping [3]. Additional constraints can also be present such as delay [26], efficient use of energy [6], and redundancy [36]. Some of the VNEP variants allow path splitting. Others do not. When path splitting is enabled, virtual links are mapped to multiple paths in the substrate network.

The VNEP was shown to be NP-hard by a reduction from the bin packing problem [32]. Due to the difficulty of solving the VNEP, few exact algorithms have

been proposed in the literature. For most practical purposes, heuristic algorithms can provide good sub-optimal solutions for the problem.

Single VNEP Variant

This section describes the VNEP variant that maps a single virtual network into the substrate. Thus, a VNEP instance has as input a virtual network and a physical substrate network. The physical substrate is represented by an undirected graph $G^S = \left(V^S, A^S\right)$ with a CPU capacity of C_s for each physical node $s \in \mathrm{V^S}$ and a bandwidth capacity B_a for each arc $a \in A^S$. The virtual network is represented by an undirected graph $G^V = \left(V^V, A^V\right)$ along with a demand C_v for each virtual node $v \in V^V$ and a bandwidth demand of B_k for each virtual link $k \in A^V$.

The objective of the proposed problem is to find a feasible mapping of the virtual nodes and links onto the physical network with minimal cost. A feasible mapping is a pair of functions (f_v, f_e): a mapping of nodes $f_v : V^V \to \mathrm{V^S}$ and a mapping of links $f_{e=(w,u)} : A^V \to P$, where P is the set of paths in the substrate graph with endpoints $f_v(w)$ and $f_v(u)$. Each virtual node has to be mapped into a single substrate node with enough CPU capacity to host it. A substrate node can host at most one virtual node. Each virtual link $(w, u) \in A^V$ has to be mapped to a path in the physical graph between the nodes $f_v(w)$ and $f_v(u)$. An arc can host several virtual links, but the sum of their demands should not surpass the capacity of the arc. The cost of a mapping is the amount of bandwidth used in the physical network by the mapping.

Figure 2 presents an instance of the problem composed of a physical network with four nodes (left) and a virtual network with three nodes (center). Edges and nodes are labeled with their capacities or demands. The optimal mapping is shown on the right side of the figure. The optimal solution is to map node a to C, b to A, and c to B; the virtual link (a, b) is mapped to $C - B - A$, and the virtual link (b, c) is mapped to $A - B$. The cost of this solution is 50.

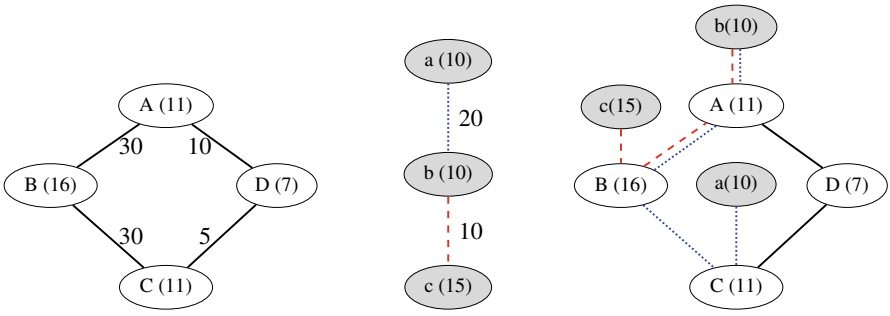

Fig. 2 An input instance for the VNEP (left and center) and the corresponding optimal solution (right)

An ILP model for VNEP with path splitting was presented in [13], while [2] considers a single path variant of the problem. Based on these models, [32] presented the ILP model below. Let the decision variables $x_{vs} = 1$ iff the substrate node s hosts the virtual node v. And let $y_{vwst} = 1$ iff the physical link (s, t) hosts the virtual link (v, w).

$$\min \sum_{(s,t)\in A^S} \sum_{(v,w)\in A^V} B_{vw}\, y_{vwst}$$

$$s.t. \sum_{v\in V^V} C_v x_{vs} \leq C_s \qquad \forall s \in V^S \tag{21}$$

$$\sum_{s\in V^S} x_{vs} = 1 \qquad \forall v \in V^V \tag{22}$$

$$\sum_{v\in V^V} x_{vs} \leq 1 \qquad \forall s \in V^S \tag{23}$$

$$\sum_{t\in V^S} (y_{vwst} - y_{vwts}) = x_{vs} - x_{ws} \qquad \forall (v, w) \in A^V, s \in V^S \tag{24}$$

$$\sum_{(v,w)\in A^V} B_{vw} y_{vwst} \leq B_{st} \qquad \forall (s, t) \in A^S \tag{25}$$

$$x_{vs} \in \{0, 1\} \qquad \forall v \in V^V, s \in V^S \tag{26}$$

$$y_{klmn} \in \{0, 1\} \qquad \forall (k, l) \in A^V, (m, n) \in A^S \tag{27}$$

The objective function minimizes the amount of bandwidth used. Constraints (21) ensure that the substrate capacities are not surpassed. Constraints (22) enforce that every virtual node is mapped to a substrate node, while (23) enforce that every substrate node hosts at most one virtual node. Constraints (24) ensure that every virtual link is mapped to a path into the substrate graph. Finally, constraints (25) ensure that the bandwidth capacities of physical edges are not surpassed.

Heuristic Approaches for the VNEP

Since the problem is NP-hard, and only small instances can be solved optimally [32], heuristics are a natural choice as solution approach to tackling this problem. In

this section, we discuss the main heuristic solution approaches adopted by different studies applied to variants of the problem.

Some authors use rounding schemes in an attempt to provide a solution for the problem. In [14] and [2] the authors present ILP models for different variants of VNEP, which they deemed impractical to solve optimally on large instances. To scale the instance sizes, they present rounding schemes applied to the relaxed solutions in order to obtain integer solutions. In both cases, a feasible solution is not guaranteed, but in practice the rounded solution is usually feasible.

In [14] a relaxation of the problem is solved by a solver, and a rounding algorithm is then applied to define to which substrate node each virtual node is mapped. Once nodes are mapped, a multicommodity flow algorithm is applied to determine the substrate path taken for each virtual link. The node mapping works as follows. One virtual node is mapped at a time. For each virtual node, a cluster comprised by a set of substrate nodes is defined according to a distance given as input. Among these nodes, one is selected for hosting the virtual node. The node is chosen according to the mapping variable and other input values.

In [2] the rounding scheme is different. Among the node mapping variables, the highest real value is rounded to 1, defining a mapping to a virtual node. Thus, this variable is fixed, and the relaxed problem is solved again. This procedure is repeated until all virtual nodes are mapped. In fact, four variations of this procedure were proposed in the paper. A similar procedure is applied to link mapping variables.

Considering metaheuristics, ant colony optimization is among the most used. Table 2 presents a summary of results found in the literature. The first column indicates whether the problem is the one defined in the previous section (basic) or if it has additional constraints. In this case, the type of additional constraints that impacts the solution of the problem the most is indicated. Column $|V^V|/|V^S|$ presents the number of virtual ($|V^V|$) and substrate nodes ($|V^S|$) of the largest network considered in the computational results for each reference indicated in the third column of the table. Finally, the last column presents the solution approach of each work indicated in the previous column. The solution approaches are simulated annealing (SA), rounding on the relaxed problem (LP-R), ant colony optimization (ACO), and branch and price (B and P).

Table 2 Solution approaches for solving the VNEP applied in different contexts

Additional constraints	$\|V^V\|$ / $\|V^S\|$	Reference	Solution approach
Node mapping	10/50	[13]	LP-R
QoS requirements	10/100	[17]	ACO
Repository of images	10/50	[2]	LP-R
Multiple mappings	–/35	[11]	ACO
Security	10/500	[4]	SA
Basic	8/80	[32]	B&P

Construction Heuristics for the VNEP

In [31, 32] the authors show that providing in polynomial time a solution that is guaranteed to be feasible is possible only if $P = NP$. Rounding schemes can also be used as construction heuristics. Thus, any proposed method generates solutions not guaranteed to be feasible. In [32] a construction heuristic was used at each node of the branch, bound tree aiming at improving the lower bound for that branch of the tree and then bounding branches earlier. The proposed heuristic works as follows. Each virtual node v is mapped to the free physical node s for which the value of $x_{v,s}$ is the largest. After all nodes are mapped, a breadth-first search is used to map virtual links to paths in the physical substrate graph. The mapping of edges can fail if no path with sufficient bandwidth is found.

In [4] a constructive heuristic is proposed and used by a simulated annealing metaheuristic algorithm. Virtual nodes are placed semi-randomly on substrate nodes, and then physical paths are allocated between these routers for each virtual link. The paths are calculated through Dijkstra's algorithm. The algorithm considers the weight of each physical link (i,j) to be the number of virtual links previously mapped to it and added by one. This weight calculation aims at favoring the selection of physical paths with higher amounts of free resources.

Local Search Heuristics for the VNEP

The most common neighborhoods used in this problem are the `swap` and `change`. In the `swap`, two virtual nodes swap the substrate nodes that host them. In the `change` neighborhood, a virtual node is moved to a substrate node which was not hosting any virtual node [4].

Conclusions

In this chapter, we discussed several network problems. A few computationally easy problems are presented since often they are the core of more complex problems. Moreover, often a small modification of a computationally easy problem can lead to an NP-hard problem. A fundamental multicommodity NP-hard problem was presented, and then two other real-world and more complex problems were discussed in detail: the weight setting problem (WSP) and the virtual network embedded problem (VNEP).

The WSP is used mainly for determining OSPF routing in telecommunication networks. However, it also finds applications in road networks, as the tollbooth problem described in this chapter. Some components of the main algorithms applied to solve the WSP in telecommunication networks were presented, and the problem was discussed. A similar approach was taken with regard to the VNEP. The problem was presented, motivated by components of proposed algorithms. Both are NP-hard network problems whose main solution methods rely on heuristics.

With the increase of the input data of almost all problems, the use of heuristics as a solution approach tends to increase. When designing a heuristic algorithm,

it is essential to justify the decisions taken by the algorithms proposed and the parameters used, and besides reporting the results, statistical analysis is always important to clarify the efficiency of the methods.

quality of communication, the energy consumption, and the network lifetime. Moreover, due to the large-scale aspect inherent in some applications, traditional exact solution approaches are not practical, so heuristics may be adopted instead. The chapter starts by introducing the main concepts in the design of WSN and a wide range of problems and applications. Basic formulations and algorithms are also discussed, together with their benefits and drawbacks.

Introduction

Wireless sensor networks (WSN) are a special kind of ad-hoc networks used to monitor events and phenomena in a given place [1, 2]. They have become popular due to their wide applicability in many different areas such as environmental (wildlife and environment), industrial (mines, production, manufacture), and health, in order to monitor temperature, humidity, pressure, and movement [3–5]. The study of such networks has been a fruitful area of research over the years and continues to enable the permanent evolution of technologies.

WSN consist of autonomous, small, and compact devices capable of performing activities such as sensing, processing, and communication. These devices are sensor nodes, and among them, may have one or more special nodes called sink, which is responsible for collecting the sensed data and managing the network. The sensors are made up of sensing boards, processor, communication radio, and battery. Because of their purposes, size, and low cost, they have serious restrictions of energy, low performance, and small radius of communication. For networks installed in areas with difficult access, it becomes unviable exchange or recharge the battery of a sensor. These characteristics imply a limited lifetime of the sensors and of the network itself.

The sensors are used to monitor a working area within a certain radius of coverage, besides being able to exchange information with other sensors and sinks. Two major communication patterns are often adopted: data collection and data dissemination. Data collection consists of sensors sending the collected data to a sink, while data dissemination concerns information from a sink being sent to the sensors. Those communication processes can be performed through one (single) or more (multi) hops or links. In this chapter whenever referring to the transmission of information, both senses are being considered. A sink aggregates the information received from sensors and usually has unlimited or renewable energy. It can be static or mobile, visiting the monitored region and collecting information from the sensors.

The sensor nodes are generally static but may also have mobility [6–8]. *Mobile WSN* consist of a number of sensors that can move on their own and interact with the physical environment. A sensor in a mobile network can also sense, process

information, and communicate like a static node. Mobility may be applied to the whole network or only to a subset of sensors. The degree of mobility can vary, including constant movement of the sensors or alternating periods of mobility/immobility. Those factors impact directly the network dynamics. Alongside with mobile networks, there are four more types of networks, which are distinguished mainly with respect to the place where the sensors are deployed. The sensors can be deployed on land, underground, and underwater [2]. A *terrestrial network*, for instance, consists of several sensors deployed on land, either in an ad-hoc or in a preplanned manner. In an *underground network*, the sensors are placed in caves, mines, or underground, while on an *underwater network*, the devices are deployed into rivers or oceans. Among these networks one can define a *multimedia network*, where the sensors are used to handle multimedia data. While a dense deployment of sensors is often employed in a terrestrial WSN, in an underwater WSN, a sparse deployment is used. The maintenance cost and difficulty of implementation of each network are directly dependent on the application constraints.

The classification of WSN depends primarily on their application. They are commonly classified into monitoring and tracking categories. Monitoring applications include patient monitoring in medical centers, security detection, habitat monitoring, power, inventory location, factory and automation processes, seismic and structural monitoring in the industrial or public context, and home-office environmental monitoring to provide basic services to smart environments, among others. Tracking applications include military missions, wildlife tracking, and traffic control. Consequently, the technologies used for each WSN are directly dependent on the network type. Refer to Yick et al. [2] for a survey of sensor technologies in practical situations.

WSN can also be classified into homogeneous or heterogeneous. WSN are said to be homogeneous, when composed by devices with the same hardware capabilities (processor, memory, battery, and communication device features). Conversely, WSN are heterogeneous when composed by devices with different capabilities. Another possibility to classify WSN is based on their organization. The networks can be hierarchical or flat. A sensor network is hierarchical when nodes are grouped for the purpose of communication, otherwise it is flat.

The lifetime of a WSN can be defined as the network operation time until the first sensor fails due to lack of energy. This chapter does not treat cases of failure for other reasons, such as mechanical failure or if a sensor is destroyed. Another definition of lifetime is given by the monitoring time until the coverage of the entire working area and network connectivity are not guaranteed.

Many factors influence the design of WSN. Fault tolerance, scalability, energy consumption, production cost, environment, network topology, hardware constraints, and transmission rate are some points to be considered. Due to the low battery capacity of the sensors, the energy consumption is one of the most important constraints on WSN [9]. In this context several problems are addressed to ensure coverage, monitoring, and connectivity, aiming to maximize the network lifetime within a minimum quality standard or quality of service (QoS) (QoS usually refers to quality as perceived by the user and/or application). In spite of

energy consumption being the most critical factor in WSN design, other parameters such as number of sensors, coverage, and network connectivity must also be considered.

The problems that appear in the context of WSN are studied independently or in an integrated manner. In general, to define them it is supposed that the working area to be covered is divided into small squares which represent points or demand nodes that require coverage by at least one sensor. This is a well-known approach applied in wireless network design. Each point concentrates the demand of its square. A point is considered covered by a sensor when the referred sensor is able to monitor it and if the point is within the radius of coverage of that sensor. The smaller are the square dimensions, the closer they are to describing continuous area. In the literature there are several works that do not make use of this discretization process, opting to explore the continuous space. Another assumption usually found in the literature is the use of unit disk graph to model the communication among sensors. A homogeneous transmission range for the sensors is considered and taken as the disk radius. Many works employ this model, although transmission ranges can be heterogeneous and also not defined as perfect disks. However, due to its theoretical simplicity, it is commonly applied. An evolution of this model, named quasi unit disk graph is proposed in [10].

Many algorithms can be devised to deal with WSN problems. Regarding optimality guarantees, they can be divided into exact approaches and heuristics. The former comprise algorithms developed to solve mathematical models based on integer linear programming (ILP), while the latter include proposals which relieve optimality conditions in order to provide scalability. Also, algorithms can perform in a centralized or distributed fashion. Centralized algorithms concern decision-making is done by a single entity in the network owning global information of the entire network. This entity is usually a sink node which is able to disseminate the solution for all sensors in the network. On the other hand, distributed algorithms indicate that many entities in the network take a joint decision based only on local information. Global information can improve the optimization process but is not always available and may not be applied in practice due to the overhead not allowed in real-time applications. Local information seems more reasonable in practice, but suffers from lower-quality solutions compared to the ones with global information. An alternative to take advantage of both methods is to use clustering, which can optimize locally inside each cluster. Thus, both exact methods and heuristics can be accomplished in such hybrid solutions. Distributed algorithms concern a wide topic of research [11–14] and are out of scope of this chapter.

The remainder of the chapter is organized as the following. A brief definition of classical problems appearing in WSN is presented in section "Problem Definition". Mixed integer linear programming formulations for these problems are outlined in section "Optimization Models". The aim is to formally describe some problems and give some intuition about exact solution approaches. Heuristic methods applied on the design of WSN are addressed in section "Heuristic Methods". Finally, the chapter is closed in section "Conclusion".

Problem Definition

To monitor inhospitable and inaccessible environments, sensors are deployed in an ad-hoc manner, launched from an aircraft or an unmanned vehicle. Thus, it is not possible to know beforehand their exact locations. However, knowing the location of these sensors is generally important to route data and to ensure connectivity. The problem of defining the positions of the sensors is known as *localization problem*. Some localization methods include Global Positioning System (GPS), beacon (anchor) nodes, and proximity-based localization that make use of the coordinates of neighbor nodes to determine their own localization. A review of location problems in WSN is given in [15].

It is straightforward to note that a fundamental requirement in the design of WSN is to ensure coverage of the working area. This problem is named as the *coverage problem*. The coverage level can be total or partial. In general, full coverage is often preferred. Therefore, the coverage problem chooses a set of active sensors such that each point is within a range of at least one sensor. The loss of coverage in at least one point can be characterized as end of the network lifetime.

To monitor accessible environments, the sensors may be optimally deployed in a preplanned manner. The *placement (deployment) problem* seeks to minimize the number of sensors deployed in order to guarantee connectivity and coverage of the entire monitoring area. The placement problem is a variant of the well-known art gallery problem [16], the problem of placing the fewest number of guards in a given area such that the surveillance is guaranteed. For the following problems, a usual assumption is to consider that the location of the sensors is known.

Another fundamental requirement in the design of WSN is the connectivity. The data collected by the sensors must be delivered to the sinks. Thus, routes must be established connecting each active sensor to a sink. A feasible route consists of links between pairs of sensors/sinks that respect the communication radius of each node. The fewer is the number of links, the smaller is the energy consumption. The *routing problem* aims to find feasible routes from each active sensor to the sinks, or vice versa, while optimizing a given resource. A solution for the routing problem consists of rooted trees, centered at the sinks, spanning a subset of active sensors. Automatically, the sensors nearest to the sinks may spend too much energy given the number of routes traversing those nodes. Such a drawback is known as the sink neighborhood problem [17]. There are two kinds of routing methods: reactive routing methods and proactive routing methods. In reactive methods the routes are calculated just in time. In proactive methods the routing tables are created and stored regardless of the moment the routes are used. However, in networks with large number of sensors, storing the routing tables can lead to excessive usage of memory. To overcome this problem, the sensors can be clustered and communication hierarchies be defined.

The sensors consume energy to perform communication, process, and aggregate data, besides maintenance, activation, or deactivation processes. There are several ways of dealing with the energy consumption. One possibility to extend the network

lifetime is to use a large number of sensors to ensure the desired coverage. However, to avoid using too much energy at a redundant coverage, the sensors do not perform at the same time. In this case, each sensor can be active, working on the network, or stay on standby, sleep mode, since energy consumption is extremely low in this mode. When active sensors fail due to depletion of their batteries, new sensors must be activated. The optimization problem arising in this context is the *density control problem* (DCP). The purpose of DCP is to schedule a sequence of activation and deactivation of sensor nodes in order to minimize the energy consumption and maximize the network lifetime. The network lifetime comes to an end when the network requirements are no longer ensured.

All the problems above have been considered for flat WSN. Whereas the communication among sensors and sinks is one of the most expensive operations in terms of energy consumption, an alternative to flat networks is to set hierarchies. In hierarchical networks, the sensors are clustered, and a single sensor is elected as the *cluster-head* in each cluster. It is up to the cluster-head aggregating and transmitting the information directly to a sink or through other cluster-heads. In such a *clustering problem*, from time to time, the cluster-head role can be swapped among the sensors within the same cluster to avoid premature failure due to lack of energy. Some classical combinatorial optimization problems such as p-median and p-center may apply in a clusterization scheme.

In the routing problem for hierarchical WSN, two kinds of routes are considered: *intra-cluster* route and *inter cluster* route. In intra-cluster routes the communication occurs among sensors and cluster-head within the same cluster through single or multi-hop strategies. In intercluster routes the connections are among cluster-heads and sinks. In both levels a tree topology must be defined to transmit the information from the sensors to their cluster-heads and from the cluster-heads to the sinks.

In some applications the mobility of the sinks is explored to gather sensed information through the network. This approach prevents the sensors to spend their limited energy in relaying of messages through a long path until the sinks. However, the message delivery latency can increase significantly, thanks to the long route traversed by a sink to visit the whole working area. In order to go around of such problem, clustering schemes must be used so that each sink only visits a reduced set of sensors (for instance, the cluster-heads). In this context, the communication between sensors and sink is only possible through a cluster-head using multi-hop or single-hop approaches to define the *intra-cluster* routes. Classical optimization problems such as shortest path and traveling salesman problem (TSP) are used to model the trails traversed by the mobile sinks.

Figure 1 illustrates optimization problems in WSN. Different tasks and objectives may be desired requiring specific approaches to deal with the problems described. In Fig. 2, for instance, two different approaches are presented exploring the mobility of the sink. In the first approach, a mobile sink visits each sensor in the working area to collect sensed data. This problem can be modeled with the TSP. Another alternative is to define a reduced TSP route, defining a subset of sensors to be visited by the mobile sink such that all the other sensors are close enough to establish the communication. This approach can be seen as a TSP by neighborhood.

Optimization Models

As presented earlier, many optimization problems arise in the design of WSN. Many of these problems are variants of classical combinatorial optimization problems that can be formulated as linear mixed-integer programming (MIP) models [18]. In the following, mathematical models for some of these problems are presented.

Coverage and Density Control

Mathematical formulations for coverage and density control problems can be found in [19–21]. The models consider the following notation: $S = \{1, \ldots, n\}$ is the set of sensors; $P = \{1, \ldots, p\}$ is the set of demand points to be covered by the sensors; matrix $A(n \times p)$ indicates whether a sensor $i \in S$ is able to cover ($a_{ij} = 1$) or not ($a_{ij} = 0$) the point $j \in P$ regarding the sensing range R_s^i. To each sensor $i \in S$, an activation energy E_a^i is also assigned.

A formulation to the coverage and density control problems uses binary variables $\{x_i \in \mathbb{B} : i \in S\}$ and $\left\{y_{ij} \in \mathbb{B} : i \in S,\ j \in P\right\}$ to define a subset of sensors selected to be active and the coverage relationship between S and P. If $x_i = 1$ holds, sensor $i \in S$ is active. If $y_{i,j} = 1$, demand point $j \in P$ is covered by sensor $i \in S$. Then, the coverage and density control formulation is given by:

$$\min \left\{ \sum_{i \in S} E_a^i x_i : (x, y) \in (2) - (5) \right\} \tag{1}$$

$$\sum_{i \in S} a_{ij} \ \ y_{ij} \geq 1 \qquad \forall j \in P; \tag{2}$$

$$a_{ij} \ \ y_{ij} \leq x_i \qquad \forall i \in S, \qquad \forall j \in P; \tag{3}$$

$$y_{ij} \in \{0, 1\} \qquad \forall i \in S, \qquad \forall j \in P; \tag{4}$$

$$x_i \in \{0, 1\} \qquad \forall i \in S. \tag{5}$$

Constraints (2), (3), (4), and (5) assure that active sensors cover the set of demand points. Constraints (2) guarantee that every demand point $j \in P$ is covered by at least one sensor $i \in S$. Constraints (3) ensure that only active sensors can provide the coverage of demand points. Constraints (4)–(5) impose variables to be binary. Finally, objective function (1) minimizes the energy consumed by the activation of sensor nodes.

Routing or Connectivity

Mathematical models exploring connectivity in the context of WSN are described in [19, 21, 22]. The models consider a set of static sinks $M = \{1, \ldots, m\}$ and a communication range (R_c^i) associated with each sensor $i \in S$. The matrix $B(n \times (n + m))$ indicates whether a sensor or sink $i \in S$ and $j \in S \cup M$ relies $(b_{ij} = 1)$ or not $(b_{ij} = 0)$ within the communication range R_c^i of each other. To each sensor $i \in S$ is also assigned the routing energy (E_r^i) required to communicate with other sensors or sinks.

Let $\left\{z_{jk}^i \in \mathbb{B} : i \in S,\ j \in S, k \in S \cup M\right\}$ denote decision variables used to indicate whether the sensors $j \in S$ and $k \in S \cup M$ belong $(z_{jk}^i = 1)$ or not $(z_{jk}^i = 0)$ to the communication path from sensor $i \in S$ to a sink node k. Alongside with the decision variables x_i defined in the first model, the routing problem, modeled as routing trees, can be formulated as:

$$\min \left\{ \sum_{i \in S} E_a^i \ \ x_i + \sum_{i \in S} \sum_{j \in S} \sum_{k \in S \cup M} E_r^i \ \ z_{jk}^i : (x, z) \in (7) - (12) \right\} \tag{6}$$

$$\sum_{k \in S \cup M} b_{jk} \; z^i_{jk} \leq x_j \quad \forall i \in S \backslash \{k\}, \quad \forall j \in S \backslash \{k\}; \tag{7}$$

$$\sum_{j \in S} b_{jk} \; z^i_{jk} \leq x_k \quad \forall i \in S \backslash \{k\}, \quad \forall k \in S \backslash \{j\} \cup M; \tag{8}$$

$$\sum_{j \in S} b_{jk} \; z^i_{jk} - \sum_{l \in S \cup M} b_{kl} \; z^i_{kl} = 0 \quad \forall i \in S, \qquad \forall k \in S \backslash \{i\}; \tag{9}$$

$$- \sum_{l \in S \cup M} b_{kl} \; z^i_{kl} = -x_i \qquad \forall i \in S, i = k; \tag{10}$$

$$z^i_{jk} \in \{0, 1\} \qquad \forall i \in S, \, j \in S, k \in S \cup M \tag{11}$$

$$x_i \in \{0, 1\} \qquad \forall i \in S. \tag{12}$$

Here, constraints (7), (8), (9), (10), (11), and (12) ensure connectivity among sensors and sinks. Constraints (7)–(8) assure that communication is only allowed among active sensors. Constraints (9) guarantee the flow balance for transshipment nodes. Constraints (10) indicate that the flow originates at active sensors. Constraints (11)–(12) impose the domain of the variables. Finally, the objective function (1) minimizes the routing and activation energies consumed.

Clustering and Mobile Sink

Valle et al. [23] proposed an integrated model for clustering and routing problems. The model considers a set of mobile sinks $M = \{1, \ldots, m\}$ and a set of arcs $A = \{(i, j), (j, i) : \forall i, j \in S, \, i \neq j\}$. Each arc $(i, j) \in A$ denotes a possible point-to-point movement for a sink. Additionally, d_{ij} is the Euclidean distance between i and $j \in S$. It is assumed that all sinks start from an initial sensor $i = 1$ and return to an artificial node 0, such that $\bar{A} = A \cup \{(i, 0) : \forall i \in S \backslash \{1\}\}$ and $\{(i, 0) : d_{i0} = d_{1i}, \forall i \in S \backslash \{1\}\}$. It is important to point out that each cluster-head is visited only once and by exactly one sink; a sensor $i \in S$ must be a cluster-head or be covered by a cluster-head; at least one cluster-head should belong to the set of neighbors of sensor i: $N(i) = \left\{ j \in S : d_{ij} \leq R^i_c \right\}$.

In order to model the integrated clustering and routing problem, assume the following decision variables: $\left\{ r^m_i \in \mathbb{B} : m \in M, i \in S \right\}$, taking value $r^m_i = 1$ if sensor $i \in S$ is a cluster-head in the route of the sink $m \in M$, otherwise $r^m_i = 0$; $\left\{ w^m_{ij} \in \mathbb{B} : m \in M, (i, j) \in \bar{A} \right\}$ that takes value $w^m_{ij} = 1$ if arc $(i, j) \in \bar{A}$ belongs to route of the sink $m \in M$, otherwise $w^m_{ij} = 0$; $\left\{ v^m_{ij} \in \mathbb{R}_+ : m \in M, (i, j) \in \bar{A} \right\}$, indicating the flow, originated at m, traversing arc $(i, j) \in \bar{A}$; and, finally, $\{h \in \mathbb{R}_+\}$

that denotes the longest length among all routes. The integrated clustering and routing problems can be formulated by the following MIP model:

$$\min \{h : (r, w, v, h) \in (14) - (27)\} \tag{13}$$

$$\sum_{i \in S \setminus \{1\}} v_{1,i}^m = \sum_{i \in \{0\} \cup S \setminus \{1\}} r_i^m \quad \forall m \in M; \tag{14}$$

$$\sum_{j \in \{0\} \cup S \setminus \{1\}} v_{ij}^m - \sum_{j \in S} v_{ji}^m = -r_i^m \quad \forall i \in S \setminus \{1\}, \quad \forall m \in M; \tag{15}$$

$$\sum_{i \in S} v_{i,0}^m = 1 \quad \forall m \in M; \tag{16}$$

$$v_{ij}^m \leq n w_{ij}^m \quad \forall (i, j) \in \bar{A}, \quad \forall m \in M; \tag{17}$$

$$w_{ij}^m \leq r_i^m \quad \forall (i, j) \in \bar{A}, \quad \forall m \in M; \tag{18}$$

$$w_{ij}^m \leq r_j^m \quad \forall (i, j) \in \bar{A}, \quad \forall m \in M; \tag{19}$$

$$\sum_{m \in M} r_i^m \leq 1 \quad \forall i \in S \setminus \{1\}; \tag{20}$$

$$\sum_{m \in M} \sum_{j \in N(i)} r_j^m + \sum_{m \in M} r_i^m \geq 1 \quad \forall i \in S \setminus \{1\}; \tag{21}$$

$$\sum_{j \in S \cup \{0\}} w_{ij}^m \leq 1 \quad \forall i \in S, \qquad \forall m \in M; \tag{22}$$

$$h \geq \sum_{(i,j)} \in \bar{A}\, d_{ij} w_{ij}^m \quad \forall m \in M; \tag{23}$$

$$r_1^m = r_0^m = 1 \quad \forall m \in M; \tag{24}$$

$$r_i^m \in \{0, 1\} \quad \forall i \in S \cup \{0\}, \quad \forall m \in M; \tag{25}$$

$$v_{ij}^m \geq 0 \quad \forall (i, j) \in \bar{A}, \quad \forall m \in M; \tag{26}$$

$$w_{ij}^m \in \{0, 1\} \quad \forall (i, j) \in \bar{A}, \quad \forall m \in M. \tag{27}$$

Constraints (14), (15), (16), (17), (18), (19), (20), (21), (22), (23), (24), (25), (26), and (27) ensure the integration of clustering and routing problems using mobile sinks. Constraints (14), (15), and (16) guarantee the flow conservation for nodes {1}, $S\backslash\{1\}$ and {0}, respectively. Note that constraints (14) assure that the flow of commodity m starting at node 1 is equal to the number of cluster-heads to be visited in the route plus the artificial node {0}. On the other hand, constraints (15) impose that each node i visited by $m \in M$ must consume a unit of flow. Inequalities (17), (18), and (19) are coupling constraints, ensuring that commodities only traverse arcs selected for the route and arcs of the route have endpoints consuming a unit of flow. Constraints (20) guarantee that a cluster-head is visited once by a single route. Constraints (21) assure that each sensor is a cluster-head or has a cluster-head as neighbor. Taken together, constraints (14), (15), (16) and (22) guarantee the topology of selected arcs induce M elementary routes connecting vertices 1 and 0. Constraints (23) define the longest length among all routes to be minimized by the objective function (13). Constraints (24) impose that the starting node 1 and the final artificial node 0 are part of all routes. Finally, constraints (25), (26), and (27) define the domain of variables.

Models (1), (6), and (13) can be implemented in optimization packages and solved with a branch-and-bound (BB) algorithm. However, the main drawback of this approach is that only instances of limited size are solvable in feasible computational time. Since WSN are designed as large-scale networks, it is not expected that a traditional BB is able to solve the problem to optimality. Therefore, one must resort to heuristic-based methods to tackle the problems.

Heuristic Methods

This section draws attention to heuristic-based methods used in the design of WSN. In general, heuristics are designed to face challenging and complex optimization problems in which exact optimization methods fail, especially when dealing with time-constrained online applications that are combinatorial in nature. Due to the practical and technological relevance of WSN, heuristics are preferentially the methods to be used. However, each heuristic is designed to tackle a specific problem. So, a given approach may not be generalized to solve different problems. Motivated by the need of general solution strategies, optimization researches have been focusing on the study of metaheuristics. A metaheuristic combines intensification and diversification procedures to perform guided searches through one or more neighborhood structures. Some metaheuristics used in the design of WSN are greedy randomized adaptive search procedure (GRASP) [24], path relinking (PR) [25], simulated annealing (SA) [26], iterated local search (ILS) [27], tabu search (TS) [28], variable neighborhood search (VNS) [29, 30], genetic algorithms (GA) [31], memetic algorithms (MA) [32], ant colony optimization (ACO) [33], and particle swarm optimization (PSO) [34]. For supplementary reading, Glover and Kochenberger [35] are referred to provide a good overview of the most popular metaheuristics. In addition to [36–40], here, the reader can find some hints of

how to use heuristics to solve practical WSN optimization problems when studied independently or in an integrated manner.

Sensor Location, Placement, and Coverage

As indicated above, the design of WSN has to concern with several classical problems. These include localization, placement, coverage, density control, clustering, routing, and sink mobility. In general, the purpose of solving these problems is to maximize the network lifetime, keeping connectivity, ensuring coverage, and reducing cost. Many existing applications require information about the geographic position of each node in the network. So, the localization problem must be solved first. The heuristics proposed in the literature for localization are generally based on GPS system, beacon (anchor) nodes, and proximity-based localization. These methods make use of the position of neighbor sensors, obtained during the installation of the network, to determine the position of a sensor. Molina and Alba [41], for instance, proposed heuristics based on SA, GA, and PSO to solve the localization problem. Their heuristics determine the sensor nodes locations using the trilateration technique. The global objective of their heuristic is to minimize the measured distance error comparing the node-to-node distances with the distance measured when using GPS. Shahrokhzadeh et al. [42] proposed a centralized (solved by a sink) SA-based heuristic for solving sensor nodes localization problem. Their heuristic is based on Euclidean distance and mathematical techniques, such as trilateration and triangulation.

The placement of the sensors is a key factor in the design of WSN. The deployment may be an activity performed during the installation of a network or may also be a continuous process to replace failed sensors or to improve the coverage over a certain area. As stated above, the placement problem seeks to minimize the number of sensors deployed in order to guarantee connectivity and coverage of the entire monitoring area. A number of deterministic greedy heuristics can be described to determine the minimum number of sensor needed. In general, those methods try to anticipate the sensor deployment in all candidates' points and keep the best position selected. Brazil et al. [43] modeled the placement problem as a version of the Steiner problem and solved it by means of a greedy-based heuristic. Sasikumar et al. [44] proposed two-phase heuristics for placing sensors in a heterogeneous network, called nearest to base station and max residual capacity. In this work, they separate the nodes on: sensors, relay nodes (RN), and base station (sink node). The RN node performs functions equivalent to a cluster-head, but may have unlimited energy. In the first phase, their heuristics place the RN nodes, wherein the placement problem is modeled as the minimum set covering problem. Then the sensors are placed on the second phase with a greedy criterion based either on the distance to the RN nodes or on residual energy remaining on the node. To solve the sink placement problem, Laszka et al. [45] provided a GA-based heuristic. SA-based heuristics for placement and coverage problems were also developed in [46].

Deschinkel [47] concentrates on a centralized scheme to solve the coverage problem, where a large number of sensors are randomly deployed in the monitoring area. The problem was modeled as the non-disjoint cover sets problem and solved by means of a column generation (CG) heuristic. In this procedure the subproblem is solved with a heuristic for the classical set covering problem that uses the dual multipliers from the master problem. They compare the results obtained by the heuristic with that provided by a MIP solver. Cardei et al. [48] also deal with coverage problem. The interesting aspect of their work is given when the authors consider the property that each sensor has adjustable sensing ranges. To solve the problem, a greedy-based heuristic was used.

Density Control, Clustering, Routing, and Sink Mobility

The solution algorithms for the placement problem may define a dense network. This characteristic increases the robustness against failures, however, leads to a large redundancy that can result in congestion and waste of energy. To overcome this problem, the density control problem is used to select a subset of sensors to be active while keeping the others inactive (sleep mode), which allows the reduction of the initial topology. Delicato et al. [49] formulated the DCP problem as a knapsack problem. In this approach, the expected time horizon is divided in small time periods. For each period, a subset of sensors must be activated. By formulating the DCP as a knapsack problem, each period is equivalent to a knapsack, so the problem is to find a set of nodes (items) to keep active (to be inserted in a knapsack) per period. In their model, coverage and connectivity are also considered. To solve the problem, a greedy-based heuristic was proposed. In this heuristic the sensors are sorted by their residual energy and then, following the given preference, the sensors are set to be active (inserted in a knapsack).

An interesting and effective multi-start (MS)-based heuristic to solve the density control problem is given by Karasabun et al. [50]. Their heuristic is composed by two phases, a constructive routine to define a set of initial active sensors and an iterative improving local search procedure. To ensure the network connectivity, the Steiner problem is solved over the active sensor nodes.

Clustering is another optimization problem considered when defining the network topology. The clustering problem directly contributes for the scalability of networks. Many existing protocols for defining clusters and selecting cluster-heads associated with them are based on random algorithms or heuristics to classical combinatorial optimization problems, such as p-median, dominating set, and set covering problems. In such approaches, every sensor node is either in a set of cluster-heads or is assigned to a cluster-head. In general, among the cluster-heads, a multi-hop communication scheme is used, while inside a cluster multi- and/or single-hop communication could be used. Santos et al. [51] modeled the clustering problem as the independent dominating set problem. Two greedy heuristics are described in that reference.

Matos et al. [52] call attention to the importance of rotating the sensor that acts as cluster-head within a single cluster. Cluster-heads consume much more energy than a sensor that does not perform this feature, since they need to aggregate, send, and receive sensing data. Thus, cluster-head rotation helps to avoid a premature death of a sensor, disconnecting the network. The rotation can be done from time to time or after some amount of data has been transferred by the network. In addition, Matos et al. [52] also proposed a centralized GRASP-based heuristic with path relinking as an intensification phase to solve the clustering problem. The problem was modeled as the p-median problem, where the cluster-heads are chosen among the alive sensors. The intra-clusters communication follows the single-hop strategy. Their heuristic is composed of three phases. In the constructive phase, a feasible solution is generated by the randomized greedy algorithm described in [53]. Then, a swap local search is applied. Finally, a path relinking routine is applied as intensification phase. To attest the effectiveness of their approach, they compared their heuristic with methods described in [54, 55]. Albath et al. [56] consider that a sensor to be selected as cluster-head must have enough residual energy. In their work, the problem of properly choosing cluster-heads was modeled as the minimum dominating set problem.

Looking for metaheuristics methods, Ferentinos and Tsiligiridis [57] described a GA-based heuristic used in an agriculture application. Their algorithm is designed to solve clustering and density control problem while respecting connectivity constraints. Another GA-based heuristic for clustering problem is addressed by Kuila et al. [58]. Ting and Liao [59] described the clustering problem as the k-cover problem and solved it with a MA-based heuristic.

The transmission of sensing data and the dissemination of information in WSN are referred as the routing problem. This problem is defined mainly when the nodes position and the cluster-heads selected are already known. The main objective when solving the routing problem is to guarantee the network connectivity. Routing in WSN design is tackled by many authors [19, 21, 22, 60] through a multi-hop strategy and fixed sink nodes as well as through mobile sinks [23, 61, 62].

Minimum spanning tree, shortest path, and TSP are preferentially used to model the routing problem in WSN design. In general the edge weight (length or cost) represents the energy needed to transmit data. Thus, routing algorithm based on Kruskal, Prim, Dijkstra, Bellman-Ford, or TSP methods can be applied. As stated in section "Problem Definition", the sink neighborhood problem [17] arises when dealing with fixed sink nodes. To overcome that problem, some alternatives take place. Some works consider multiple sinks or, in some contexts, explore the network by mobile sinks. More sinks result in shorter routes from sensors to their closest sink, while mobility may lead to an efficient scheme for the energy control.

Centralized and distributed heuristics to control and coordinate the current movement of multiple sinks seeking for the lifetime maximization in WSN are described by Basagni et al. [63]. In this reference, a sink is considered active when it is stopped, waiting for the sensor data, and inactive when it is moving through the network. In their approach at least one sink must move at a time, so it is necessary to define a schedule for the movements of sinks. The routing scheme was modeled with TSP problem and solved by a Christofides' heuristic [64].

To control the sink movements, Basagni et al. [17] introduced a distributed heuristic, named greedy maximum residual energy. In their heuristic, a sink defines its own route by moving from its current location to a new position by giving preference to areas with the highest residual energy. More precisely, the greedy criterion of the proposed heuristic is the amount of energy left in the sensors around a mobile sink that moves in direction of the sensors with higher energy to collect their data.

Integrated Problems

Most the works found in the WSN literature describe hierarchical approaches to the design of networks. Those works are drawn for solving WSN problems in multiple steps. Although less, there are works in the literature that address a number of classical WSN problems in an integrated manner [21, 65–72]. A natural clustering and routing problem is the minimum connected dominating set problem [73–75], the problem of finding a connected dominating set of cluster-heads with smallest cardinality. Aioffi et al. [66], for instance, have provided a constructive heuristic to an integrated problem, named integrated clustering and routing problem (ICRP). Their proposed heuristic is based on the cheapest insertion algorithm for the Euclidean TSP. In such method, a set of routes is iteratively defined, one for each mobile sink, at the same time as the sensors are grouped into clusters. Each sink node visits some cluster-heads, in such a way that every sensor node in the network is either a cluster-head visited by a route or lies within a cluster associated with a cluster-head in one of the possible routes. The greedy criterion of the proposed heuristic is based on the distance among the last cluster-head assigned to a route and the other cluster-heads not routed yet. Hybrid heuristics based on GRASP and ILS metaheuristics were also applied to solve the problem. Another integrated approach is due to Xing et al. [65] that also studied clustering and routing problems. To solve the problem, a heuristic was used in the following schemes. First, it solves the Steiner problem to select the cluster-heads and then uses a TSP local search heuristic to find a route for each mobile sink.

A TS-based heuristic for an integrated coverage, sink location, and routing problems can be found in Guney et al. [68]. The heuristic starts by finding near-optimal sensor locations satisfying the coverage requirements, and then it solves the sink location and the data routing problem modeled as the p-median problem. Türkogullari et al. [76] proposed a hybrid heuristic to solve large instance of an integrated problem involving sensor placement, density control, sink location, and routing problem with low conservation, energy consumption, and budget constraints. In such algorithm, the optimal sensor-to-sink routes are solved as a linear program (LP), while the sink location problem is modeled as a set covering problem and solved by a disjoint sets heuristic. Another heuristic based on exact approach, used to solve large and real-life sink location and routing problems, could be found in [77].

Table 1 Description of the cited references on heuristic-based methods for WSN problems. Consider the following acronyms list: coverage problem (CP), density control (DCP), localization problem (LP), routing problem (RP), clustering problem (CL), and placement problem (PP). Multi-hop communication (MhC), fixed sink (FS), mobile sink (MoS), and multiple sink (MuS)

Table 1 summarizes the previous cited works, highlighting the problems solved and the heuristic methods used. For an overview of the mathematical aspects of network optimization problems, we also refer to [78–81].

Conclusion

In this chapter, an overview of classical optimization problems and solution methods in the design of wireless sensor networks are presented. WSN have been widely studied due to their importance in many practical applications. Unlike a general

network, WSN are designed for specific applications and take into account the application goals, the associated costs, the hardware capabilities, and other system constraints. Therefore, optimization techniques are shown to be an essential part in the design of new protocols. The integration of two or more problems, such as coverage, routing, density control, clustering, and so on, requires even more sophisticated approaches to achieve high-quality solutions. It is straightforward to conclude that optimization tools play a key role in the design of WSN. The referred methods in this chapter have the capacity to significantly improve metrics such as network lifetime, coverage rate, and communication delay. Looking to the future, WSN represent an attractive research area with several new possibilities where the major challenge is to approximate the theoretical tools for practical applications.

Abstract

In the last few years, a number of books and survey papers devoted to the vehicle routing problem (VRP) or to its variants or to the methods used for the solution of one or more variants of the VRP have been published. Also, in these years, the field of swarm intelligence algorithms has had a significant growth. One of the most important swarm intelligence algorithms is the particle swarm optimization (PSO). Although the particle swarm optimization was first published in 1995, it took around 10 years in order researchers to publish papers using a PSO

algorithm for the solution of variants of the VRP. However, in the last 10 years, many journal papers, conference papers, and book chapters have been published where a variant of VRP is solved using a PSO algorithm. Thus, it is significant to present a survey paper where a review and brief analysis of the most important of these papers will be given. This is the main focus of this chapter.

Keywords

Vehicle routing problem · Particle swarm optimization

Introduction

The vehicle routing problem is one of the most important problems in the field of supply chain management, of logistics, of combinatorial optimization, of transportation, and, in general, of operational research. The interest in this problem has been recently increased both from theoretical and practical aspect. There are a number of reasons for this growth. From the practical point of view, the problem is one of the most important problems in the supply chain management, and, thus, the finding of the optimal set of routes will help the decision makers to reduce the cost of the supply chain and to increase the profit. Also, in the formulation of the problem, the managers could simulate the complete network and add any of the constraints concerning the customers, the vehicles, the routes, and, also, the traffic conditions of the network and the energy consumption of the vehicles. Thus, someone could solve a realistic problem and find a near optimal set of solutions.

The reason that usually a near optimal set of solutions is found is that the problem from its origin (it was first introduced by Dantzig and Ramser in 1959 [1]) was proved to be NP-hard problem even in its simpler version, the capacitated vehicle routing problem, where the only constraint that was taken into account was the capacity of the vehicles (and later the maximum tour length constraint was added). Thus, it is impossible in real-life applications to find an optimal solution. For this reason, a number of heuristic, metaheuristic (mainly), evolutionary, and nature-inspired approaches have been proposed for the solution of the VRP and its variants. Also, exact algorithms have been proposed in order to solve the problem. They are, mainly, used for the solution of the simplest vehicle routing problems (the problems with as few as possible constraints) and for a small number of nodes.

From the theoretical point of view, there are a huge number of researchers that deal with the solution of a variant (or more variants) of the problem. These variants of the problem focus on a specific constraint, and the researchers are trying to find an algorithm that gives new best solutions in a specific set of benchmark instances in short computational time with as less as possible parameters in order to give a more general algorithm. Thus, a new researcher that he/she would like to focus to a specific variant of a vehicle routing problem, he/she could find a large number of very good papers focusing to VRP or to its variants and papers focusing to

the methods that he/she would like to implement for the solution of the problem. The most important and well-studied variants of the vehicle routing problem are the capacitated vehicle routing problem [2–6], the vehicle routing problem with time windows [7–11], the open vehicle routing problem [12], the vehicle routing problem with simultaneous pickup and deliveries [13, 14], the vehicle routing problem with backhauls [15–17], the multidepot vehicle routing problem [18–20], the stochastic vehicle routing problem [21–24], the dynamic vehicle routing problem [23, 25–27], the periodic vehicle routing problem [28], the split delivery vehicle routing problem [29], the heterogeneous fleet vehicle routing problem [30], the asymmetric vehicle routing problem [31], the vehicle routing problem with two- or three-dimensional loading constraints [32, 33], etc. Nowadays, more complicated problems have been published where more than one from the previously mentioned problems are combined in order to create a new more challenging problem. These problems are denoted from some researchers as rich vehicle routing problems [34]. However, a number of other problems have been introduced in the last years in order to cope with new needs that arise from new realistic situations of the life, like the cumulative capacitated vehicle routing problem [35], the evacuation vehicle routing problem [36], the green vehicle routing problem [37], the pollution routing problem [38], etc. Finally, there are a number of combined problems that need a solution of a vehicle routing problem, like the location routing problem [39–41], the inventory routing problem [42–44], the location inventory routing problem [45], the production routing problem [46], the production inventory distribution problem [47], and the ship routing problem [48–51]. Also, a number of publications with a real case application have been realized where the authors simulate the realistic scenario, formulate the problem (or use an existing formulation) using a combination of the existing variants or introducing a new one if it is possible, and use an existing algorithm (or propose a new one or a suitable modified variant of an existing one) to solve it.

Thus, in the last years, the EURO Working Group on Vehicle Routing and Logistics Optimization, the VeRoLog, was created (www.verolog.eu); two different series of conferences devoted to the vehicle routing problem variants and applications have been introduced, the one is an annual conference which is organized from the VeRoLog working group since 2012 and the second is a triennial workshop on freight transportation and logistics denoted as Odysseus started in Crete 2000. A number of books devoted to the vehicle routing problem have been published. The first one was published in 1988, and it was a very inspiring book for any new researcher that would like to study the vehicle routing problem or just to know about the vehicle routing problem [52]. Twenty years later, one of the two authors (Bruce Golden) of the first published book [52] published a new book [53] that summarizes the work performed in these 20 years and gives some new directions for future research. Before the publication of this book, another very successful and inspiring book was published by Paolo Toth and Daniele Vigo [14] which is the most widely read and most cited book in the field. The success of this book led the same team of authors to publish in the end of 2014 the second edition of the

book [54] which covers all the field of the vehicle routing problem with a more complete rewriting of some of the chapters of the previous edition of the book and with the new directions that have been created based on the new challenges in the field. A volume of the *Handbooks in Operations Research and Management Science* was devoted to vehicle routing problems and to more general applications, like the arc routing problem [55], and it was published in [56]. Finally, two other books devoted to the vehicle routing problem have been published in [57, 58]. Also, a large number of surveys have been published, initially, devoted to general vehicle routing problems and, nowadays, to variants of the vehicle routing problem or to methods that are applied for the solution of the vehicle routing problem or of its variants. Some of these survey papers can be found in [4–6, 34, 37, 59–76].

Thus, in this chapter, as a general review for the vehicle routing problem cannot be restricted in one chapter, we decided to focus in a specific algorithm, the particle swarm optimization (PSO) algorithm, and in the application of this algorithm for the solution of the vehicle routing problem and its main variants. This is the first survey chapter, at least to our knowledge, that is devoted to this method for the VRP. In the following sections, initially, a brief presentation of the particle swarm optimization algorithm will be given, and, then, we will present the variants of the vehicle routing problem in which a particle swarm optimization algorithm has been applied for their solution.

Particle Swarm Optimization

Particle Swarm Optimization (PSO) is a very popular global optimization method that was originally proposed by Kennedy and Eberhart as a simulation of the social behavior of social organisms such as bird flocking and fish schooling [77]. PSO uses the physical movements of the individuals in the swarm. Complete surveys, in the time that they are published, for the particle swarm optimization can be found in [78–81]. Nowadays, a complete review for the particle swarm optimization is very difficult to be performed as the range of variants and of applications of PSO covers the whole field of optimization, and, thus, only surveys in a specific subject like the one presented in this chapter (application of PSO algorithm in vehicle routing problems) can be presented without the length of the paper to increase dramatically.

In general, in a PSO algorithm, a set of solutions are used where each solution is denoted as a particle. These solutions create the swarm. In many algorithms, more than one swarms exist. Initially, the solutions are randomly initialized in the solution space. Two are the main vectors that describe a particle, the position vector (x_{ij}, where i denotes the particle ($i = 1, \cdots, N$, N is the swarm size) and j denotes the corresponding dimension of the particle ($j = 1, \cdots, d$, d is the dimension of the problem)) and the velocities vector (v_{ij}). The performance of each particle is evaluated on the predefined fitness function ($f(x)$).

Thus, each particle is randomly placed in the d-dimensional space as a candidate solution. One very simple and effective way to initialize the particles was given in

[82] where the minimum value of the solution space is denoted as $x_{\min,j}$ and the maximum value is denoted as $x_{\max,j}$. Then, the values of the solution vector for each particle are calculated from the following equation:

$$x_{ij}(0) = x_{\min,j} + r_j \left(x_{\max,j} - x_{\min,j}\right) \tag{1}$$

where r_j is a random number between (0, 1).

The velocity of the i-th particle v_{ij} is defined as the change of its position. The algorithm completes the optimization through following the personal best solution of each particle and the global best value of the whole swarm. Thus, in each iteration, except of the current position, another vector is used which is the personal best position of each particle through the iterations. The best member of the personal best position vector is the global best position of the whole swarm. Each particle adjusts its trajectory toward its own previous best position and the global best position, namely, $pbest_{ij}$ and $gbest_j$, respectively. The velocities and positions of particles are updated using the following eqs. [77]:

$$v_{ij}(t+1) = v_{ij}(t) + c_1\, rand_1 \left(pbest_{ij} - x_{ij}(t)\right) + c_2\, rand_2 \left(gbest_j - x_{ij}(t)\right) \tag{2}$$

$$x_{ij}(t+1) = x_{ij}(t) + v_{ij}(t+1) \tag{3}$$

where t is the iteration counter, c_1 and c_2 are the acceleration coefficients, and $rand_1$ and $rand_2$ are two random variables in the interval (0, 1). The values of c_1 and c_2 could be constant, or they could be adapted during the iterations. Usually in the most published papers concerning an application of PSO in a continuous or discrete problem, these values were set equal to 2. However, there is a possibility to take different values or to adjust their values during the iterations, for example, using the following eqs. [82]:

$$c_1 = c_{1,\min} + \frac{c_{1,\max} - c_{1,\min}}{iter_{\max}} \times t \tag{4}$$

$$c_2 = c_{2,\min} + \frac{c_{2,\max} - c_{2,\min}}{iter_{\max}} \times t \tag{5}$$

where $\text{iter}_{\max}$ is the maximum number of iterations and $c_{1,\min}$, $c_{1,\max}$, $c_{2,\min}$, and $c_{2,\max}$ are the minimum and maximum values that c_1 and c_2 can take, respectively. In the beginning of the procedure, the values of c_1 and c_2 are small and, then, are increasing until they reach their maximum values. By doing this, on the first iterations, there is a great freedom of movement in the particle solution space in order to find the optimum quickly.

A number of different velocity equations have been proposed during the last years. Nowadays, other researchers use one of the velocity equations proposed in

the past that have been proved to perform well (mainly, the inertia equation or the constriction equation), or, less frequently, they propose a new one which either is a variant of a previously published equation or simulates something from the nature in which the specific researcher focuses in his/her study. The most important and known velocities equations are the following:

- Inertia particle swarm optimization (IPSO) [83]:

$$v_{ij}(t+1) = w v_{ij}(t) + c_1\, rand_1 \left(pbest_{ij} - x_{ij}(t)\right) + c_2\, rand_2 \left(gbest_j - x_{ij}(t)\right) \tag{6}$$

  The difference between this variant and the one presented on Eq. (2) is the use of the inertia weight w. The inertia weight w is adapted during the iterations and is given by the following equation:

$$w = w_{\max} - \frac{w_{\max} - w_{\min}}{\text{iter}_{\max}} \times t \tag{7}$$

  where $w_{\max}$ and $w_{\min}$ are the maximum and minimum values of the inertia weight.
- Constriction particle swarm optimization [84]:

$$v_{ij}(t+1) = \chi\Big(v_{ij}(t) + c_1\, rand_1 \left(pbest_{ij} - x_{ij}(t)\right) + c_2\, rand_2 \left(gbest_j - x_{ij}(t)\right)\Big) \tag{8}$$

  where the constriction factor, χ, is used:

$$\chi = \frac{2}{|2 - c - \sqrt{c^2 - 4c}|} \text{ and } c = c_1 + c_2,\ c > 4 \tag{9}$$

- Another version of the constriction particle swarm optimization [82]:

$$v_{ij}(t+1) = \chi\Big(v_{ij}(t) + c_1\, rand_1 \left(pbest_{ij} - x_{ij}(t)\right) + c_2\, rand_2 \left(gbest_j - x_{ij}(t)\right)\Big) \tag{10}$$

  The only difference from the previous version is the use of the parameter k in the constriction factor [82]:

$$\chi = \frac{2k}{|2 - c - \sqrt{c^2 - 4c}|} \text{ and } c = c_1 + c_2,\ c > 4 \tag{11}$$

- Clerc and Kennedy [84] proposed a simpler form of the constriction factor, the **condensed form**, for the calculation of the velocities of the particles:

$$v_{ij}(t+1) = \chi\left(v_{ij}(t) + c\left(p_{mj} - x_{ij}(t)\right)\right) \tag{12}$$

where

$$\chi = \frac{2}{|2-c-\sqrt{c^2-4c}|} \text{ and } c = c_1 + c_2, c > 4 \tag{13}$$

And

$$p_{mj} = \frac{c_1 pbest_{ij} + c_2 gbest_j}{c}. \tag{14}$$

- Cognition-only particle swarm optimization [85]
  In this variant, the velocity equation is given by:

$$v_{ij}(t+1) = v_{ij}(t) + c_1\, rand_1 \left(pbest_{ij} - x_{ij}(t)\right) \tag{15}$$

  The social factor of velocities equation is not used.
- Social-only particle swarm optimization [85].
  In this variant, the velocity equation is given by:

$$v_{ij}(t+1) = v_{ij}(t) + c_2\, rand_2 \left(gbest_j - x_{ij}(t)\right) \tag{16}$$

  The cognition factor of velocities equation is not used.
- Local neighborhood topology particle swarm optimization [82]:

$$\begin{aligned} v_{ij}(t+1) = v_{ij}(t) &+ c_1\, rand_1 \left(pbest_{ij} - x_{ij}(t)\right) \\ &+ c_2\, rand_2 \left(lbest_{ij} - x_{ij}(t)\right) \end{aligned} \tag{17}$$

  where the term of *gbest* in the previous algorithms has been replaced with the term *lbest*, which means that instead of a global best population, a local best population is used.

$$lbest_{ij} \in N_i \mid f\left(lbest_{ij}\right) = \min f\left(x_{ij}\right), \forall x \in N_i \tag{18}$$

  The neighbor N_i is defined by [82]:

$$\begin{aligned} N_i = pbest_{i-n_{N_i}}(t), \ldots, pbest_{i-1}(t), pbest_i(t), \\ pbest_{i+1}(t), \ldots, pbest_{i+n_{N_i}}(t) \end{aligned} \tag{19}$$

  A particle's best position ($pbest_{ij}$) in a swarm is calculated from the equation:

$$pbest_{ij} = \begin{cases} x_{ij}(t+1), & \text{if } f\left(x_{ij}(t+1)\right) < f\left(x_{ij}(t)\right) \\ pbest_{ij}, & \text{otherwise} \end{cases} \tag{20}$$

  The optimal position of the whole swarm is calculated by the equation:

$$gbest_j \in \{pbest_{1j}, pbest_{2j}, \cdots, pbest_{Nj}\} \mid f(gbest_j) = \min\{f(pbest_{1j}), f(pbest_{2j}), \cdots, f(pbest_{Nj})\} \tag{21}$$

Most applications of PSO have concentrated on the optimization in continuous space, while a lot of work has been done to the discrete optimization problems beginning from the next two papers [83, 86]. In the following, a pseudocode of the particle swarm optimization algorithm is presented.

algorithm `Particle Swarm Optimization`
Initialization
Select the number of swarms
Select the number of particles for each swarm
Initialization of the position and velocity of each particle
Calculation of the initial cost function (fitness function) value of each particle
Keep global best particle (solution) of the whole swarm
Keep personal best of each particle
Main Phase
Do until the maximum number of iterations has not been reached:
    Calculate the velocity of each particle
    Calculate the new position of each particle
    Evaluate the new fitness function of each particle
    Update the best solution of each particle
    Update the best particle of the whole swarm
Enddo
Return the best particle (the global best solution)

Application of Particle Swarm Optimization Algorithm in Vehicle Routing Problems

In this chapter, the papers in which a variant of the particle swarm optimization algorithm is applied for the solution of a variant of the vehicle routing problem are presented. In this section, an analysis is given on how these papers have been selected. As there are a large number of papers in the literature, we will in the most important of them. A very difficult task is to define which of the papers are the "most important" ones. We use a number of criteria to show the impact of each paper in the research community. The first criterion is the impact factor of the journal or the importance of the conference in which the paper has been published. The second criterion is the number of citations (based on Google Scholar) that each paper has received through the years. Papers that have been published in the current year are not expected to have a large number of citations. However, some of them based on their computational results are included in the analysis. Finally, the third criterion is the computational results given in each paper. There are a number of

papers that have demonstrated their PSO variant giving results in one or in a small set of instances. These papers are not analyzed as the effectiveness of their variant is not sufficiently proved. Also, there are a number of papers that, although they have been published in very good journals, they present a PSO variant for the solution of a real-life application and they do not give a comparative analysis with other algorithms from the literature in benchmark instances; thus, it is very difficult to show the effectiveness of the PSO variant. These kinds of papers are not included in the analysis. Finally, there are a number of papers that they present a novel PSO procedure, they apply the method in classic sets of benchmark instances, and their computational results are competitive with the results of the most effective algorithms from the literature. This last category of papers is those that are analyzed in this chapter.

Main Variants of VRP Solved by PSO

The main variants of the vehicle routing problem that a particle swarm optimization algorithm has been applied are the following.

Capacitated Vehicle Routing Problem *Abbreviation:* ***CVRP*** *Definition:* Each vehicle must start and finish its tour at the depot. Capacity constraints of the vehicles. Maximum tour duration of each route. Not split deliveries allowed. Customers have only demands and service time [14, 53, 62, 63].

Open Vehicle Routing Problem *Abbreviation:* ***OVRP*** *Definition:* Same constraints as in the CVRP except that the vehicles do not return in the depot after the service of the customers [12].

Vehicle Routing Problem with Time Windows *Abbreviation:* ***VRPTW*** *Definition:* Same constraints as in the CVRP and in addition each customer must be serviced within a specific time window. Vehicles and depots may, also, have a time window. Minimization, initially, of the number of routes and, then, minimization of the total traveled distance [10, 14, 52, 53, 57, 87].

Vehicle Routing Problem with Simultaneously Pickup and Delivery *Abbreviation:* ***VRPSPD*** *Definition:* Same constraints as in the CVRP. The customers require not only delivery of products but, also, a simultaneous pick up of products from them. It is assumed that the delivery is performed before the pickup and that the vehicle load should never be negative or larger than the vehicle capacity [14, 52, 53, 57].

Vehicle Routing Problem with Stochastic Demands *Abbreviation:* ***VRPSD*** *Definition:* A vehicle with finite capacity leaves from the depot with full load and has to serve a set of customers whose demands are known only when the vehicle arrives to them. A route begins from the depot and visits each customer exactly once and returns to the depot. This is called an a priori tour, and it can be seen as a template for the visiting sequence of all customers [21, 24, 88].

Dynamic Vehicle Routing Problem *Abbreviation:* ***DVRP*** *Definition:* In dynamic problems, part or all of the input is unknown and is revealed dynamically during the design or execution of the routes [74].

Multidepot Vehicle Routing Problem *Abbreviation:* ***MDVRP*** *Definition:* More than one depots are used for the customers' service. There is a possibility for each customer to be clustered and served from only one depot, or the customers may be served from any of the depots using the available fleet of vehicles [20, 89].

Vehicle Routing Problem with Stochastic Travel Times *Abbreviation:* ***VRPSTT*** *Definition:* In this variant, the travel time between every pair of nodes is a random variable related to traffic jam, road maintenance, or weather conditions. The stochasticity appears in the arcs (road) of the network due to unexpected conditions [90].

Vehicle Routing Problem with Fuzzy Demands *Abbreviation:* ***VRPFD*** *Definition:* In this variant, the demands could be represented as fuzzy variables.

Periodic Vehicle Routing Problem *Abbreviation:* ***PVRP*** *Definition:* In this problem, vehicle routes must be constructed over multiple days where during each day within the planning period, a fleet of capacitated vehicles travels along routes that begin and end at a single depot [91]. The objective of the PVRP is to find a set of tours for each vehicle that minimizes total travel cost while satisfying the constraints of the problem [91].

Location Routing Problem *Abbreviation:* ***LRP*** *Definition:* In this variant, the optimal location to be used for the storage facilities have to be decided. From these locations, the vehicles will begin their routes, in a way that the total cost of the routing (distance, fuel, time, etc.) and facility location (running costs, rent or property cost, etc.) will be the minimum. At the same time, the optimal routes for the vehicles have to be found in order to satisfy the demand of the customers [40, 41, 92, 93].

Location Routing Problem with Stochastic Demands *Abbreviation:* ***LRPSD*** *Definition:* In this variant, the same constraints as in the case of the location routing problem hold except that the demands of the customers have stochastic and not deterministic values.

Team Orienteering Problem *Abbreviation:* ***TOP*** *Definition:* This is a variant of the vehicle routing problem with profits or pricing. In this problem, a set of locations is given, each one with a score. The goal is to determine a fixed number of routes, limited in length, that visit some locations and maximize the sum of the collected scores [94]. The objective of the TOP is to construct a certain number of paths starting at an origin and ending at a destination that maximize the total profit without violating predefined limits [95].

Production Routing Problem *Abbreviation:* ***PRP*** *Definition:* This variant is a hybridization of VRP with production problems. These problems are very complicated problems as they include, among others, decisions concerning the number of workers to be hired, the quantities of products to be produced using various strategies, the amount of inventories to be maintained, the assignment of the customers in different manufacturing plans or depots, and, finally, the design of the routes in order to satisfy the customers' demands.

Ship Routing Problem *Abbreviation: SRP Definition:* In this variant, the optimum routing and scheduling of different types of ships are calculated [48–51, 96].

Vehicle Routing Problem with heterogeneous fleet *Abbreviation:* ***HVRP*** *Definition:* In this variant, instead of an homogeneous fleet of vehicles, the company uses a set of vehicles with different capacities, and, thus, the fleet of vehicles is heterogeneous.

Inventory Routing Problem *Abbreviation:* ***IRP*** *Definition:* In this variant of the vehicle routing problem, a simultaneous allocation of inventories and decision of routing schedules is realized. The objective of the IRP is to minimize the total cost (the distribution and inventory costs of retailers) [42, 43].

Vehicle Routing Problem with Uncertain Demands *Abbreviation:* ***VRPUD*** *Definition:* In this variant, the demand is uncertain with unknown distribution.

Vehicle Routing and Scheduling Problem *Abbreviation:* ***VRSP*** *Definition:* In general, the goal of VRSP is to determine the set of trips that a vehicle will make during the day in order to reduce the transportation costs.

Other variants of VRP, combinations of VRP with other problems, or real-life applications of VRP that have been solved using a variant of a particle swarm optimization algorithm are the distance constraint vehicle routing problem [97], the multiple destination routing problem (MVRP) [98], the multivehicle assignment problem (MVAP) [99], the production routing problem [46], the berth allocation problem [100], the disaster relief logistics [101], the garbage collection system [102], the integrated production and distribution [103], the urban transit routing problem [104], the production and pollution routing problem [105], the reducing vehicle emissions and fuel consumption [106], the pedestrian-vehicle mixed evacuation (P-VMEP) [107], the time-dependent vehicle routing problem (TDVRP) [108], the emergency vehicle scheduling problem [109], the emergency logistics (EL) [36, 110], the evacuation vehicle routing problem (EvVRP) [111], the environmental vehicle routing problem (EnVRP) [112], the integrated production scheduling and vehicle routing [113], and the reverse logistics (RL) [114].

Table 1 presents the number of papers (journal papers, international conference papers, and book chapters, denoted as Journal, Conf, and BC in the table, respectively) in which a variant of the particle swarm optimization algorithm has been used for the solution of a variant of the vehicle routing problem. As it was expected, most of the papers concern an application of a PSO variant to the capacitated vehicle routing problem with eight journal papers published. There is no other variant of VRP with more than three journal papers. However, in the vehicle routing problem with time windows, there are a large number of conference papers and book chapters (nine in total). As we can see, a variant of PSO algorithm has been applied in 27 different variants of vehicle routing problem. In total, there are 37 journal papers and 52 international conference papers and book chapters with a PSO variant in a vehicle routing problem.

Although when the particle swarm optimization algorithm was initially proposed, there were no any applications of the algorithm for the solution of the vehicle routing problem; in the last years, a number of researchers have solved a variant of VRP using a PSO algorithm. In Table 2 journals that have published at least one paper with this topic are presented. Journals are sorted based on their impact factor for

Table 1 Number of papers using particle swarm optimization in each variant of the vehicle routing problem

2015 (denoted as I.F. in the table) that it is presented in column three. Finally, in columns 4 and 5, the number of papers (denoted as Nr in the table) that has been published in each journal and the total number of citations of all papers based on Google Scholar on 30 May 2017 (denoted as TNrCit in the table) are presented.

Different PSO Variants

As it is mentioned earlier, the main problem of the application of a PSO algorithm for the solution of a VRP was that the PSO algorithm is suitable for continuous optimization problems and the VRP is a combinatorial optimization problem with a specific structure in the solution which needs in most cases a path representation in order to have an effective algorithm. Thus, there are a number of algorithms that use a 0/1 representation of the solution. However, these algorithms are not the most effective algorithms for the solution of this kind of problems. We mentioned that

from the first years that PSO was proposed, there were implementations of PSO [83] suitable for discrete optimization problems but not for routing type problems. Thus, the first effective application of a PSO algorithm in VRP was in 2006 [116]. Since then a number of different algorithms have been proposed that are suitable for the solution of a VRP variant. Most of them are hybridized with a local search algorithm, as almost every evolutionary algorithm if it is applied for the solution of a VRP problem. In the following, we present and analyze the most important variants of PSO that have been applied for the solution of a VRP variant. The choice was performed using the same criteria that were mentioned earlier, especially the one concerning the effectiveness of the algorithms.

SR-PSO. One of the most used representations of PSO for the solution of a VRP variant denoted as SR-PSO (SR-1 PSO or SR-2 PSO) was proposed in [115] where two representations of the particles were used for the solution of the CVRP. In the

first one, the particle consists of $n + 2m$ dimensions. The first n dimensions are related to customers (each customer is represented by one dimension). The last $2m$ dimensions are related to vehicles (each vehicle is represented by two dimensions as the reference point in the Cartesian map). The priority matrix of vehicles is constructed based on the relative distance between these points and customers' location [115]. A customer is prioritized to be served by the vehicle which has the closer distance. In the second representation, the particle consists of a $3m$-dimensional particle where it is decoded as a real number. All dimensions are related to vehicles; each vehicle is represented by three dimensions: two dimensions for the reference point and one dimension for the vehicle coverage radius [115]. The algorithms use a number of local search algorithms. A number of papers either from the same authors or from other research groups have used the same representations for solving a VRP variant.

The research group that proposed this representations have applied them for the solution of the vehicle routing problem with time windows [143], of the vehicle routing problem with simultaneously pickups and deliveries [130] (the most important publication of an application of PSO-based algorithm for solving a VRP based on the number of citations), of the multidepot VRP with pickup and deliveries [182] and [181], and of the location routing problem [137].

Other researchers that used the same encoding and decoding scheme for solving a VRP variant are the one from Hu et al. [190] that proposed a hybrid chaos-particle swarm optimization algorithm (HPSO) for solving VRPTW. In [191], a variant of the algorithm was proposed for the solution of a vehicle routing problem with uncertain demands. In [141], a variant of the algorithm was presented for a rich vehicle routing problem, the vehicle routing problem with heterogeneous fleet, mixed backhauls, and time windows (VRPHFMBTW).

Quantum PSO—QPSO. One of the first PSO implementations for the solution of the CVRP was the one published in [116]. In this PSO implementation, a quantum discrete PSO algorithm is used [192]. The algorithm is hybridized with a simulated annealing algorithm [193] for the improvement of the particles. They use a zero one encoding scheme where value equal to one means that the vehicle serves the customer and value equal to zero means that another vehicle will serve the customers. The dimension of the vector is equal to $N \times K$ where N is the number of nodes and K is the number of vehicles.

HybGenPSO. In [118], a hybridization of a genetic algorithm with a particle swarm optimization, algorithm for the solution of the CVRP was presented. In this memetic algorithm, the role of the genetic algorithm was to create the new generations, and the role of the PSO algorithm was to improve the population between two different generations. Thus, it was a memetic algorithm with the difference that usually in a memetic algorithm, each member of the population is evolved between two generations using a local search algorithm, while in this memetic algorithm, the population was evolved using a global search algorithm. This idea was inspired by the fact that in real life, each member of a population is evolved by reacting with other members of the population and not by itself. The algorithm uses the inertia equation for the velocities (Eq. 6) and was tested in the

two classic sets of benchmark instances, and a number of best-known solutions were found.

HybPSO. In [119], a hybrid particle swarm optimization algorithm was used for the solution of the capacitated vehicle routing problem. The algorithm is an improved version of the algorithm used in [138] for the solution of the location routing problem, and it uses the same three algorithms in the hybridization phase, the multiple phase neighborhood search—greedy randomized adaptive search procedure (MPNS-GRASP), the expanding neighborhood search (ENS) [194], and the path relinking (PR) [195]. The first method is used for the creation of the initial solutions, the second one is used as a local search phase, and the third one is used for the movement of the particles. The difference of the algorithm proposed in [119] from the algorithm denoted as combinatorial neighborhood topology PSO (proposed in [126]) is that the first one uses a transformation between continuous and discrete values and vice versa based on the relative position indexing [196] and it, also, uses a procedure that does not affect the solution of each particle. In the combinatorial neighborhood topology PSO, no transformation is needed at all. The algorithm proposed in [119] uses the inertia equation for the velocities (Eq. 6). The algorithm was tested in a classic set of benchmark instances, and a number of best-known solutions were found.

In [167], a new version of the hybrid particle swarm optimization algorithm that was presented in [119] for the solution of the CVRP was presented where instead of using the expanding neighborhood search algorithm for the improvement of each particle separately, the variable neighborhood search algorithm was used [197]. Another difference is that the inertia velocities equation has been replaced by the constriction velocities equation (Eq. 8).

In [171], an improved version of the hybrid particle swarm optimization algorithm that was presented in [167] for the solution of the OVRP was presented where instead of using the variable neighborhood search algorithm for the improvement of each particle separately, a simpler local search algorithm based on 2-opt and 3-opt algorithms was used. Also, in the initialization phase of the algorithm, the particles start from random values, thus avoiding the use of a more sophisticated procedure. The reason that this simpler local search algorithm and the random initial values were used was that the calculation of the objective function of the VRPSDs is much more difficult and time-consuming than the calculation of the objective function of a simpler variant of VRP and, thus, the use of a simpler local search algorithm avoids the increase of the computational time of the whole procedure. Eight different versions of velocities equation were used in order to test which one of them is the most appropriate for the selected problem.

CNTPSO. In [138], a hybrid particle swarm optimization algorithm was used for the solution of the location routing problem. The PSO algorithm was hybridized with three other effective algorithms, the multiple phase neighborhood search—greedy randomized adaptive search procedure (MPNS-GRASP) [198], the expanding neighborhood search (ENS) [194], and the path relinking [195].

The novelty of the paper was that a procedure was used where there is no transformation from continuous to discrete values and the movement of the particles

was performed using a path relinking procedure [195], where the current solution of the particle was used as starting solution and the target solution was either the local best particle or the global best particle. This was the first step of the very successful and effective topology that was denoted as combinatorial neighborhood topology and was used for the solution of the capacitated vehicle routing problem [126]. The velocities equation used was the inertia one (Eq. 6). In [126], one of the most successful versions of the PSO for the CVRP was published, denoted as combinatorial neighborhood topology PSO. This algorithm does not need a transformation from continuous to discrete values, and, thus, there is no loss of any information of good solutions that have been created in an iteration. In this algorithm, the position equation (Eq. 3) of the particles has been replaced by a path relinking strategy. The role of the velocities equation is limited to show which particle (or combination of particles) will be followed by the selected particle based on some conditions. This version of PSO is a very efficient version as it was proved by its application in the classic set of benchmark instances where better solutions were found compared to the ones found by other versions of PSO in less computational time.

In [172], an improvement of the CNTPSO was presented where a combination of this topology with an expanding neighborhood topology (ENT) is used. In this topology, there are not a standard number of local neighbors, but the number of local neighbors begins from a small number and increases using some conditions. When the number of neighbors becomes equal with the number of particles, then a global best PSO algorithm is used. The algorithm uses the same local search algorithm and the same initialization procedure as the algorithm presented in [171].

An improved version of CNTPSO with expanding neighborhood topology was presented in [188] for the solution of the location routing problem and of the location routing problem with stochastic demands. The difference of this algorithm from the initial CNTPSO is that it uses simultaneously a global neighborhood topology and the expanding neighborhood topology as it was described previously.

An adaptive version of CNTPSO is presented in [150] for the solution of the vehicle routing problem with time windows. In this version, all parameters (acceleration coefficients, iterations, local search iterations, upper and lower bounds of the velocities and of the positions, and number of particles in each swarm) are adapted during the procedure, and, thus, the algorithm works independently and without any interference from the user.

h_PSO. In [132, 133], two different algorithms for the solution of VRPSPD problem using a PSO algorithm were presented. Initially, it was presented as a conference paper [133], and its improved version was published as a journal paper in [132]. The authors presented a hybridization of PSO algorithm with a variable neighborhood search algorithm and used an annealing-based mechanism in order to maintain the diversity of particles. The inertia velocities equation was used (Eq. 6). They used a representation that began with a giant tour without taking into account the route restrictions, and, then, they used a decoding scheme to partition the giant tour into feasible routes. The procedure that they used is denoted as split procedure,

and it was first presented by Prins in the frame of an evolutionary algorithm for the solution of the CVRP [199]. The algorithms were tested in the usually used benchmark set of instances for the problem, and a number of new best solutions were found.

DAPSO. The most important application of a particle swarm optimization algorithm for the solution of a dynamic vehicle routing problem was presented in [160]. In this paper, the authors solved the DVRP with dynamic requests, and a procedure was used where a partial static VRP was solved each time a new request was received. The authors hybridized the particle swarm optimization algorithm with a variable neighborhood search algorithm for the solution of the problem (DAPSO). The representation used in this work is a simple discrete representation which expresses the route of m vehicles over the n customers to serve. The representation allows the insertion of dynamic customers in the already planned route, and it is a permutation of the customers where as a DVRP is solved, the authors keep the coordinates of the customers, the time in which each customer is served, and if a customer has been served or not. Another very interesting application of PSO algorithm in this problem was presented in [162] where a multiswarm PSO algorithm was applied, a number of benchmark instances were solved, and comparisons with algorithms from the literature were given. Finally, a third publication of the same group of authors using a PSO algorithm was presented in [163].

SPSO. One of the most important applications of a PSO algorithm in the solution of the vehicle routing problem with time windows is the one presented in [144]. In this paper, the proposed SPSO-VRPTW treated the discrete search space as an arc set of the complete graph that was defined by the nodes in the VRPTW and regarded the candidate solution as a subset of arcs. A set-based representation method was proposed to characterize the discrete search space. The search space is represented by a universal set S. The elements in S can be divided into D dimensions.

2MPSO. A two-phase particle swarm optimization algorithm for the solution of the DVRP was presented in [164], and later it was improved in [161]. They presented an algorithm where a new equation of velocities for the particles was presented where local and global search topologies were combined.

PVPSO. In [165], a PSO algorithm for the OVRP is presented. The authors used a standard PSO for the encoding and the decoding procedure where all the elements of the positions vector are sorting in descending order and, then, the first is added in the first route, the second in the route with the least residual capacity, and so on until all elements are inserted in a route. The routes, then, were improved using one-move local search. They used the inertia equation of velocities (Eq. 6), and they tested their algorithm in a small set of instances and found very good solutions.

GLNPSO. A very interesting application of a PSO in the VRPFDs was the one presented in [178]. In this problem, the variant of VRP used included, also, soft time windows constraints, and the authors considered two objective functions, the minimization of the total travel cost and the maximization of the average satisfaction level of all customers in a fuzzy environment. The authors used a global-local-

neighbor particle swarm optimization with exchangeable particles. An illustrative example that explains how the PSO algorithm had been applied in this problem was presented and analyzed in details.

PMPSO. In [117], the authors presented an approach that uses a probability matrix as the main device for particle encoding and decoding. In the decoding phase, not only the assignment of the customers in vehicles was realized, but, also, the routing of the customers was calculated. They used a number of local search algorithms (1-1 exchange, 2-opt, Or-opt) in order to improve the solution of the particles.

MOPSO. A very interesting formulation of a multiobjective competitive open vehicle routing problem with time windows was presented in [166]. In this problem, the reaching time to customers affects the sales amount. Therefore, distributors intend to service customers earlier than rivals to obtain the maximum sales. Moreover, a part of a driver's benefit is related to the amount of sales. Thus, the balance of goods carried in each vehicle is important in view of the limited vehicle capacities. They gave a complete analysis of the new problem and of the formulation, and they used a multiobjective PSO algorithm for the solution of the problem. In this multiobjective algorithm, the nondominated solutions are stored in a repository, and, then, if a new solution dominates a solution from the repository or a personal best solution of a particle, then the new solution replaces the dominated solution.

StPSO. A very interesting paper was published in [186]. In this paper, the authors solved a very complicated vehicle routing and scheduling problem with cross-docking. They use an encoding scheme to represent the scheduling in a string. Thus, all are encoded as genes in a 1-by-n string where the length is equal to the number of vehicles. Thus, the digit in the i_{th} chromosome indicates the route number to which the i_{th} vehicle is assigned [186]. A similar variant of the algorithm has been proposed in [177] for the solution of the periodic vehicle routing problem.

NPSO. In [200], a nested PSO was given for the solution of the CVRP. Initially, feasible solutions are created in clusters using sweep algorithm, and, then, a route optimization was performed inside the clusters. The PSO was used in both phases, in the first phase for reorganizing the routes and in the second phase for leading to the optimization of the routes.

DPSO. A discrete PSO algorithm is presented in [156] for the solution of the team orienteering problem. The authors hybridized their algorithm with a variable neighborhood search algorithm. Another application of DPSO for the solution of the CVRP was proposed in [120]. The authors hybridized their algorithm with an iterated local search algorithm.

DHPD. In [201], a hybridization of a PSO algorithm with a differential evolution algorithm was presented. In the paper, an indirect representation was proposed. For N customers, each individual was encoded as a real number vector with N dimensions. The integer part of each dimension or element in the vector represents the vehicle. Thus, the same integer part represents the customer in the same vehicle. The fractional part represents the sequence of the customer in the vehicle [201].

Another similar formulation of the algorithm was proposed in [169] for the solution of the OVRP. The authors presented a very interesting representation of the particles' solution where in the encoding procedure, the customers took real values and in the decoding procedure, the customers with the same integer part are assigned in the same team (vehicle or group of vehicles if the capacity of the vehicle was violated). The authors tested their algorithm using the classic set of benchmark instances, and they obtained very good results.

MODPSO. In [136], a PSO algorithm was used for the solution of the VRPSPD. The very interesting part of the algorithm was the solution representation where the m customers were divided in $m + 1$-dimensional particles. In the decoding process of the algorithm, the particles were transformed to vehicle allocation s with the sweep algorithm, and, then, the priority matrices of customers served by the same vehicle were evaluated. Based on the two matrices, the vehicle routes were constructed.

Analysis of the Algorithms

In Table 3, the most important papers that use a variant of PSO for a solution of a variant of VRP are presented. The selection of the papers has been performed based on the criteria mentioned previously. The ranking in Table 3 is based on the number of citations that each of these papers has on 30 May 2017 on Google Scholar. Also, in Table 3, papers with a small number of citations are presented, but these papers either present very effective algorithms based on their computational results or have great potential for fast increase on the number of citations due to the year of publication. In Table 3, in addition to the number of citations, it is presented which variant of the VRP is solved (column 2), with which variant of PSO (column 3), in which journal, book, and conference it is published (column 4), and the year published (column 5). The number of citations is given in the last column.

As we can see, there is only one paper with more than 200 citations [130] with 289 citations and one that it is near to 200 (paper [116] with 198 citations). Two other papers have more than 150 citations (paper [118] with 167 and paper [115] with 162 citations). Finally, there are two papers with more than 100 citations, paper [119] with 130 citations, and paper [144] with 117 citations. In total, there are six papers with more than 100 citations. Four of them present algorithms for solving the capacitated vehicle routing problem, and the other two present algorithms for solving the vehicle routing problem with simultaneous pickup and delivery. Also, two of them ([130] and [115]) are works from a specific research group that have made a significant contribution in the field. In Table 3, there are, also, other four papers from the same research group (paper [143] for the solution of the VRPTW with 49 citations, paper [182] for the solution of MDVRP with 23 citations, paper [181] for the solution of MDVRP with 8 citations, and paper [137] for the solution of LRP with 3 citations). The other research group with significant contribution in the field studied in this chapter is the one that has two publications in the six

more significant publications in the field ([119] and [118]) and other six publications that are presented in Table 3 (paper [171] for the solution of the VRPSD with 76 citations, paper [138] for the solution of LRP with 67 citations, paper [126] for the solution of CVRP with 9 citations, paper [167] for the solution of OVRP with 8 citations, paper [172] for the solution of VRPSD with 7 citations, paper [188] for the solution of LRP and LRPSD with 5 citations). Of course, there are papers with significant impact that are presented in this table as papers with 78 citations [160], papers with 74 citations [144], or papers with 70 citations [165] which have influenced a large number of researchers.

One of the most important tables in this survey is the last one (Table 4). In this table, the computational results of the most important papers are summarized and presented analytically. In this table, they are not presented papers that the proposed algorithm was tested in one or in a small set of instances, especially when these instances are not available in the Internet. Also, they are not presented papers that the proposed PSO algorithm solves a real-life problem as we cannot compare the results and we cannot see their effectiveness. The only papers that are presented are the ones that the proposed algorithm was tested in one or more well-known set(s) of benchmark instances, and the authors presented their results in such a way that the results are comparable with the computational results of other algorithms from the literature. In Table 4 in the first column, a reference of the paper is given, in the second column the problem(s) that is (are) solved is mentioned, and in the third, fourth, and fifth columns, the number of sets of benchmark instances, the number of instances in each set (NBI), and the range in which the number of nodes of each set fluctuates are given for each paper, respectively. Finally, in the last four columns, the number of new best solutions found in the paper in the year of its publication (NBS), the number of instances in which the proposed algorithm found a solution equal to the best-known published solution (EBS), the average quality of the solutions, and the range of the qualities of the solutions are given, respectively. The quality of a solution is calculated using the following equation $\text{Quality} = \frac{(c_{\text{PSO}} - c_{\text{BKS}})}{c_{\text{BKS}}}\%$, where c_{PSO} denotes the cost of the solution found by the mentioned PSO algorithm in the corresponding paper and c_{BKS} is the cost of the best-known solution.

It was a difficult task to summarize all the results and to create this table as every researcher presents the produced results in a different way. For example, in the most important and cited paper [130], the authors present the average results in the well-known benchmark instances, and, then, they give an extensive analysis in variants of the studied problem, and it was difficult to present analytically the results of the paper. In other papers, a new set of benchmark instances is created [171], and, thus, it was difficult to give comparisons for this set of instances. However, in most of the papers that are presented in this table, we could extract the information that we would like to have in order to see the effectiveness of each one of the algorithms. In most of the algorithms presented in the table, at least a number of EBS were found, and in few of them, new best solutions were given. It is very difficult to analyze each paper separately due to space limitation, and this analysis can be found easily in each one of the papers. However, we could say that the application of PSO in VRP variants gives very interesting computational results. In most cases,

the computational results are competitive with the results of the most effective algorithms from the literature. Thus, alternative propositions exist for someone that he/she would like to apply a PSO algorithm for the solution of a VRP variant.

Conclusions

In this chapter, an analytical review of the papers proposing and applying a PSO algorithm for the solution of VRP variants was presented. In total, around 100 papers were found. In some of them, new best solutions in VRP variants were presented, in other papers the authors presented the solutions that have been found that are very good and competitive solutions and in some instances equal to the best-known solutions but not new best solutions in the VRP variant solved, in other papers the authors presented and solved a new variant of the VRP with a PSO algorithm, and, finally, there are some papers that gave only illustrative examples of how the authors worked in specific instances of a VRP variant. In general, this chapter gives to the research community a basis that someone could use if he/she would like to apply a PSO algorithm for solving a specific variant of the VRP as he/she could find what has already been published and with what results and he/she could see how the researchers cope with the problems that may arise from the application of a PSO algorithm to the VRP or to its variants.

Abstract

The scheduling of operations over resources is a relevant theoretical and practical problem with applications in many fields and disciplines, including the manufacturing industry. Scheduling problems are as varied as the reality they model. Additionally, some scheduling settings are among the hardest combinatorial problems there are. This is a perfect scenario for heuristic methods where high-quality robust solutions can be obtained in a short amount of time. This chapter concentrates on heuristics for production scheduling problems and summarizes the main results that range from simple rules to advanced metaheuristics. The importance of proper scheduling in practice is first highlighted, along with its difficulty and relevance. A summary of the scheduling notation is also given. Basic scheduling techniques, dispatching rules, combined rules, advanced heuristics, and an introduction to metaheuristics are also summarized in the chapter. While necessarily brief and incomplete, this chapter serves as an introductory point to those interested readers seeking to delve in the vast and rich world of scheduling heuristics. Some pointers to fruitful future research avenues are also provided. A large list of journal articles and monographs are provided as a reference for additional details and study.

Introduction

In a wide sense, the term scheduling deals with the allocation of tasks to resources over a finite time horizon. These resources are usually limited and therefore, tasks have to share or, more precisely, compete for them. Depending on the type of scheduling problem, there might be interrelated decisions of allocation of tasks to resources, sequencing of the tasks assigned to each resource, assignment of start and finish times to each task, and so on. The objective is to find a schedule that optimizes a given criterion or criteria. As can easily be seen, this is a very broad definition. As detailed in [1, Chap. 1] and in [2, Chap. 1], scheduling is a decision-making process that is applied to a very wide range of situations in theory and in practice. As a result, resources can encompass from machines in a factory to tools or personnel in a plant or project. Resources might also model operation rooms in a hospital or cores in a computing cluster, etc. Similarly, tasks range from manufacturing operations to be performed in a factory to surgical interventions in an operation room. The applications are virtually limitless. During this chapter the focus is on one of the most studied applications of scheduling, which is manufacturing scheduling [3]. In manufacturing or shop scheduling, tasks commonly model client's orders or jobs, and resources are the machines or production lines needed to manufacture the products. While this field inside scheduling is arguably the most studied, other

monographs deal with other areas of scheduling in detail. Such is the case of Pinedo [2] for scheduling in services, Błażewicz et al. [4] for computer scheduling, Grosche [5] for scheduling problems in the airline industry, Randolph [6] for health-care scheduling, or Briskorn [7] for scheduling in sports. This short list is just an extract of the rich and varied literature on scheduling problems.

A salient characteristic of the manufacturing scheduling scheduling field is the sheer variety of real settings found in practice. It is easy to imagine that the scheduling problem found in a factory that produces cars is quite different from a factory that manufactures light bulbs to name just two random examples. Furthermore, the underlying scheduling problems are extraordinarily difficult from a mathematical perspective as most problems are of a combinatorial nature. This variety and the difficulty of the scheduling settings have resulted in a research field that is fragmented and overly specialized. More often than not, exact mathematical procedures are devised for specific scheduling settings where rigor and mathematical elegance are set as a goal in itself, possibly neglecting the general application or practical relevance of the proposed procedures. This has resulted in the well-known "research gap" between scheduling theory and practice, as recognized initially by Graves [8], Ledbetter and Cox [9], and Ford et al. [10]. All these studies pointed out the scant application of scheduling theory into practice. McKay et al. [11] and Olhager and Rapp [12] reached the same conclusions. Dudek et al. [13], MacCarthy and Liu [14], McKay and Wiers [15], McKay et al. [16], or McKay and Wiers [17] directly addressed, at different levels, this research gap. Different state-of-the-art reviews and studies about scheduling research like those of Reisman et al. [18], Ribas et al. [19], and Ruiz and Vázquez-Rodríguez [20] concluded that real scheduling problems are seldom studied. A more complete overview of these issues is detailed in Chap. 15 of [3].

The Importance of Scheduling

Without doubt, the aforementioned research gap is not to be attributed to a lack of interest in scheduling problems from industry. Good scheduling practice is of paramount importance in the manufacturing industry. Good schedules increase machine utilization, decrease manufacturing costs, and improve the fulfillment of delivery dates to customers ([1, 21, 22], among many others). Modern industries face a number of challenges that make scheduling as important as ever, to name just a few: (1) increasing product variety and/or configurations to reach a wider market, (2) reducing time to market, (3) shortening delivery dates to costumers, (4) high pressure in costs from emerging markets, (5) reducing production lot sizes, and (6) increasing frequency of orders from clients but of smaller size. All of the above are indicative of a transition from a mass manufacturing setting to a mass customization situation in a globalized economy. The optimized scheduling of hundreds, if not thousands, of production orders on a busy production shop floor is a must in order to meet these challenges.

Furthermore, good schedules help to identify production bottlenecks, streamline and stabilize production, minimize raw material shortages, and allow dealing with priorities in production orders. The conclusion is clear: nowadays factories must employ advanced scheduling tools in order to stay competitive amidst today's terribly competitive market.

Scheduling Is Hard

Sadly, scheduling models are remarkably hard to solve. In fact, most scheduling problems belong to the $\mathcal{NP}$-Hard class of computational problems [23]. This is also true for most combinatorial optimization problems in many other fields inside operations research like location, routing, planning, etc. However, it can be argued that most real scheduling problems are particularly hard and in practice they seem to be more difficult to solve than problems in other areas. Take for example the well-known capacitated vehicle routing problem (CVRP) for which extensive literature exists. According to Laporte [24] and to the most powerful exact methods recently proposed for the problem [25], instances of up to 135 clients and 7 vehicles can be solved to optimality. In comparison, for the job shop scheduling problem (to be defined later), a wait of more than 20 years was needed to have small instances of 10 jobs and 10 machines solved to optimality by Brucker et al. [26], and no significant advances have been made for the optimal solution of instances with just 20 jobs. By all accounts, 20 jobs are way below the normal number of jobs being processed at any time in a real industry where hundreds of tasks are being processed on a daily basis.

Furthermore, real problems are much more complex than regular job shops and have many side constraints and generalizations. There is little hope of solving real problems to optimality. At this moment it is important to raise the question of whether optimal solutions are required in practice or not. Scheduling models are just that models of real problems that are, in the best case, good approximations of the modeled reality. Real data is often put into estimates that are fed to the models. In these circumstances it makes little sense to solve an approximated model with estimated data to optimality. While it is important to study theoretical problems and constructs and to propose exact approaches for such settings (as the insight gained from those studies is invaluable), real problems often require a different approach. This approach comes in the form of heuristics. Scheduling heuristics provide quick and fast approximated solutions to even the most intricate scheduling models. Moreover, and as it will be shown, such solutions are very close to optimality, at least in the cases where the optimality gap can be calculated or estimated.

The Relevance of Heuristic Scheduling

So far it has been stated that scheduling problems are as varied as the manufacturing reality they model and among the hardest combinatorial problems there are. This

has resulted in a research gap between the theory and practice of scheduling. Furthermore, there are many practical issues that arise when deploying scheduling systems in manufacturing firms. The study of such scheduling systems is not as rich as the theoretical works. Some references are Framinan and Ruiz, Framinan and Ruiz [27, 28], and Framinan et al. [3, Chaps. 13 and 14 and references therein]. To cope with the variety of real settings, general and robust heuristics are preferable to ad hoc exact approaches that are often tailored to specific problems and objectives. In particular, metaheuristics are powerful heuristic templates that, with little instantiation, are capable of solving a wide array of differing problems to almost optimality in reduced CPU times. Still, the development of such methods for practical applications is challenging and requires finesse as well as a deep knowledge of the main constructs and results. Such is the focus of this chapter. Examples from the most noteworthy basic heuristic procedures to the most advanced metaheuristics will be highlighted. Our natural inclination is toward general simple methods that include little to no problem-specific knowledge at all as they are the most suited to practical applications. More general approaches to heuristic and metaheuristic algorithms for scheduling problems are given by Morton and Pentico [29], Hoos and Stützle [30, Chap. 9], and Framinan et al. [3].

The rest of this chapter is organized as follows: section "Notation and Classification of Scheduling Problems" formalizes scheduling problems and provides a succinct explanation of the common notation used in the literature. Section "Basic Scheduling Heuristics" presents dispatching rules and simple heuristics for some classical and basic scheduling problems. Two advanced scheduling heuristics are presented in section "Advanced Heuristic Methods." A brief introduction to metaheuristics is provided in section "Metaheuristics," along with the description of a successful and simple methodology. Finally, section "Conclusions" concludes this chapter and some pointers for future research are given.

Notation and Classification of Scheduling Problems

Most production scheduling models define a set N of n jobs with consecutive indexes, i.e., $N = \{1, 2, \ldots, n\}$. The resources are modeled in the form of a set M of m machines indexed as $M = \{1, 2, \ldots, m\}$. All sets are assumed to be independent from each other. Subindexes j and k are used to refer to jobs and i and l to machines. Some basic information associated with jobs and machines is as follows:

- A processing route. For a given job j, the route is an ordered list of machines that have to be visited in order for the job to be completed at the factory. If a job has to visit three machines (e.g., 2, 1, and 6), it is said that it has three tasks. Usually, and following this small example, the task in machine 1 cannot start until the previous task of the same job in machine 2 has finished.
- Processing times. These are commonly denoted as p_j or p_{ij}. This is the amount of time that a given job j needs at machine i. This time is fixed and usually it cannot

be interrupted. Machine i is busy while processing job j and cannot be occupied during this time by any other job.
- Due dates and weights. These are denoted by d_j and w_j, respectively. The due date models the time at which job j must be completed in the factory to be delivered to the customer. The weight captures the relative importance of the job. This data will be used later for the objectives to optimize.

Of course, a wealth of additional data might be needed for the jobs and machines, depending on the real problem to solve. However, and for the sake of brevity, the previous data suffices as a bare minimum. Furthermore, in the course of this chapter, it is assumed that all data is known and deterministic. Most figures are usually represented by nonnegative integers for simplicity. The literature on stochastic scheduling is vast. The interested reader is referred to two recent monographs and the references therein for more details [31, 32]. Additionally, the part on stochastic models in Pinedo [1] is an excellent starting point.

Types of Scheduling Problems and Notation

The literature on production scheduling is mostly partitioned according to how the machines are laid out on the production floor and also on the characteristics of the processing routes of jobs. With this in mind, the main scheduling problems relate to the following scenarios:

- Single machine problems. This is the simplest setting. There is a known number n of jobs, and each one has to be processed on a single machine, following a sequence. Most of the time only a vector p_j with the processing times of the jobs on this single machine is needed.
- Parallel machine problems. Picture the previous case but with m machines disposed in parallel. Jobs still have to be processed by one single machine, but in this case it has to be one out of the m available. Therefore, an assignment problem precedes that of the sequencing problem among all jobs assigned to each machine. The m parallel machines might be identical, uniform, or unrelated. In the case of identical parallel machines, the processing times for the jobs are independent of the machines. In the unrelated case, the processing time of a job j might change depending on which machine it is assigned to. Therefore, a processing time matrix p_{ij} is needed. The uniform parallel machine case is an intermediate situation where machines are faster or slower for all jobs by a factor.
- Flow shops. Here the m machines are disposed in series and all jobs must visit all machines in the same order. This means that the processing route is identical for all jobs and is usually assumed to be $1 \ldots, m$. Jobs are broken down into m tasks with known processing times p_{ij}. As stated before, any task for a given job is unable to start before the preceding task at the previous machine has finished. A flow shop is a very common production machine on production or assembly lines.

- Job shops. Here the main difference from flow shops is that each job has a potentially different processing route. Therefore not all jobs must visit all machines and nor do they necessarily have to be in the same order.
- Open shops. This is a much less common setting in which each job has to visit a given number of the m machines, but the route is open for the scheduling method to determine.
- Hybrid shop environments. Most real problems are actually a combination of the previous shop settings and parallel machines. Instead of having m machines disposed in series, there are m stages where at each stage i, there might be a single machine or m_i parallel machines, be these identical, uniform, or unrelated. This is, by far, the most complex and, at the same time, most general production setting.

Note that the previous short list is a massive simplification. Other production settings include assembly shops, manufacturing cells, flexible manufacturing systems (FMS), batch machines, and so on. In any case, the previous classification is the most employed one. Following this classification, the most common notation was proposed by Rinnooy Kan [33] and is a triplet $\alpha/\beta/\gamma$. The first field α covers the previous scheduling types with the values 1, P, Q, R, F, J, and O for single machine, identical parallel machines, uniform parallel machines, unrelated parallel machines, flow shop, job shop, and open shop problems, respectively. For more advanced layouts, like hybrid shops, there are extensions of this notation, like the one provided by Vignier et al. [34] and reviewed in Ruiz and Vázquez-Rodríguez [20]. The second field β is concerned with the constraints present in the problem, and the last field γ captures the objective function to optimize. These two last fields are succinctly summarized in the following sections.

Scheduling Constraints

As mentioned, there are as many scheduling constraints as product varieties and types of factories. Following Framinan et al. [3], the different scheduling constraints can be classified if they affect the processing of the jobs, operations, transportation, storage, or others:

- Process constraints. In this broad category, it might be mentioned all situations that affect the flow of the operations in the factory. Here one can find job/task precedence constraints ($\beta = \{chains, intree, outtree, tree\}$ depending on whether the precedence constraints form chains, convergent trees, divergent trees, or general trees, respectively). Here job/tasks might be subject to precedences, i.e., some jobs might not start before others have finished. Another frequent processing constraint is the setup times. Setup times model all nonproductive operations that have to be performed at machines after finishing jobs and before starting new ones. Cleaning, fixing, and reconfiguration are common setup operations. Setup times might be anticipatory/non-anticipatory and/or sequence

independent/dependent. As such, S_{ijk} models the amount of time that it is needed to setup machine i after processing job j and before processing job k. The literature on scheduling with all sorts and types of setup times is incredibly large. In parallel and hybrid layouts, jobs might have machine eligibility constraints, indicating that not all available machines can process certain jobs. Machines might also be subject to unavailability periods and/or breakdowns. Jobs might also have more general processing routes requiring stage/machine skipping or recirculation (revisiting one or more stages/machines more than once). This last circumstance is indicated as $\beta = recrc$. There are many more process constraints than the ones mentioned here. Consult Pinedo [1] or Framinan et al. [3, Chap. 4] for a more detailed account.

- Operations constraints. On many occasions the operation or task of a job on a given machine is more complicated. For example, tasks might be interrupted arbitrarily to be repeated or resumed later, possibly after having processed a task from a different job in between. Tasks from the same job might also be split to be processed by different parallel machines. Tasks/jobs might be subject to release dates, i.e., $\beta = r_j$ indicates that job j might not start processing at its first machine before time r_j due to, for example, unavailability of raw materials. Apart from release dates, there might be due dates, deadlines and due windows, etc. Another frequent characteristic is that jobs might not be allowed to wait in between machines ($\beta = nwt$). This is common in the processing of prepared foods in order to avoid breaking the cold chain. At the same time, there might be forced minimum waits for a job in between stages (cooling down, drying off), maximum waiting times, waiting windows, or even overlaps between consecutive tasks of a job. Similarly, processing times might be subject to all types of additional situations, like learning, deterioration or position dependency, etc.
- Transportation constraints. It is very common in real industries to have means of transporting unfinished jobs between machines. The list here is endless as one might have from simple manually operated pallet jacks for moving products from machine to machine to forklift trucks or even complex automated guided autonomous vehicles. Conveyor belts, handling robots, and other equipment are very common too. Depending on the scenario, transportation might be modeled as a simple fixed transportation time in between machines to very complex scheduling-routing problems when the transportation is an essential part of the process and transportation equipment is limited and expensive.
- Storage constraints. Similar to transportation constraints, production in course has to be stored somewhere. Again, and depending on the real situation, storage might be of no concern as space might be ample and/or the type of product being produced small and easy to store. However, in other situations the handling of unfinished products might be so challenging as to be a central constraint in the factory. Imagine, for example, the production of commercial airplanes where moving an airplane frame from one processing station to another is far from a trivial matter.

- Other constraints. Apart from machines one might have additional resources, like special tools, fixtures, or even the personnel operating machines. This personnel might have different degrees of skill. In some factories, machines might be able to perform more than one operation in parallel. Manufacturing firms might have more than one production center. Processing and/or setup times might be controllable depending on the resources (i.e., personnel) dedicated to them. There might be timing/shift constraints, safety concerns, etc. As indicated, the list of potential situations in practice is very long.

Scheduling Objectives

Finally, field γ is concerned with the scheduling objectives to optimize. In order to understand these, there is a need for some additional notation:

- C_j is the completion time of job j in the shop. It models the time at which the last task is completed at the last machine.
- L_j is a measure of the lateness of job j with respect to its due date d_j. $L_j = C_j - d_j$.
- T_j is a measure of the tardiness of job j where $T_j = \max\{L_j, 0\}$.

This is just a small extract of the many possibilities. Similarly, earliness can be defined when jobs finish before their due dates. From these definitions the two main groups of objective functions are those related with completion times and those with due dates:

- Completion time based. The most common one is the minimization of the maximum completion time among the jobs, usually referred to as makespan or $C_{\max} = \max\{C_1, C_2, \ldots, C_n\}$. Makespan is mainly related to maximizing machine utilization. The second most studied objective is the minimization of the total flow time, defined as $\sum C = \sum_{j=1}^{n} C_j$.
- Due date based. The most common is the minimization of the total tardiness of the jobs $\sum T = \sum_{j=1}^{n} T_j$. However, the weighted version or $\sum wT = \sum_{j=1}^{n} w_j T_j$ is more realistic as being tardy for some important jobs should be considered over being tardy for irrelevant orders.

There are tens, if not hundreds, of potential objectives. A much more detailed list is given in Chap. 5 of Framinan et al. [3]. Furthermore, the reality is often multiobjective. The extension of the γ notation for multiple objectives in scheduling is detailed in T'Kindt and Billaut [35].

Let us now give a simple example of the $F/prmu/C_{\max}$ problem or the permutation flow shop problem with makespan criterion. The example with the total flow time objective or $F/prmu/\sum C$ will be used. There are five jobs and four machines. The processing times are shown in Table 1.

Table 1 Processing times (p_{ij}) of a flow shop problem with five jobs and four machines

Machine (i)	Job (j)				
	1	2	3	4	5
1	29	37	95	85	65
2	30	62	59	11	55
3	27	21	70	62	67
4	2	6	82	80	57

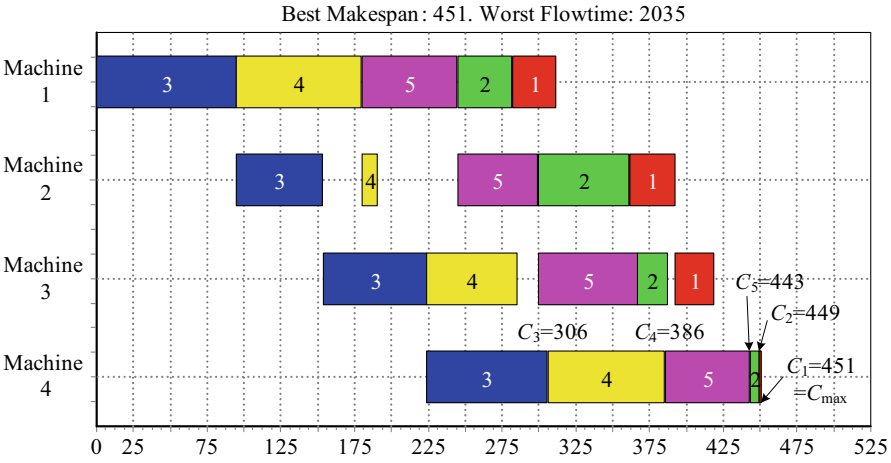

Fig. 1 Gantt chart for the permutation flow shop example with the best $C_{\max}$ which corresponds also with the worst possible $\sum C$ value

The permutation flow shop is a problem of determining a sequence for the jobs so there are $5! = 120$ possible schedules in this small example. If one calculates all of them, the best makespan value we obtain is $C_{\max*} = 451$ with the permutation or job sequence $\pi^*_{\max} = \{3, 4, 5, 2, 1\}$. The worst makespan value is $C^w_{\max} = 522$ (15.74% worse) resulting from the permutation $\pi^w_{\max} = \{1, 2, 4, 5, 3\}$. What is interesting about this example is that the best flow time value is $\sum C^* = 1{,}464$, resulting from the permutation $\pi^*_{\sum C} = \{1, 2, 4, 5, 3\}$. As one can see, $\pi^w_{\max} = \pi^*_{\sum C}$, i.e., the worst makespan solution is equal to the best flow time solution. Furthermore, the contrary is also true. For this example, the worst flow time value is $\sum C^w = 2{,}035$ (38.93% worse than the best), resulting from the permutation $\pi^w_{\sum C} = \{3, 4, 5, 2, 1\}$. As one can see, $\pi^*_{\max} = \pi^w_{\sum C}$. The conclusion is that the best possible makespan value can result in the worst possible flow time and vice versa. The two permutations in this example are depicted in Figs. 1 and 2, respectively. The completion times of all jobs in the last machine have been indicated for further examination. While this is a cherry-picked example, it is easy to find examples such as this for almost any number of jobs and machines.

Basic Scheduling Heuristics

In the early twentieth century, modern production plants started using scheduling techniques to increase productivity. Human schedulers planned production manually without any aid other than pen and paper. The situation today has not changed much for most industries where basically spreadsheets are used to program production, but simple rules are used to obtain effective schedules. These simple rules are often referred to as list scheduling rules, dispatching rules, or priority rules. Some of them will be briefly explained. More advanced dispatching rules will be explained later.

Some Simple Dispatching Rules

Dispatching rules are usually forward heuristics where new tasks or jobs are sequenced as they arrive or as their processing becomes feasible (i.e., all preceding tasks have been already scheduled). A decision is made over a set of eligible tasks, referred to as $\wp$. Some simple dispatching rules are the following:

- First Come First Served (FCFS): Here the job or task that entered the list of eligible tasks first is scheduled, i.e., the eligible tasks are sequenced in a first in first out (FIFO) order.
- Shortest Processing Time (SPT) First: The pending eligible with the shortest processing time goes first, i.e., given m machines, the task k that satisfies the following expression is chosen: $p_{ik} = \min_{j=1}^{|\wp|} \{p_{ij}\}$. While simplistic, SPT

results in the optimal solution for the single machine total flow time problem ($1\|\sum C$). The contrary rule to SPT is the longest processing time (LPT) first rule.

- Earliest Due Date (EDD) First: This is a dispatching rule that considers due dates. Basically the pending task with the earliest due date is scheduled first. EDD is optimal for the problems $1\|T_{\max}$ and $1\|L_{\max}$.

Note that these dispatching rules are extremely fast; all of them have a computational complexity of $\mathcal{O}(n \log n)$, n being the number of jobs or tasks to be scheduled. They have many other advantages like their simplicity and ease of application. Furthermore, they are easy to understand which is something valued by human schedulers. There are literally hundreds of dispatching rules and they have been comprehensively studied. It is suffice to cite just some of the exiting reviews in Panwalkar and Iskander, Blackstone et al., Haupt, and Jayamohan and Rajendran [36–39].

An Application to the Parallel Machine Problem

In general, dispatching rules, albeit general, fast, and simple, are overly myopic and produce subpar results, especially when compared to more elaborated constructs. However, in some cases they provide strong solutions. The following example applies to the identical parallel machine problem with makespan criterion or $P//C_{\max}$. In this problem only the assignment of jobs to machines is relevant, as the sequence at each machine has no effect on the maximum completion time. There are n jobs to be scheduled in m identical parallel machines with the only input data being a vector with the processing times p_j. The $P//C_{\max}$ is $\mathcal{NP}$-Hard even for two machines [40].

Real results from an exam scheduling problem of a big company in the USA (Pearson VUE) are presented. This company has 5000 test centers in 175 countries in which all types of certifications, admissions, and exams are taken. The problem solved is the scheduling of different exams every week of a given year at each center in the USA so as to minimize the number of hours that each center is open to the public. Each center has a number of seats in which exams can be taken. Therefore, each center is modelized as an identical parallel machine problem in which the number of seats is the number of machines. The objective is to minimize the makespan as this translates directly into a minimization of the opening hours. The different exams are job types, and registrations for a given exam by users at a given week are the jobs to be scheduled at the given center in that week. All 219 centers in the USA for the 52 weeks of 2012 were solved. This resulted in a total of 11,261 different identical parallel machine problems with 1,244,063 jobs in total. The largest center had 308 machines (seats) available, and the biggest number of jobs to solve in a given week and center was 638.

The algorithm of choice is the aforementioned LPT, which for the parallel machine case is simple. Jobs are ordered from longest to shortest processing times, and the first m are assigned to the m parallel machines. Then, each job in the ordered list is assigned to the first freed machine. This LPT is known to have a worst-case performance guarantee of $\frac{4}{3} - \frac{1}{3m}$ [41]. This means that for large m values, the solution given by LPT should be at most around 33% worse than the optimal makespan. Now the results of the LPT with the solutions obtained by a state-of-the-art solver (CPLEX 12.5) are compared. The experiments were run on a computing cluster with 240 cores in total (XEON E5420 processors running at 2.5 GHz.) and 480 GBytes of RAM memory. Around 93% of problems could be solved to optimality and the average gap obtained was 0.57%. However, more than 80 h of CPU time were needed in the cluster (time limit for each problem solved was set to 300 s, which was reached in 851 cases). Comparatively speaking, the LPT resulted in a gap in respect to the MIP optimal solution or lower bound of just 0.91%. The total CPU time of the application of the LPT for all 11,261 problems was just 17.16 s on a single computer and most of this time was the processing of the input data and generation of the solution files.

The conclusion is clear. For some problems, including real ones, the application of simple dispatching rules can result in extraordinary performance in negligible CPU times.

Elaborated Dispatching Rules

Many authors have explored more intricate procedures. A clear example is the apparent tardiness cost (ATC) composite dispatching rule proposed by Vepsalainen and Morton [42]. This rule is excellently explained in Pinedo [1]. The ATC rule was presented for job shop problems with total weighted tardiness criterion but has been successfully applied to different problems as well. The rule is applied to all jobs and an index is calculated. The job with the highest index is scheduled and then the rule is calculated again for the remaining $n - 1$ jobs. In total ATC is computed $n \cdot (n + 1)/2–1$ times resulting in a computational complexity of $\mathcal{O}\left(n^2\right)$. The index is calculated for each job j, and each time a machine is free as $I_j(t) = \frac{w_j}{p_j} \cdot e^{\left(\frac{\max\left\{d_j - p_j - t, 0\right\}}{K\overline{p}}\right)}$ where $\overline{p}$ is the average of the processing times and K is a parameter that needs to be fixed. ATC was expanded for the consideration of setup times by Lee et al. [43] resulting in the apparent tardiness cost with setups or ATCS. Here the index is further complicated: $I_k\,(t,\, j) = \frac{w_k}{p_k} \cdot e^{\left(\frac{\max\{d_k - p_k - t, 0\}}{K_1\overline{p}}\right)} \cdot e^{\left(-\frac{s_{jk}}{K_2\overline{s}}\right)}$. As one can easily see, the calculations quickly become cumbersome; the rule is also harder to understand and to apply which basically defeats many of the advantages of dispatching rules. The benefits are better performance and objective function values.

Advanced Heuristic Methods

Advanced heuristics usually include problem-specific knowledge exploiting theoretical properties of scheduling problems. Alternatively, some methods aim at deriving better schedules starting from previous schedules. These latter approaches have been known as improvement heuristics. The distinction between basic or constructive heuristics and improvement heuristics is not so clear on many occasions. In any case, most of the time constructive heuristics have a natural stopping criterion, i.e., the method stops when a complete schedule or sequence has been built. Improvement heuristics don't have such a direct stopping criteria.

Most improvement heuristics and metaheuristics (to be succinctly reviewed in the next section) are strongly based on local search techniques. Local search is a heuristic exploration technique with a strong methodological background ([30], among many others). Local search requires at least the following ingredients: (1) A definition of what is a neighboring solution of a sequence; (2) a way to explore the neighbors of a solution; (3) an acceptance criterion, i.e., when a neighboring solution must replace the current one; and (4) when and how to stop the local search. Usually the main and most important issue is how to represent a solution and how to define a neighborhood from that representation. In most scheduling problems, solutions are indirectly represented as permutations of integers. The most employed neighborhoods are swap and insert where two jobs exchange their positions in the sequence in the case of swap and a job is extracted from its position and inserted into another position in the case of insert. In the following section, a very successful heuristic for the flow shop problem is detailed. It is based on the exploration of the insertion neighborhood in a constructive phase. Later another effective heuristic is briefly described but this time for the job shop problem and based on a different methodology the decomposition of the scheduling problem into smaller subproblems.

The NEH Heuristic for the Permutation Flow Shop and Makespan Criterion

The NEH heuristic of Nawaz et al. [44] is one of the most successful advanced heuristics. It was originally proposed for the permutation flow shop with makespan criterion ($F/prmu/C_{\max}$). It is powerful and capable, with hundreds of applications and references to many scheduling problems. Reviews like those of Turner and Booth [45], Taillard [46] or Ruiz and Maroto [47] recognize its capacity. The NEH exploits the fact that jobs with large total processing times must be sequenced as early as possible. The NEH consists of three steps:

1. The total processing times of the jobs in all machines are calculated: $P_j = \sum_{i=1}^{m} p_{ij}, \quad j = (1, \ldots, n)$.
2. Jobs are sorted in descending order of P_j, so that the first job is the one that has the highest time requirements. These sorted jobs are stored in a list ℓ.

3. The first two jobs of the list ℓ, referred to as $\ell_{(1)}$ and $\ell_{(2)}$, are extracted. The two possible partial sequences made up from these two jobs are constructed and their respective makespan values calculated. In other words, the two following partial sequences are tested: $\{\ell_{(1)}, \ell_{(2)}\}$ and $\{\ell_{(2)}, \ell_{(1)}\}$. From the two sequences, the one with the minimum partial $C_{\max}$ value is retained for the next iterations.
4. The main loop of the NEH starts here. At each iteration, the job at position k of the list ℓ, i.e., $\ell_{(k)}$, $k = (3, \ldots, n)$ is extracted. This job $\ell_{(k)}$ is inserted into all possible solutions of the partial incumbent sequence, and the sequence resulting in the lowest partial $C_{\max}$ value is retained for the next iteration. For example, let us suppose that the best partial sequence obtained up to a given point is $\pi_p = \{\ell_{(1)}, \ell_{(3)}, \ell_{(2)}\}$ and that $k = 4$; therefore, job $\ell_{(4)}$ has to be inserted in the four possible positions of the partial sequence: $\pi^1_{p+\ell_{(4)}} = \{\ell_{(4)}, \ell_{(1)}, \ell_{(3)}, \ell_{(2)}\}$, $\pi^2_{p+\ell_{(4)}} = \{\ell_{(1)}, \ell_{(4)}, \ell_{(3)}, \ell_{(2)}\}$, $\pi^3_{p+\ell_{(4)}} = \{\ell_{(1)}, \ell_{(3)}, \ell_{(4)}, \ell_{(2)}\}$, and $\pi^4_{p+\ell_{(4)}} = \{\ell_{(1)}, \ell_{(3)}, \ell_{(2)}, \ell_{(4)}\}$. For the next step ($k = 5$), the sequence with the lowest partial $C_{\max}$ value from the four previous possible sequences is retained.

As one can see, NEH is basically based upon insertions of jobs into a partial sequence that is constructed step after step. Step 1 has a complexity of $\mathcal{O}(nm)$. The second step is just an ordering and takes $\mathcal{O}(n \log n)$. The third step requires just two calculations of two small sequences and can be disregarded. Most CPU time is needed by step 4. In step 4 there is a loop of $n - 2$ iterations where at each step k, k insertions of job $\ell_{(k)}$ are carried out into a partial sequence that contains $k - 1$ jobs, and for each insertion one needs to calculate the $C_{\max}$ value of k jobs (including the inserted one). In total, $\frac{n(n+1)}{2} - 3$ insertions are carried out, being n of these complete sequences at the last iteration. Therefore, the computational complexity of the NEH is $\mathcal{O}\left(n^3 m\right)$. A closer look shows that when inserting the k-th job in position, let us say, j, all $C_{i,h}$, $h = \{j - 1, j - 2, \ldots, 1\}$ were already calculated in the previous insertion and there is no need to recalculate. Taillard [46] exploited this idea by which all insertions in a given step can be calculated in $O(nm)$ effectively reducing the complexity of the NEH to $O(n^2 m)$. This faster variant is referred to as NEHT or NEH with Taillard's accelerations.

The NEH was computationally tested against 25 other heuristics, including other more recent and complex heuristics in Ruiz and Maroto [47]. The experiments demonstrated that the NEH is superior to all other tested methods and at the same time much faster. This was supported by statistical analyses. In the results, NEH showed an average percentage deviation from the best solutions known in the 120 instances of Taillard [48] of just 3.33%. Although this is an average result, NEH rarely goes beyond 7%. Furthermore, NEH is actively used as a seed sequence for metaheuristic techniques.

The NEHT was also evaluated by Rad et al. [49] with surprising results. For example, in the 10 instances of the largest size (500×20) from the benchmark of Taillard [48], NEHT managed to give an average percentage deviation from the best known solutions (these solutions have been proved to be "almost optimal" with very small gaps between the highest known lower bound and lowest known upper

bound or best solution known) of just 2.24%. Furthermore, this 2.24% deviation from a very close to optimum solution was achieved in an average of just 0.0773 s. Extensions of the NEH presented in the same paper of Rad et al. [49] resulted in much better performance, reaching an average percentage deviation from best known solutions of just 1.4% in CPU times under 2 s.

With these results, it is easy to see why the NEH is such an important and widely studied heuristic. Studies about the NEH have been numerous over the years. The papers of [49–57] and more recently Fernandez-Viagas and Framinan [58] are some examples. Furthermore, the NEH does not rely on specific problem knowledge, and it is relatively easy to extend it and apply it to different scheduling problems. Such extensions are numerous in the scheduling literature, mainly over flow shop problems but also in hybrid settings and other problems.

A Brief Introduction to the Shifting Bottleneck Heuristic for the Job Shop Problem

The shifting bottleneck heuristic or SBH for short was initially proposed by Adams et al. [59] for the job shop problem and makespan minimization ($F//C_{\max}$). Many improvements on the initial SBH for the same problem were presented over the following years. Additionally, SBH has been extended by many authors to other objectives and problems. It is a very interesting method because it mimics the reality of a production floor. In real factories one production stage or machine is usually the bottleneck of the whole plant, i.e., productivity or the measured objective is hard to improve unless the scheduling or capacity of this stage is improved. SBH tries to optimize the schedule of the bottleneck machine first as the contribution of this machine to the final makespan is large. Since in a job shop there are m machines and jobs are made of many tasks with precedence relationships among them, scheduling only the bottleneck machine is not straightforward. The procedure can be simply described as follows:

1. Determine the bottleneck machine.
2. Schedule all previous tasks of the n jobs on the other machines to obtain the release dates (r_j) of the jobs on the bottleneck machine.
3. Schedule all subsequent tasks of the n jobs on the other machines to obtain the due dates (d_j) of the jobs on the bottleneck machine.
4. Schedule the bottleneck machine as a single machine problem with release dates and due dates, minimizing the maximum lateness ($1/r_j, d_j/\max L_j$).
5. Repeat all previous steps for the remaining $m - 1$ machines until all machines have a sequence.

Note that the single machine problem is solved m times. The $1/r_j, d_j/\max L_j$ is in itself a hard problem. However, efficient methods do exist for its solution. In particular, the original SBH heuristic of [59] uses the algorithm of [60]. Additional details about the SBH procedure, including examples, are given in [1] and in [3].

The performance of the SBH is outstanding, especially if one considers that the job shop problem is incredibly hard to solve. Back at the time the authors were able to solve problems of up to 50 jobs and 10 machines to optimality in some cases. As a result, the literature on the SBH is incredibly large. More details about this heuristic and many other related bottleneck decomposition methods are given in the book of [61].

Metaheuristics

While heuristics are usually devised for specific problems with a given objective function, they are, in principle, more generic. This distinction is far from clear as many heuristics are indeed general as well, like the aforementioned NEH. In any case, metaheuristics can be seen as general algorithmic templates that exist without the particular problem or application. Additionally, metaheuristics are commonly more demanding and CPU intensive than regular heuristics. The desired effect of this additional computation is a better solution quality. Other common characteristics of metaheuristics are mechanisms to escape local optimality and to reduce the effect of the myopic nature of heuristic approaches by diversification mechanisms. The field of metaheuristics is interdisciplinary and terribly prolific with literally thousands of papers being published every year in many different fields, not to mention the large number of monographs dedicated to them. Scheduling being an important problem, the application of metaheuristics to scheduling is frequent. A good starting point are the books of [30, 62].

Metaheuristics are roughly grouped into families or classes. Each family stems from a basic metaheuristic template that, with relatively few modifications, can be applied to a specific scheduling problem, and reasonable results might be obtained. To obtain very high-quality solutions, more specific operators and local search schemes are usually needed. This also results in slower methods. The main categories are simulated annealing, tabu search, genetic algorithms, ant colony optimization, scatter search, variable neighborhood search, GRASP and iterated local search, etc. In the following section, the main constructs inside most metaheuristic algorithms are described, to be followed by a brief description of a successful metaheuristic that is at the same time simple: iterated greedy.

Main Concepts of Metaheuristics in Scheduling

Most metaheuristic classes require at least the instantiation of some of the following elements:

- Representation of the solution. At the lowest level, solutions contain variables and these might be continuous, discrete, binary, etc. A representation is just how the variables are represented and arranged. In scheduling problems that require permutations and an array or list of integers, each one representing a job is

an indirect representation of the final solution. Such a solution is "scheduled" (i.e., starting and finish times for each job and/or task are calculated) in order to calculate the desired objective function. For parallel machine problems where only the assignment is relevant (e.g., the $P//C_{\max}$), each job might have an integer indicating the machine to which it is assigned to. The representation is very important for the final performance of the metaheuristic.

- Initial solution or population generation. Most metaheuristics require an initial solution to start the process. Population-based metaheuristics require a set of solutions. The easiest procedure is to randomly generate these initial solutions. Of course, this results in initial solutions of mediocre quality. The most commonly employed alternative is to use high-performance heuristics to generate initial schedules.
- Intensification and diversification mechanisms. Initial solutions are worked on through local search and/or other procedures like selection and crossover in genetic algorithms. The objective is to find new and better solutions. There are many procedures and techniques but all of these fall more or less into what is referred to as intensification. To avoid stagnation in the search process, most metaheuristics include diversification mechanisms by which existing solutions are disrupted or altered (or new solutions are generated) in order to allow the intensification procedures to work over different parts of the solution and search space.
- Acceptance criterion. New solutions generated through the intensification and diversification processes have to be examined in order to decide if they replace current incumbent solutions or not. The simplest scenario is when new solutions are accepted if and only if they improve on the current or best objective function value found so far during the search. This criterion leads to premature convergence and stagnation, and most metaheuristic templates consider more elaborated alternatives where worse solutions might be accepted, often temporarily.
- Termination criterion. Metaheuristics iterate continuously unless a user-given termination criterion is met. For most metaheuristics, optimality is not guaranteed. Furthermore, most applications of metaheuristics do not have an indication of when an optimal solution has been found in order to stop the search. Therefore, common termination criteria include a number of iterations or a consecutive number of iterations without improvements (or small improvements), elapsed CPU time, etc.

The previous operators are only a very small list where not even all of them might be needed to construct a simple method. Furthermore, elaborated metaheuristics might have many operators and procedures. Actually, in the last decade, many natural or man-made processes have inspired a real tsunami of metaheuristic methods. As a result there are algorithms that are referred to as particle swarm, imperialist competitive, honey bees, fruit flies, and even more bizarre methods like intelligent water drops or galaxy optimization. Currently, such "novel" methods are

being criticized. The papers of [63, 64] are two examples. In this chapter these criticisms are supported and very successful, but at the same time really simple metaheuristic is described.

Iterated Greedy as an Example of a Simple- and High-Performing Method

The first application of the concepts of iterated greedy (IG) to a scheduling problem was presented by [65]. The authors dealt with the permutation flow shop problem with makespan criterion ($F/prmu/C_{\max}$). Being a metaheuristic, IG starts from an initial heuristic solution. Then three phases are iteratively applied until a termination criterion is met. The first phase is a partial destruction of the current solution. Some jobs are randomly removed from the permutation. The second phase is the reconstruction of the (now) incomplete solution. All removed jobs are inserted, one by one, into all positions in the partial solution using the NEH heuristic. Each job is placed into the position resulting in the best objective function value. An optional step is a local search each time a complete solution is obtained. This local search is carried out in the insertion neighborhood until local optimality. The third last step is an acceptance criterion. A detailed pseudoalgorithm listing is given in Fig. 3.

As one can see, IG carries out intensification with the reconstruction and local search operators and diversification with the destruction. The acceptance criterion is a simplification of simulated annealing. With a constant temperature factor, worse solutions are accepted with a probability that decreases with the quality of the new solution.

The results of the IG method for the permutation flow shop problem are state-of-the-art even today. According to the results of [65], IG was able to reduce the average relative percentage deviation from the best known solutions in the 120 instances of [48] to just 0.44% in little under a minute on average. It was computationally and statistically demonstrated that IG produced better results than competing methods. Later, [66] were able to further reduce this deviation to 0.22% using a simple island model parallel version of the IG.

IG has been applied to different scheduling problems with good results. Ruiz and Stützle [67] extended the previous results with the consideration of sequence-dependent setup times. IG for no wait and blocking flow shops were studied by [68, 69], respectively. IG showed excellent performance in no-idle and mixed no-idle flow shops in [70] and [71]. Non-permutation flow shops were approached by [72]. Distributed scheduling problems have been solved with IG methods by [73, 74]. IG also gives good results in other objectives aside from makespan like tardiness in [75] or total flow time in [76], to name just a few. Multi-objective extensions of IG have proven effective for Pareto flow shops without and with setups in [77] and in [78], respectively. Parallel machine problems were successfully solved with IG methods by [79]. Finally, hybrid flow shops were studied by [80] and complex

end

Fig. 3 Iterated greedy (IG) algorithm. (Adapted from [65]). *random* is a random number distributed uniformly in the range [0, 1]. Temperature and *destruct* are the two parameters of IG

realistic hybrid flow shops by [81–83]. There are many other applications of the IG methodology to other scheduling problems and also to several other combinatorial problems as well.

What is noteworthy about all previous studies is that IG algorithms are shown to produce state-of-the-art results that on many occasions are competitive or better than those produced by other much more complex metaheuristics.

There are highly successful applications of different metaheuristics for practically every formulated scheduling problem. Many are listed in [3] and the references therein.

Conclusions

In this chapter the scheduling field has been introduced, pointing out its relevance, difficulty, and hardness. Scheduling problems are varied, hard, and difficult to solve optimally. However, in many settings, obtaining approximated solutions of sufficient quality is within reach if modern heuristic methodologies are employed. The notation of scheduling problems has been introduced. A succinct explanation of simple dispatching rules is provided. An example that shows the lack of correlation between otherwise seemingly correlated objectives has been presented which again highlights the fact that scheduling problems are neither easy nor intuitive. Furthermore, in a briefly summarized application, it has been shown how a very simple dispatching rule can result in almost optimal solutions for real problems of a large size. Even though elaborated and combined dispatching rules are powerful, advanced heuristic methods are many times better. The NEH method for the flow shop and the SBH for the job shop are the clearest examples. High-performance and close-to-optimal solutions are perfectly possible in negligible CPU times. Finally, in an ever-growing field, metaheuristics propose themselves as modern heralds of flexibility, robustness, and finest solution quality. A summary of the iterated greedy method has been presented which apart from the previous qualities manages state-of-the-art results without unnecessary complexities in its design.

As for the future of scheduling heuristics, it is argued for even simpler and more robust approaches, capable of solving hard and varied scheduling problems with little to no instantiation and adaptation. Such frameworks and methodologies could prove invaluable in closing the gap between the theory and practice of scheduling.

Abstract

The development of high-quality software systems is a complex process involving various phases and activities. As software systems grow in size and complexity, these tasks become increasingly challenging for developers, and a significant effort is needed to maintain software quality during its evolution and prevent systems from becoming costly, error-prone, and unsatisfactory. To address these issues, researchers have sought to automate various tasks within the software development process. Search-Based Software Engineering (SBSE)

is a research area that focuses on reformulating software engineering tasks as optimization problems and designing algorithms to solve them. By automating these tasks, SBSE aims to enhance software quality, reduce the burden on developers, and lower associated costs. This chapter provides an introduction to the field of SBSE, detailing some of the most widely studied families of optimization problems in the field: software project scheduling, optimal feature selection, software test case generation, and software module clustering. The chapter concludes with some insights and references for further reading.

Search-Based Software Engineering · Software Project Scheduling · Optimal Feature Selection · Test Case Generation · Software Module Clustering

Introduction

Software plays a crucial role in the proper functioning of modern systems, controlling a wide range of electronic devices, from ubiquitous tools like mobile phones to critical systems in aircraft and medical instruments. Over the past few decades, computer programming has revolutionized the world and is expected to continue doing so in the coming years. As software systems grow in size and complexity, navigating them becomes increasingly challenging. To address these issues, the scientific community has intensified its efforts to automatically enhance and correct software systems.

Search-Based Software Engineering (SBSE) is a research area that focuses on reformulating Software Engineering (SE) tasks as optimization problems and designing optimization algorithms to solve them. By applying optimization techniques to SE tasks, the SBSE community aims to improve the quality of software systems, correct code errors, and generally facilitate the work of software developers.

Although some preliminary works from the twentieth century can be classified within the field of SBSE, [81, 82, 92, 137, 168, 172], the term itself was first coined in 2001 by Mark Harman and Bryan F. Jones [58]. In their work, the authors described SBSE as an emerging field of SE research and expressed their expectation of a "dramatic development of the field" [58]. More than 20 years later, in 2024, the Symposium on Search-Based Software Engineering (SSBSE) celebrated its 16th edition [76]. Throughout the first 11 editions, more than 290 authors from 25 countries had already contributed to the main track of SSBSE [36]. The contributions of the SBSE community to reputed journals have also been significant.

SBSE problems are typically classified according to the phases of the software development process in which they arise. The life cycle of a software project encompasses all activities performed to evolve a system from its conception to its retirement [70]. To ensure the creation of high-quality code, software engineers

Table 1 Classification of some families of optimization problems identified in the SBSE research field according to the phase within an SDLC where they mostly arise, based on related literature [40, 59, 124, 147, 150, 152]

are advised to follow a structured approach known as the Software Development Life Cycle (SDLC). An SDLC is a framework that defines, orders, and establishes transition criteria for various stages, each containing several processes and activities related to the system's life cycle [70]. Although the exact number of phases can be debated, SDLCs generally include the following phases: requirements definition, analysis and design, software development, testing, and maintenance. Implementing a defined SDLC model has been shown to enhance the quality of software products [174].

Following the structured approach of SDLC, Table 1 presents a classification of various SBSE problems according to the SDLC phase in which they arise primarily, based on the related literature [40, 59, 124, 147, 150, 152]. As observed, SBSE problems emerge in numerous SDLC phases, ranging from project management to software maintenance.

In the following sections, we will describe some of the most relevant problems in the literature. Software project scheduling is discussed in section "Software Project Scheduling"; optimized feature selection is presented in section "Optimal Feature Selection"; software test case generation is detailed in section "Test Case Generation"; and software modularity clustering is described in section "Software Module Clustering." Finally, conclusions are presented in section "Conclusion."

Software Project Scheduling

Software project management focuses on ensuring that a software product meets the elicited requirements and is delivered on time and within budget [152]. This involves identifying tasks, estimating the efforts required to complete them, identifying dependencies and bottlenecks, and assigning resources (typically, employees) to tasks. Typically, a schedule in the form of a Gantt chart is produced to detail these decisions [41]. For large projects, creating such a schedule is a complex task, and the number of possible schedules is vast [41]. The problem becomes increasingly challenging when considering additional factors such as the skills of each employee and uncertainty. Therefore, automating project scheduling with the optimization of certain objectives, such as completion times or cost reduction, can offer significant benefits to software development teams.

Software Project Scheduling (SPS) is an optimization problem that focuses on finding the optimal assignment of tasks to employees and determining the best order in which these tasks should be tackled to optimize a set of objectives, such as minimizing completion times, reducing associated costs, and minimizing overtime planning [152].

In Fig. 1, a flow chart provides an overview of SBSE approaches for the SPS problem, based on [59]. As illustrated, there are two main activities, represented by rounded rectangles filled in red: the search process, conducted by search-based optimization techniques, and the evaluation, performed by an evaluator. Additionally, there are three types of data items, represented by green polygons. The input to the optimization methods can contain various kinds of information:

- **Tasks information**: This set of inputs includes information about (i) the tasks that need to be performed; (ii) the effort estimates for each task, which may encompass cost estimates, duration estimates, or both; and (iii) the dependencies between tasks, as some tasks cannot be initiated until a specified set of tasks has been completed.
- **Staff information**: This set of inputs comprises information about (i) the staff available to work on the project; (ii) the costs associated with including each employee; and (iii) the amount of work each employee can dedicate to the project (e.g., hours per day).
- **Skills information**: This set of inputs contains information about (i) the skills of each staff member and (ii) the skills required to perform each task.

Although Fig. 1 includes tasks, staff, and skills information for completeness, not all the inputs described are always considered for SPS problems. In the literature, authors have considered different levels of detail for these problems. For instance, some authors only consider tasks and staff information [9], while others include the level of proficiency in different skills [27, 117, 160]. Additionally, some have considered differences in costs between normal and overtime work hours [27]. Regardless of the level of detail, the information provided is then used as input for search-based optimization techniques that attempt to find the optimal solution.

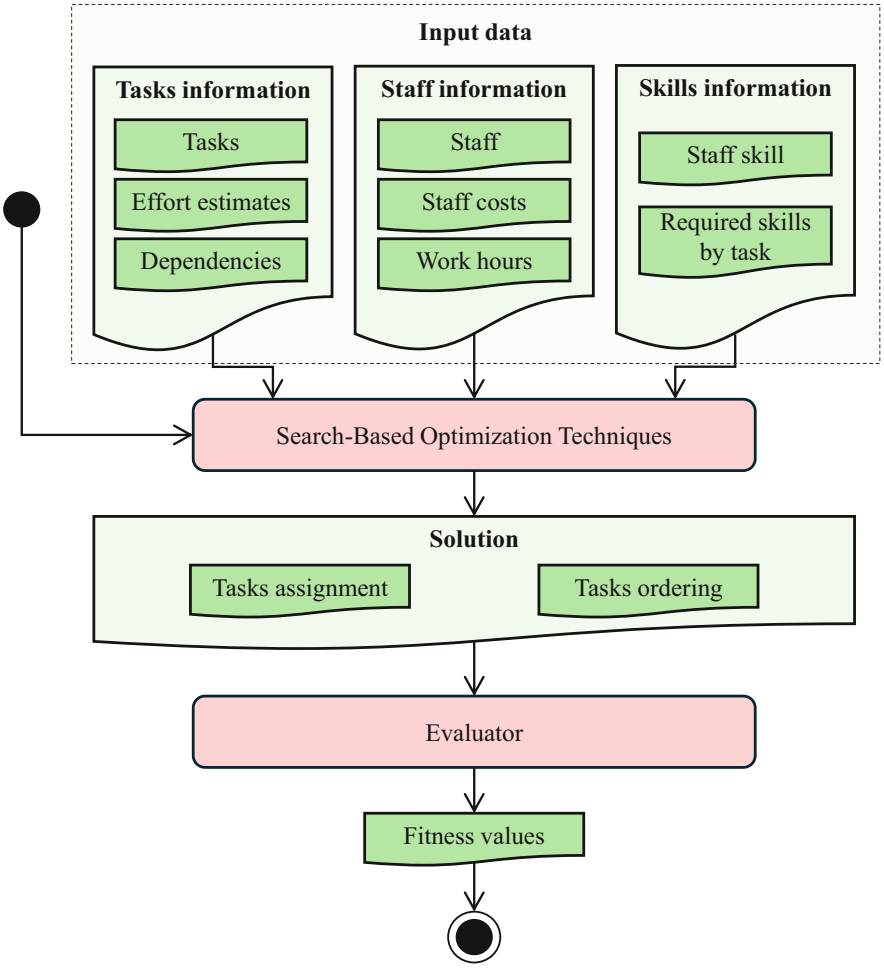

Fig. 1 Generic overview of SBSE approaches for the SPS problem, based on [59]

In this context, as illustrated in Fig. 1, a solution involves assigning personnel to tasks (tasks assignment) and determining the order in which these tasks are tackled (tasks ordering). This solution is then evaluated. Depending on the number of objective functions, the SPS can be approached in a mono-objective or multi-objective manner. A common goal is to minimize the completion time [9], meaning the shorter the project duration, the better. Similarly, minimizing the costs associated with the project is often considered [5, 27].

Moreover, the planning of software projects, like project planning in general, is subject to risks, such as product flaws, task delays, and budget reductions. Consequently, some works also consider risk [51, 90, 180]. For instance, some authors use optimistic and pessimistic estimations of the input information to design robust approaches [9]. Additionally, the challenges posed by risks during

project completion have naturally led researchers to propose dynamic approaches [128, 160]. These approaches account for various dynamic events that may arise during the project, such as the addition or removal of tasks, or changes in personnel. Thus, in addition to other objectives, the robustness and/or stability of the solutions (i.e., making small adjustments in response to dynamic events) is rewarded [160].

To solve the SPS problem, various metaheuristic schemes have been employed as the basis for the development of search algorithms. Table 2 provides a chronological summary of some of the proposals for the SPS discussed in this section, detailing the year of publication (Year), the metaheuristic approaches used (Method(s)), the quality aspects evaluated (Objective function (s)), whether a single (Single-objective) or multi-objective (Multi-objective) approach was used, and whether a dynamic approach was considered (Dynamic). As can be observed, the most prevalent approach has been the use of Genetic Algorithms (GAs) [5, 9, 26, 50, 179,

180]. While many researchers propose different variations of the general scheme or specific crossover and mutation operators, it is also common to see standard GAs such as NSGA-II or SPEA2 [31, 32, 51].

In addition, some authors have proposed heuristics based on other schemes. For example, Chen et al. [27] introduced a method based on Ant Colony Optimization. Minku et al. [117], along with an evolutionary algorithm, proposed a method based on local search. Nigar et al. [128] proposed two different heuristic methods to build initial solutions as part of a multi-objective evolutionary algorithm scheme: One heuristic focuses on minimizing completion time, while the other focuses on minimizing project costs.

Other works include proposals based on simulated annealing and hill climbing methods [41], a firework algorithm [29], a Q-learning-based memetic algorithm [161], a cooperative coevolutionary GA [162], and a particle swarm optimization approach [164]. Recently, an integer linear program formulation was proposed as an alternative approach to the problem [110].

The SPS problem is one of the most extensively studied problems in the SBSE literature. There are numerous formulations of the problem, each with different input data, objectives, and constraints, as well as a variety of approaches. For a more comprehensive overview of the literature on this problem, we refer the reader to other relevant sources [46, 151, 152, 170].

Optimal Feature Selection

A Software Product Line (SPL) is defined as "*a set of software-intensive systems that share a common, managed set of features satisfying the specific needs of a particular market segment or mission and that are developed from a common set of core assets in a prescribed way*" [33]. In essence, an SPL is a family of software products based on a common architecture, incorporating common and variable elements [130]. Maintaining an SPL facilitates systematic reuse of software components in a family of similar products, resulting in significant improvements in cost, quality, time to market, and developer productivity [169].

To develop an SPL, a Product Line Architecture (PLA) must be designed. This architecture specifies the common and variable elements of the product family and their relationships [88]. Essentially, a PLA encompasses the core design model of an SPL [35]. Consequently, the quality of a PLA is crucial for the success of an SPL [140]. However, designing a high-quality PLA is time-consuming, costly, and prone to errors [112]. Additionally, several conflicting metrics measure the quality of PLAs, making optimization problems related to PLAs often multi-objective in nature.

With respect to PLA design, there are two primary categories of problems [88]. The first category focuses on PLA generation, which involves identifying PLA components and configuring the architecture. The second category addresses PLA evolution, including the refactoring and remodularization of existing PLAs, with an emphasis on improving these architectures. Most studies in the literature focus on PLA refactoring and remodularization [88].

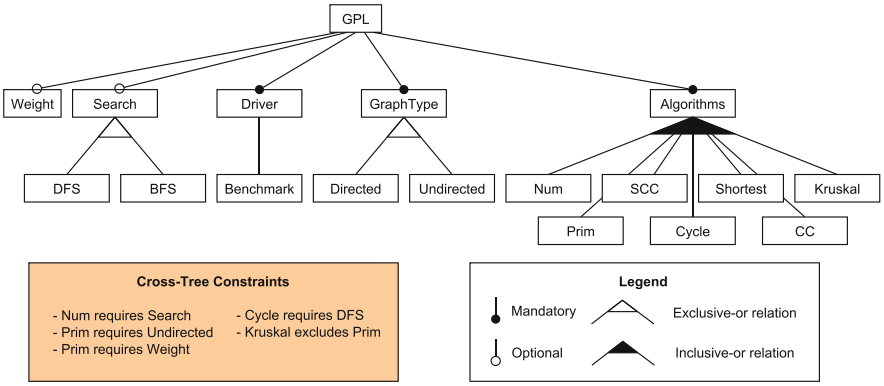

Fig. 2 A sample feature model for a Graph Product Line (figure adapted from [101])

Feature models (FMs) have become the de facto standard for modeling features of an SPL [101]. A feature is a behavior of a software product that is visible to the end user and is of interest to some stakeholders [156]. FMs model features in a tree-like structure, where nodes represent features and edges represent relations between features. By considering the relations between nodes, an FM denotes the set of feature combinations that the products of an SPL can have [83]. Figure 2 represents the FM for a Graph Product Line (GPL) [100]. The GPL is a case study SPL that has been widely used in the literature [101]. In the GPL, a product is a collection of algorithms that can be applied to a graph. In an FM, each node, except the root, represents a feature. A feature can only be included in a product if its parent feature is included as well. Following the example presented, "DFS" could not be included if "Search" was not included. There are four types of relations that can appear in an FM. A *mandatory feature* has to be selected whenever its parent is selected. In the example, the graph type needs to be defined. An *optional feature* might be selected if its parent is selected, but it is not mandatory. In the example, a graph may or may not have weights. An *exclusive-or relation* indicates that only one of the features in the group can be selected. In the example, a graph can be either "Directed" or "Undirected," but not both. An *inclusive-or relation* indicates that any number of the features in the group can be selected, as long as at least one is selected. In the example, more than one algorithm can be selected. Finally, there might also be cross-tree constraints in the FM. These constraints impose certain restrictions in the selection of features within the model. For instance, in the GPL depicted, "Prim" algorithm can only be selected if the graph is "Undirected" and has weights. Notice that even from such a simple FM, there are 73 possible combinations [101]. As SPLs become larger, the number of possible combinations becomes enormous. Large product lines, such as the Linux kernel, include more than 6000 features [156]. Indeed, the problem of optimal feature selection has been shown to be NP-hard [173].

For the optimal selection of features in PLAs, various quality attributes are frequently considered. These attributes may include correctness (i.e., valid feature

selection), richness of features (the more features, the better), reuse of previously used features, avoidance of known defects, and minimization of costs.

Regarding the availability of instances, the Software Product Lines Online Tools (SPLOT) project at the University of Waterloo represents one of the largest efforts to provide feature models of varying sizes [115]. SPLOT instances have been used to obtain numerous results concerning SPLs [156].

As is common in many SBSE problems, most algorithmic approaches propose the use of GAs [14, 34, 35, 87, 165]. Table 3 presents a chronological summary of works studying the problem of optimal features selection. Most considered objectives related to the correctness, cost, the number of known defects, use

of features not used before, and richness of features. As it can be observed, many authors have explored the performance of widely used algorithms such as NSGA-II, SPEA2, and IBEA. Moreover, several operators specifically tailored for the problem have been proposed and integrated into these well-known algorithms [64, 65, 178]. Additionally, some authors have proposed hybridizations between IBEA and constraint satisfaction solvers [62], satisfiability modulo theory solvers [53], and differential evolution [181]. Given the high number of constraints in large feature models (FMs), some authors proposed using correct (i.e., valid) configurations as seeds in the initial population of solutions, which yielded good results [153, 156]. Hierons et al. [63] proposed a method named ShrInk Prioritise, which included new objectives and was integrated into other algorithms, including NSGA-II, IBEA, and MOEA/D. There are also approaches that propose the use of exact methods to solve the problem of optimal feature selection [129].

Finally, to support the methods available in the literature for PLA optimization, a tool was needed to allow users to select different approaches and visualize the proposed solutions. To this end, a tool named OPLA (optimization for PLAs) was presented at the 7th SSBSE in 2015 [44]. This tool receives a class diagram representing a PLA, performs an optimization process, and allows the visualization of changes through a graphical interface.

As discussed in this section, there are numerous works studying optimization problems regarding SPLs, ranging from PLA design to feature selection, each with different input data, objectives, constraints, and approaches. For a more comprehensive overview on this subject, we refer the reader to other relevant sources [88].

Test Case Generation

Software testing is a crucial undertaking for ensuring the quality and reliability of software products [171]. It involves the "*set of activities conducted to facilitate discovery and evaluation of properties of test items*" (i.e., work products to be tested) [73]. The primary goals of software testing are to (i) detect defects, (ii) gather information about a test item, and (iii) create confidence in the correct functioning of the software system. Depending on the type of test item under evaluation, tests can be divided into different levels, such as unit testing, integration testing, and system testing, depending on granularity [73].

Unit testing focuses on testing software units, which are atomic-level software components that can be subjected to standalone testing, isolated from the rest of the system [70]. It is a widely adopted practice because tests are usually simple, fast, and effective in verifying software components at a low level [152]. Integration and system testing focus on higher levels, testing the correct interaction between different components or the observable behaviors of the system. By performing unit testing first, one can then test compound behaviors between different software components to obtain comprehensive tests for complex applications [56]. However, creating tests is a process that requires time and effort. It also requires deep knowledge of the system, experience in designing tests, and programming capabilities.

In this context, test automation and optimization tools are invaluable assets for creating tests quickly and comprehensively, leading to improved software quality and reduced development costs. Consequently, Search-Based Software Testing (SBST) has emerged as a cost-effective approach to address the impracticality of exhaustive manual testing [39].

Various problems are studied within the field of test optimization, which can be primarily classified into test case generation, test case selection, test case prioritization, and test suite minimization. In test generation, the objective is to create test cases that cover all components of the code [39]. Test selection focuses on identifying subsets of test cases that are sufficient to meet certain requirements. Test case prioritization involves ranking test cases to guide the testing process effectively. Finally, test case minimization aims to identify and remove redundant or ineffective test cases.

Although challenges remain, the success of search algorithms is evident in the emergence of SBST tools such as EvoSuite [49], Randoop [133], or TestSpark [155]. These frameworks employ various strategies, including Local Search, Novelty Search, SPEA2, NSGA-II, and GAs in general. Perhaps the most notable example of the success of SBST approaches is Sapienz [111], a tool introduced in 2016 that was later integrated into Facebook's software development process [6]. This integration spurred further interest in SBSE tools [80].

In the context of SBST, unit test generation is one of the most studied problems, leading to a dedicated survey as early as 2004 [114]. The first work on search-based techniques for testing, focused on generating tests that executed different paths within the code, was published in 1976 [116].

To address the test case generation problem, various formulations have been proposed in the literature. In general, the objective is to generate a set of test cases that cover a set of test targets [135]. That is, a set of test cases is a solution, and the best solution is the one that tests all the targets.

Figure 3 presents an example method named "Dominance," which evaluates the dominance relation between two objective vectors in a multi-objective optimization context. Given two vectors (*vector1* and *vector2*) and the number of objectives (n), the method returns the following:

- A negative number (-1) if *vector1* dominates *vector2* ($vector1 \succ vector2$)
- A positive number (1) if *vector2* dominates *vector1* ($vector1 \prec vector2$)
- Or zero (0) if neither dominates the other ($vector1 \not\succ vector2$ and $vector1 \not\prec vector2$)

All objectives are assumed to be minimized. The pseudocode of the method is shown on the left, and the corresponding activity diagram is shown on the right. The line numbers in the pseudocode correspond to the numbers in the activity diagram. As can be observed, different statements are executed depending on the input. If *vector1* dominates *vector2*, then lines 12 and 19 are not executed. If neither vector dominates the other, lines 16–20 are not executed. A possible goal of the test case generation problem might be to generate a set of test cases that execute all lines, with each statement being a test target of the system under testing. Greater coverage

Algorithm 1 Dominance

```
1:  procedure DOMINANCE(vector1, vector2, n)
2:      firstBetter ← false
3:      secondBetter ← false
4:      i ← 0
5:      while i < n do
6:          if vector1[i] < vector2[i] then
7:              firstBetter ← true
8:          else if vector1[i] > vector2[i] then
9:              secondBetter ← true
10:         end if
11:         if firstBetter & secondBetter then
12:             return 0
13:         end if
14:         i ← i + 1
15:     end while
16:     if firstBetter then
17:         return -1
18:     else
19:         return 1
20:     end if
21: end procedure
```

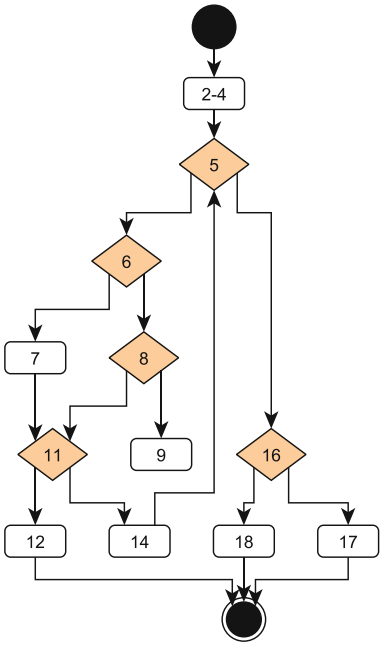

Fig. 3 Pseudocode for identifying dominance relations between two objective vectors (left) and corresponding activity diagram (right). Line numbers in the activity diagram match those in the pseudocode

of targets indicates a better solution. This might be the simplest formulation of the problem. However, depending on the definition of the test targets, other variants can be identified:

- **Branch Coverage**: To reach a given code statement, it is sufficient to execute the branch where that statement is located. Therefore, a natural alternative to statement coverage is to try to generate a set of tests that execute all the conditional statement branches in the code. That is, each branch of the code execution flow represents a different test target. The optimal solution is a set of test cases that covers all branches of the code, therefore achieving complete coverage, since all code statements are executed [135].
- **Mutation Testing**: A test suite without oracles (e.g., assert statements on the outputs of a class under test) merely checks whether some test items are executed [48]. Therefore, they are only sensitive to errors like segmentation faults or runtime exceptions. For most errors, the absence of an automated oracle implies manual review. In this context, mutation testing has received significant attention in the literature. A mutant is a variant of the original artifact that has been modified to mimic real faults. A test suite is said to cover or kill a mutant if the observable state or return values differ between the original artifact and the mutant. If the test leads the mutant to a state that differs from the original artifact, the mutant is said to be weakly killed [48]. If the test case contains an assertion

that evaluates to false when executed on the mutant and true when executed on the original class, the mutant is said to be strongly killed by the test case [48]. The goal is to find a set of test cases that kills all mutants. To guide the search, the objective function also considers distances toward state infection (i.e., a difference in the execution state immediately after the mutated statement) and toward propagation of infection (i.e., the possibility of observing a different state in the execution trace of the statements following the mutated one) [135].

In the aforementioned approaches, the objective functions evaluate the test suite by summing all distances across test cases simultaneously. However, a multi-objective approach may be more suitable in this context. In [135], the authors proposed a many-objective formulation, where the objectives are the individual distances from each test target. The solution is a set of test cases, each evaluated based on the coverage of individual test targets rather than total coverage. This formulation incentivizes the creation of test cases for previously uncovered targets. This generic formulation can then be specialized for branch, statement, or mutation coverage by redefining the set of test targets and the distance measures.

For the many-objective formulation, a method named Dynamic Many-Objective Sorting Algorithm (DynaMOSA) was proposed in 2018 [135]. This method extends the general scheme of evolutionary algorithms by using a preference criterion to rank solutions, prioritizing those closer to uncovered targets. DynaMOSA has become the reference method for the test generation problem and is currently the default algorithm used in the EvoSuite tool [49]. Nevertheless, there is still room for improvement, and open issues remain to be solved. Consequently, researchers continue to work on the test case generation problem and related issues, such as test case prioritization and minimization.

Table 4 presents a chronological summary of works regarding test case generation included in this section, detailing the year of publication (Year), the metaheuristic approaches used (Method(s)), the quality aspects evaluated (Objective Function(s)), and whether a single (Single-objective) or multi-objective (Multi-objective) approach was used. As in most areas of SBSE, the majority of proposals for SBST problems are based on nature-inspired metaheuristics [89]. The most studied frameworks in this context are genetic algorithms (GAs) [15,23,96,103,188]. In addition to GAs, Betts et al. [20] proposed a surrogate-based optimization method focusing on autonomous vehicle software. Others have proposed using a GA-based fuzzing method to find security vulnerabilities in industrial control systems [175] or using genetic programming for test generation [43]. Moreover, some authors have investigated hybridizations of GAs with artificial neural networks [61]. As is often the case, the efficiency of standard GAs, such as NSGA-II, NSGA-III, SPEA2, and IBEA, has also been investigated [52,54,78,113].

In contrast to GAs, some authors have proposed methods based on alternative schemes. For example, some have proposed methods based on ant colony optimization to reduce the test suite of software product lines [21, 22, 157]. Other works have focused on adapting cuckoo search algorithms to software test case generation [4, 159] or firefly algorithms for mutation testing [158, 163] and test case prioritization [86]. Similarly, simulated annealing has been investigated for

generating test suites [57]. Additionally, particle swarm optimization methods [37, 91, 105] and artificial bee colony algorithms [3, 166] have also been studied for test case generation. Ferrer et al. [45] proposed a hybrid matheuristic called *Construct, Merge, Solve & Adapt*, which was compared with four other methods for testing software product lines. Other works have proposed approaches that include differential evolution [154], memetic algorithms [16], or interactive approaches for

SBST problems [39]. Finally, it is worth noting that the large language models have emerged as promising techniques for many code-related tasks, including the generation of code tests, and some authors are already exploring this line of research [2].

As highlighted in this section, SBST is an active area of research and one of the most extensively studied problems by the SBSE community since its inception. Consequently, the introduction provided here only scratches the surface. For more in-depth information on the subject, we refer the reader to the following relevant sources [18, 89, 136, 152, 171].

Software Module Clustering

According to Lehman's laws of software evolution, formulated between 1974 and 1996 [94], software systems often deteriorate over time due to evolving needs and continued changes, becoming prone to errors (Lehman distinguishes programs into three categories: S, P, and E [95]. Lehman's laws of software evolution apply to E-programs, which are written to perform real-world activities, as opposed to S- and P-programs, which are written to perform specific tasks and do not evolve over time). Among the eight laws proposed by Lehman, four are directly related to the importance and necessity of software maintenance to maintain software quality [94]. According to the ISO (https://www.iso.org/home.html), product quality is defined by eight attributes: functional suitability, reliability, performance efficiency, usability, security, compatibility, maintainability, and portability [72]. Among these attributes, maintainability is defined as the "*degree of effectiveness and efficiency with which a product or system can be modified by the intended maintainers*," including corrections, improvements, or adaptations [72].

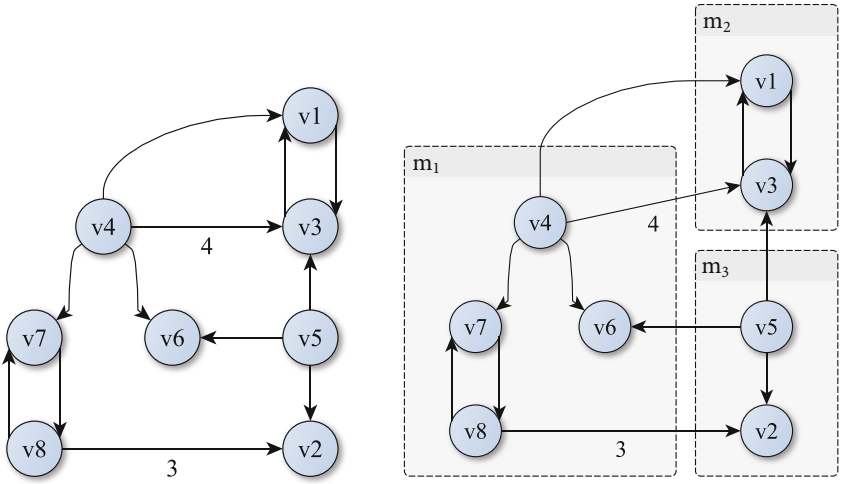
Software maintenance is primarily concerned with providing cost-effective support to a system, ensuring its continued ability to provide services [70]. This support encompasses various corrective, adaptive, perfective, and preventive actions [17]. Despite its critical role, software maintenance is often perceived as a less significant phase, leading to a lack of recognition, motivation, and support [38, 99]. However, it is the most expensive phase of the SDLC, with studies indicating that up to 80% of the total costs are allocated to software maintenance [28]. Notably, a substantial portion of the effort in this phase is dedicated to understanding the existing software [125].

One of the most significant SBSE problems encountered during the software maintenance phase is the Software Modularity Clustering Problem (SMCP). The objective of SMCP is to reorganize a software project to enhance its modularity. According to the ISO, modularity is defined as the set of "*software attributes that provide a structure of highly independent components*" [71]. In an optimal modular structure, components within the same module are strongly related (high cohesion) and weakly connected to components in other modules (low coupling). There are various interpretations of what constitutes a software component, such as a file, a class, or a package. Although the terms "module" and "component"

are sometimes used interchangeably, it is important to note that their definitions are not standardized [71]. In this context, we will use the term "component" to refer to individual elements (files and classes) and "module" to refer to collections of components (packages or folders). Therefore, the primary goal of SMCP is to reorganize the components of a software project into modules to facilitate the understanding of software projects and thereby reduce maintenance costs.

In the context of the SMCP, software projects are typically represented using a graph structure known as a Module Dependency Graph (MDG) [69]. An MDG is a specific type of artifact dependency graph that illustrates the dependencies between components within a graph structure. There are other types of graph that model different aspects of software projects, which are not discussed here [69]. Formally, an MDG is defined as a directed weighted graph, where the vertices correspond to the components of the source code, the edges denote the dependencies between these components, and the weights of the edges indicate the strength of these dependencies.

Figure 4a illustrates the MDG of a hypothetical software project comprising 10 distinct components. Component one, represented by $v1$, has two dependencies (e.g., method calls, inheritance, etc.) on component two, represented by $v2$. Consequently, the edge connecting $v1$ to $v2$ has an associated weight of two. Similarly, component four ($v4$) depends on components one ($v1$), three ($v3$), six ($v6$), and seven ($v7$), among others.



(a) Example MDG with eight vertices.

(b) A possible solution for the MDG of Figure 4a with three modules.

Fig. 4 Example of an MDG (**a**) and a solution for that instance (**b**). Vertices represent the components of the source code, edges represent the dependencies between those components, and weights represent the strength of the dependencies. For the sake of simplicity, only weights with a value greater than one are depicted

Given an MDG, a solution for the SMCP is represented by a clustering of the graph's vertices. Specifically, a solution is a set of non-empty, disjoint subsets of vertices. Figure 4b presents a possible solution for the MDG of Fig. 4a. As illustrated, the components are grouped into three distinct modules: m_1, m_2, and m_3. Specifically, $m_1 = v4, v6, v7, v8$, $m_2 = v1, v2, v3$, and $m_3 = v5, v9, v10$.

In the SMCP, variants exist that differ in how they evaluate the quality of modular organizations. Table 5 provides a chronological summary of articles that study the SMCP. For each work listed, the year of publication, the metaheuristic framework, and the objective function or functions studied are reported. In addition, the table specifies if the problem was studied in a single- (S.O.) or multi-objective (M.O.) approach. As can be observed, the first approach to the SMCP was proposed by Mancoridis et al. in 1998 [108]. These authors introduced the Modularization Quality (MQ) objective function, which calculates the value of modularity as a trade-off between coupling and cohesion. This metric was later extended into two variants to accelerate its computation and improve results: BasicMQ [122] and TurboMQ [118]. As indicated in the table, MQ has become the most widely studied problem in the SMCP literature. However, alternative variants have also been proposed [1, 7, 66, 75, 127, 141, 145].

Furthermore, some authors have proposed multi-objective approaches for the SMCP, which appear to be more suitable in this context [186]. The first to study the SMCP as a multi-objective optimization problem were Praditwong et al. [143], who introduced two approaches: the Maximizing Cluster Approach (MCA) and the Equal-Size Cluster Approach (ECA). Over time, other multi-objective variants have been proposed [68, 77, 123, 149], including extensions of MCA and ECA [30].

Regardless of the metric used to evaluate the quality of solutions, a variety of metaheuristics have been proposed for the SMCP. It is important to note that since the SMCP is proven to be NP-complete [24], exact methods are not suitable except for very small software projects [118]. Instead, approximate search-based metaheuristics are more appropriate [36, 59, 150].

In this context, population-based methods have traditionally been favored in the literature for the SMCP. These include methods based on GAs [42, 79, 104, 107, 127, 143], firefly algorithm [106], estimation of distribution algorithm [77, 167], harmony search [7], multi-agents [66, 67], hyper-heuristics [93], artificial bee colony [8, 30], interactive methods [149], particle swarm optimization [144, 145], and NSGA-III [123].

In contrast, some authors have noted the absence of efficient single-solution metaheuristics such as iterated local search or variable neighborhood descent in the literature [150]. To address this gap, several trajectory-based metaheuristics have been proposed as effective alternatives to traditional population-based approaches, achieving competitive results. Early proposals in this area were based on hill climbing [84, 104, 108, 109, 119, 122] or simulated annealing [1, 120, 121]. More recently, algorithms based on metaheuristics such as large neighborhood search [126], variable neighborhood search [184, 185], multi-objective variable neighborhood search [183, 186], and greedy randomized adaptive search procedure combined with variable neighborhood descent [182] have been proposed.

Table 5 Chronological summary of proposals for the SMCP.
Acronym key (alphabetically sorted) · **Method:** Estimation of Distribution Algorithms (EDA); Evolutionary Call-Dependency Graph Modularization (E-CDGM); Firefly Algorithm (FA); General Variable Neighborhood Search (GVNS); Genetic Algorithm (GA); Graph-Based Modularization Algorithm (GMA); Greedy Randomized Adaptive Search Procedure (GRASP); Grid-Based Large-Scale Many-Objective PSO (GLMPSO); Harmony Search (HS); Hill Climbing (HC); HC based on semantic dependency graph (HCS); Hybrid GA (HGA); Harmony Search (HS); Imperialist Competitive Algorithm (ICA); Interactive Evolutionary Approach (IEA); Iterated Local Search (ILS); Large Neighborhood Search (LNS); Many-Objective ABC (MaABC); Multi-Agent Evolutionary Algorithm (MAEA); Multi-Objective Hyper-Heuristic Evolutionary Algorithm (MHypEA); Next Ascent HC (NAHC); Non-Dominated Sorting Genetic Algorithm III (NSGA-III); Pareto Envelop-Based Selection Algorithm (PESA); Particle Swarm Optimization (PSO); Simulated Annealing (SA); Steepest Ascent HC (SAHC); Two-Archive ABC (TA-ABC); Variable Neighborhood Descent (VND). · **Objective function(s):** Cohesion, Coupling, Package Count index, and package Size index (CCCS); Dependency Quality and Connection Quality (DQCQ); Entropy-Based Objective Function (EOF); Equal-Size Cluster Approach (ECA); Extended ECA (E-ECA); Extended MCA (E-MCA); Function of Complexity Balance (FCB); Interactive Fitness Function (IFF); Linear Compound Criteria (LCC); Maximizing Cluster Approach (MCA); Modularization Quality (MQ); MQ, Non-Extreme Distribution, Coupling, and Cohesion (MQNCC); Multifactor Module Clustering (MFMC); Multi-Objective Fitness Function (MOF); Similarity-Based MQ (SM); Structure of packages, Semantics coherence, and History of changes (SSH)

As can be observed, software maintenance is a phase that demands significant effort to uphold high-quality code and provide effective support. The SMCP is an actively researched problem, with ongoing advancements needed to integrate the proposed approaches into industry workflows. For further information on this area, we refer the reader to relevant sources [150, 186].

Conclusion

Software is a critical asset for the proper functioning of modern societies. High-quality software leads to efficient processes, user satisfaction, and reduced economic costs. However, software development is inherently complex, making software engineering an essential discipline. Given the importance of software engineering and the complexity of the tasks involved in any software development process, optimizing these tasks is highly desirable. Search-Based Software Engineering (SBSE) is a research area that formulates software engineering tasks as optimization problems and designs and implements optimization techniques to solve them. Due to the complexity of the tasks and the vast number of potential solutions in real-world software projects, heuristic procedures are considered the most promising approaches.

In this chapter, we have reviewed four families of the most widely studied optimization problems in the area: software project scheduling, optimized feature selection, test case generation, and software module clustering. However, SBSE encompasses many problems that are actively studied across all phases of the software development life cycle. Therefore, the aforementioned families represent

only a subset of the research field. Although the field is rapidly maturing, many open issues and challenges remain to be investigated. The practical nature of the problems studied in SBSE offers a complex yet appealing scenario for the study of optimization techniques. Specifically, SBSE problems provide a suitable context for exploring multi- or many-objective optimization techniques to address conflicting quality metrics or objectives. Additionally, interactive approaches that involve software developers in the optimization process offer promising directions.

Finally, as highlighted in this chapter, most heuristic approaches in this area are based on nature-inspired metaheuristics, such as genetic algorithms, ant colony optimization methods, and artificial bee colony algorithms. Recent advances have also been made using trajectory-based metaheuristics, such as the greedy randomized adaptive search procedure and variable neighborhood search. While these metaheuristic frameworks show promise for the problems at hand, further work is needed, particularly in multi- or many-objective contexts.

Abstract

This chapter overviews some string selection and comparison problems, with special emphasis on the optimization and operational research perspective. It also proposes a simple and efficient ILP-based heuristic that can be used for any of the considered problems.

Introduction to String Problems

Among string selection and comparison problems, there is a class of problems known as *string consensus*, where a finite set of strings is given and one is interested in finding their consensus, i.e., a new string that agrees as much as possible with all the given strings. In other words, the objective is to determine a string, called consensus, because it represents—in some way—all the given strings. The idea of representation and of being in consensus can be related to several different objectives listed in the following:

i. The consensus is a new string whose total distance from all given strings is minimum (*closest string problem*).
ii. The consensus is a new string close to most of the given strings (*close to most string problem*).
iii. The consensus is a new string whose total distance from all given strings is maximum (*farthest string problem*).
iv. The consensus is a new string far from most of the given strings (*far from most string problem*).

Computational intractability of the general string consensus problem was first proved in 1997 by Frances and Litman [10] and in 1999 by Sim and Park [34].

As a constring of the linear coding of DNA and proteins, many molecular biology problems have been formulated as computational optimization problems involving strings and strings. Biological applications of computing distance/proximity among strings occur mainly in two varieties. Some require that a region of similarity be discovered, while other applications use the reverse complement of the region, such as designing probes or primers. In the following, some relevant biological applications are outlined.

Creating Diagnostic Probes for Bacterial Infections

Probes are strands of either DNA or RNA that have been modified (i.e., made either radioactive or fluorescent) so that their presence can be easily detected. One possible application of string problems arises in creating diagnostic probes for bacterial infections [18, 25]. In this scenario, given a set of DNA strings from a group of closely related pathogenic bacteria, the task is to find a substring that occurs in each of the bacterial strings (as close as possible) without occurring in the host's DNA.

Probes are then designed to hybridize to these target strings, so that the detection of their presence indicates that at least one bacterial species is likely to be present in the host.

Primer Design

Primers are short strings of nucleotides designed such that they hybridize to a given DNA string or to all of a given set of DNA strings with the aim of providing a starting point for DNA strand synthesis by polymerase chain reaction (PCR). The hybridization of primers depends on several conditions, including some thermodynamic rules, but it is largely influenced by the number of mismatching positions among the given strings, and this number should be as small as possible [12, 13, 21].

Discovering Potential Drug Targets

Another biological application of string selection and comparison problems is related to discovering potential drug targets. Given a set of strings of orthologous genes from a group of closely related pathogens and a host (such as a human, crop, or livestock), the goal is to find a string fragment that is more conserved in all or most of the pathogens' strings but not as conserved in the host. The information encoded by this fragment can then be used for novel antibiotic development or to create a drug that harms several pathogens with minimal effect on the host. All these applications reduce to the task of finding a pattern that, with some error, occurs in one set of strings (closest string problem) and/or does not occur in another set (farthest string problem). The far from most string problem can help to identify a string fragment that distinguishes the pathogens from the host, so the potential exists to create a drug that harms several but not all pathogens [12, 13, 21].

Motif Search

A motif is a string that occurs *approximately preserved* as a substring in some/-several of the DNA strings of a given set. Approximately preserved means that the motif occurs with changes in at most t positions for a fixed nonnegative integer t. The importance of a motif lies in its characteristic of being a candidate for substrings of noncoding parts of the DNA string that have functions related to, e.g., gene expression [12, 13].

For most consensus problems, Hamming distance is used instead of other alternative measures, such as, for example, the editing distance. The biological reasons justifying this choice are very well described and motivated by Lanctot et al. in [18–20] and can be summarized claiming that the "edit distance is more suitable

to measure the *amount* of change that has happened, whereas the Hamming distance is more suitable to measure the *effect* of that change."

The remainder of this chapter is organized as follows. The next section lists notation and definitions used throughout the chapter. The following four sections are devoted to the closest string, the close to most string, the farthest string, and the far from most string problem, respectively. All these problems are mathematically formulated and their properties are analyzed. The most popular solution techniques for them are surveyed, along with the computational results obtained and analyzed in the literature. The second last section reports computational results that demonstrate empirically the efficiency of the state-of-the-art algorithms. Concluding remarks and future directions are discussed in the last section.

Notation

Throughout this chapter, the following notation and definitions will be used.

- An *alphabet* $\Sigma = \{c_1, c_2, \ldots, c_k\}$ is a finite set of elements, called *characters*.
- $s^i = (s^i_1, s^i_2, \ldots, s^i_m)$ denotes a string of m characters (that is, of length m) over alphabet Σ, i.e., $s^i_j \in \Sigma,\ j = 1, 2, \ldots, m$.
- Given two strings s^i and s^l on Σ such that $|s^i| = |s^l|$, $d_H(s^i, s^l)$ denotes their Hamming distance and is given by

$$d_H(s^i, s^l) = \sum_{j=1}^{|s^i|} \Phi(s^i_j, s^l_j), \tag{1}$$

  where s^i_j and s^l_j denote the character at position j in string s^i and in string s^l, respectively, and $\Phi : \Sigma \times \Sigma \to \{0, 1\}$ is a predicate function such that

$$\Phi(a, b) = \begin{cases} 0, \text{ if } a = b; \\ 1, \text{ otherwise.} \end{cases}$$

- For all consensus problems, each string s of length m over Σ is a valid solution.

The Closest String Problem (CSP)

Given a finite set of strings Ω on Σ, the problem is to find a *center string* $s^* \in \Sigma^m$ such that the Hamming distance between s^* and all strings in Ω is minimal; in other words, s^* is a string to which a minimal value d corresponds such that

$$d_H(s^*, s^i) \leq d, \quad \forall\, s^i \in \Omega.$$

The closest string problem can be formulated as an integer linear program (ILP). In fact, let $\Sigma_k \subseteq \Sigma$ be the set of characters appearing at position k in any of the strings from Ω.

For each $k = 1, 2, \ldots, m$ and $j \in V_k$, let us define the following binary variables:

$$x_{ck} = \begin{cases} 1, & \text{if character } c \in \Sigma_k \text{ is used at position } k \text{ of the solution;} \\ 0, & \text{otherwise.} \end{cases}$$

Then, the CSP admits the following ILP formulation:

$$\min d \tag{2}$$

subject to:

$$\sum_{c \in \Sigma_k} x_{ck} = 1 \quad \text{for } k = 1, 2 \ldots, m \tag{3}$$

$$m - \sum_{k=1}^{m} x_{s_k^i k} \leq d \quad \text{for } i = 1, 2 \ldots, n \tag{4}$$

$$d \in \mathbb{N}^+, \tag{5}$$

$$x_{ck} \in \{0, 1\}, \qquad \text{for } k = 1, 2, \ldots, m, \ \forall\, c \in \Sigma_k. \tag{6}$$

Equalities (3) guarantee that only one character is selected for each position $k \in \{1, 2, \ldots, m\}$. Inequalities (4) impose that, if a character in a string s^i is not in the solution defined by the x-variables, then that character will contribute to increasing the Hamming distance from solution x to s^i. Finally, (5) forces d to assume a nonnegative integer value and (6) define the decision variables.

This problem was first studied in the area of coding theory [33] and has been independently proved computationally intractable in [10] and in [19, 20].

In 2004, Meneses et al. [31] used a linear relaxation of the above-described mathematical model to design a branch and bound algorithm. At each iteration, the next node in the branching tree to be explored is the one with the smallest linear relaxation objective function value (also known as the *best bound first strategy*). Once the next node is selected and an optimal fractional solution $x'_{ck} \in [0, 1]$ obtained, $k = 1, \ldots, m$, $\forall\, c \in \Sigma_k$, for the linear relaxation of the corresponding subproblem, the algorithm branches on the fractional variable x_{ck} with maximum value of x'_{ck}. The bounding phase is very important in any branch and bound algorithm: the better the computed bound, the smaller the number of nodes that need to be explored and that can therefore be pruned. For the bounding phase, Meneses et al. computed an initial bound selecting one of the given input strings and modifying it until a local optimal solution is found. The authors have empirically shown that their branch and bound algorithm is able to solve in reasonable running times small-size instances with 10–30 strings each of which is 300–800 characters long.

Further exact methods proposed for the CSP are fixed-parameter algorithms [14, 24, 36] that are applicable only when the maximum Hamming distance among all pairs of strings is small. In fact, since these algorithms are designed to solve the decision version of the problem, it is necessary to apply them multiple times in order to find an optimal solution that minimizes the Hamming distance.

The first approximation algorithm for the CSP was proposed in [20] with a worst-case performance ratio of 2. It is a simple algorithm that constructs an approximate feasible solution in a purely random fashion. Starting from an empty solution, the algorithm randomly selects the next element to be added to the solution under construction.

Better performance approximation algorithms proposed in the literature are based on the linear programming relaxation of the previously described ILP model. The basic idea consists of solving the linear programming relaxation of the ILP model and using the result of the relaxed problem to find an approximate solution to the original problem. Following this line, [20] also proposed a $\frac{4}{3}(1+\epsilon)$-approximation algorithm (for any small $\epsilon > 0$) that uses the randomized rounding technique for obtaining an integer 0-1 solution from the continuous solution for the relaxed problem. The randomized rounding technique works by defining the value of a Boolean variable $x \in \{0, 1\}$ to be $x = 1$ with a certain probability y, where y is the value of the continuous variable corresponding to x in the relaxation of the original integer programming problem. In 1999, [21] used the rounding idea to design a polynomial time approximation scheme (PTAS). A PTAS is a special type of approximation algorithm that, for each $\epsilon > 1$, yields a performance guarantee of ϵ in polynomial time. Thus, this can be viewed as a way of getting solutions with guaranteed performance for any desired threshold greater than one. The PTAS proposed in [21] is also based on randomized rounding, which is refined to check results for a large (but polynomially bounded) number of subsets of indices. However, since many iterations involve the solution of a linear relaxation of an ILP model, the algorithm becomes impractical for any instance with large strings. To efficiently deal with real-world scenarios and/or medium- to large-size problem instances, several heuristic and metaheuristic algorithms have been proposed in the last few years.

In 2005, [22] designed a genetic algorithm and a simulated annealing algorithm, both in their sequential and their parallel versions. Genetic algorithms (GAs) are population-based metaheuristics that have been applied to find optimal or near-optimal solutions to combinatorial optimization problems [11, 16]. They implement the concept of *survival of the fittest*, making an analogy between a solution and an *individual* in a *population*. Each individual has a corresponding *chromosome* that encodes the solution. A chromosome consists of a string of *genes*. Each gene can take on a value, called an *allele*, from some alphabet. A chromosome has an associated *fitness level* which is correlated to the corresponding objective function value of the solution it encodes. Over a number of iterations, called *generations*, GAs evolve a population of chromosomes. This is usually accomplished by simulating the process of natural selection through mating and mutation. For the CSP, starting from an initial randomly generated population, at each generation $0 \leq t \leq \texttt{number} - \texttt{generations}$ of the Liu et al.'s GA, a population $P(t)$ of

popsize strings of length m is evolved and the fitness function to be maximized is defined as the difference $m - d_{\max}$, where $d_{\max}$ is the largest Hamming distance between an individual of the population $P(t)$ and any string in Ω. The production of offspring in a GA is done through the process of mating or crossover and Liu et al. used a multipoint crossover (MPX). In more detail, at a generic generation t, two parental individuals x and y in $P(t)$ are randomly chosen according to a probability that is proportional to their fitness. Then, iteratively until the offspring is not complete, x and y exchange parts between two randomly picked points. The resulting offspring have a new order of the strings, one part from the *first parent* and the other part from the *second parent*. Afterward, a mutation of any individual in the current population $P(t)$ is executed with some given probability. During this phase, two positions are randomly chosen and exchanged in the individual.

In their paper, Liu et al. proposed also a simulated annealing (SA) algorithm for the CSP. Originally proposed in [17], in the optimization and computer science research communities, simulated annealing is commonly said to be the "oldest" among the metaheuristics and surely one of the first techniques that had an explicit strategy to escape from local minima. Its fundamental idea is to allow moves resulting in solutions of worse quality in terms of objective function value than the current solution (uphill moves) in order to escape from local minima. The origin of simulated annealing and the choice of the acceptance criterion of a better quality solution lies in the physical annealing process, which can be modeled by methods based on Monte Carlo techniques. One of the early Monte Carlo techniques for simulating the evolution of a solid in a heat bath to thermal equilibrium is due to [28], who in 1953 designed a method that iteratively (until a stopping criterion is met) generates a string of states of the solid in the following way. At a generic iteration k, given a current state i of the solid (i.e., a current solution x):

- E_i is the energy of the solid in state i (objective function value $f(x)$).
- A subsequent state j (solution $\overline{x}$) is generated with energy E_j (objective function value $f(\overline{x})$) by applying a *perturbation mechanism* such as displacement of a single particle ($\overline{x}$ is a solution "close" to x).
- If $E_j - E_i < 0$ (i.e., $\overline{x}$ is a better quality solution), j ($\overline{x}$) is accepted; otherwise, j ($\overline{x}$) is accepted with a probability given by

$$\exp\left(-\frac{E_j - E_i}{k_B T_k}\right) \qquad \left[\exp\left(-\frac{f(\overline{x}) - f(x)}{k_B \cdot T_k}\right)\right],$$

  where T_k is the heat bath temperature and k_B is the Boltzmann constant.

As the number of performed iterations increases, the current temperature T_k is decreased resulting in a smaller probability of accepting not improving solutions. For the CSP, Liu et al.'s SA sets the initial temperature T_0 to $\frac{m}{2}$. The current temperature T_k is reduced every 100 iterations according to the "geometric cooling schedule," that is, $T_{k+100} = \gamma \cdot T_k$, where $\gamma = 0.9$. The stopping criterion is to reach a current temperature less than or equal to 0.001. Despite the interesting ideas

proposed in [22], the experimental analysis involves only small instances with up to 40 strings of length 40.

For the special case of $|\Omega| = 3$ and $|\Sigma| = 2$, [23] designed an exact approach called distance first algorithm (DFA), whose basic idea is to let the Hamming distance $d_H(s^*, s^i)$, $i = 1, 2, 3$, be as close as possible. The algorithm decreases the distance between the string that is farthest from the other two strings and solution s^* while increasing the distance between the string that is closest to the other two strings and solution s^*. For the general case, the authors proposed a polynomial-time heuristic resulting from a combination of local search strategies inspired by [31] and an approximation algorithm called largest distance decreasing algorithm (LDDA), which is based on similar ideas as DFA.

More recently, [35] proposed a novel heuristic (TA) based on the Lagrangian relaxation of the ILP model of the problem that allows the decomposition of the problem into subproblems, each corresponding to a position of the strings. The proposed algorithm combines a Lagrangian multiplier adjustment procedure to obtain feasibility and a tabu search as a local improvement procedure. In [6], Della Croce and Salassa described three relaxation-based procedures. One procedure (RA) rounds up the result of continuous relaxation, while the other two approaches (BCPA and ECPA) fix a subset of the integer variables in the continuous solution at the current value and let the solver run on the remaining (sub)problem. The authors also observed that all relaxation-based algorithms have been tested on *rectangular instances*, i.e., with $n \ll m$, and that the instances such that $n \geq m$ are harder to solve due to the higher number of constraints imposed by the strings, which enlarges the portion of non-integer components in the continuous solution of the problem. In an attempt to overcome this drawback, [5] designed a multi-start relaxation-based algorithm (called the selective fixing algorithm) that for a predetermined number of iterations takes a feasible solution as input and iteratively selects variables to be fixed at their initial value until the number of free variables is small enough that the remaining subproblem can be efficiently solved to optimality by an ILP solver. The new solution found by the solver can then be used as the initial solution for the next iteration. The authors have experimentally shown that their algorithm is much more robust compared to the state-of-the-art competitors and can solve a wider set of instances of different types, including those with $n \geq m$.

Xu and Perkins [37] proposed a WFC-CSP, a novel heuristic algorithm inspired by wave function collapse (WFC) techniques to solve the CSP. WFC is a constraint-based algorithm that was developed by game developer Maxim Gumin in [15] for procedural content generation. As summarized by [30], "the key idea is an extension of standard constraint solvers with a minimal entropy heuristic that randomly directs the solver's search in a way that follows a user-specified frequency distribution without compromising the efficiency of the search procedure." In case that a conflict is reached, Gumin's algorithm globally restarts instead of backtracking locally. Experimental results conducted by [37] show that WFC-CSP efficiently solved small-sized and large-sized CSP instances across different configurations.

The Close to Most String Problem (CTMSP)

The closest string problem can be seen as a special case of the so-called close to most string problem (CTMSP), which consists in determining a string close to most of the strings in the input set Ω. This can be formalized by saying that, given a threshold t, a string s^* must be found maximizing the variable l such that

$$d_H(s^*, s^i) \leq t, \text{ for } s^i \in P \subseteq \Sigma \text{ and } |P| = l.$$

$$\textbf{max} \sum_{i=1}^{n} y_i \tag{7}$$

subject to:

$$\sum_{c \in \Sigma} x_{ck} = 1 \quad \text{for } k = 1, \ldots, m \tag{8}$$

$$\sum_{k=1}^{m} x_{s_k^i k} \geq m \cdot y_i - t \quad \text{for } i = 1, \ldots, n \tag{9}$$

$$x_{ck}, y_i \in \{0, 1\}$$

Constraints (8) ensure that for each position k of a possible solution exactly one character from Σ_k is chosen. Constraints (9) ensure that y_i can only be set to 1 if and only if the number of differences between $s^i \in \Omega$ and the possible solution (as defined by the setting of the variables x_{ck}) is less or equal than t. Remember, in this context, that s_k^i denotes the character at position k in $s^i \in \Omega$.

Despite its similarity with the CSP, the CTMSP has not been widely studied. In [4] it was proved that this problem has no polynomial-time approximation scheme (**PTAS**) unless **NP** has randomized polynomial-time algorithms.

The Farthest String Problem (FSP)

Given a finite set of strings Ω over alphabet Σ, a problem complementary to the CSP is that of finding a string $s^* \in \Sigma^m$ farthest from the strings in Ω. This type of problem can be useful in situations such as finding a genetic string that cannot be associated with a given number of species.

Like the CSP, the farthest string problem can be formulated mathematically in the form of an ILP, where both decision variables and constraints have an interpretation which is contrary to the one in the CSP:

$$\max d \tag{10}$$

subject to:

$$\sum_{c \in \Sigma_k} x_{ck} = 1 \quad \text{for } k = 1, 2 \ldots, m \tag{11}$$

$$m - \sum_{k=1}^{m} x_{s_k^i k} \geq d \quad \text{for } i = 1, 2 \ldots, n \tag{12}$$

$$d \in \mathbb{N}^+, \tag{13}$$

$$x_{ck} \in \{0, 1\}, \qquad \text{for } k = 1, 2, \ldots, m, \ \forall\, c \in \Sigma_k. \tag{14}$$

The computational intractability of the FSP was demonstrated in [20], where it was proved that the problem remains intractable even for the simplest case where the alphabet has only two characters.

Despite its inherent computational intractability, it has be shown in [20] that there is a PTAS for the FSP. The algorithm is based on the randomized rounding of the relaxed solution of the above-reported ILP and uses the randomized rounding technique together with probabilistic inequalities to determine the maximum error possible in the solution computed by the algorithm. Note that the mathematical formulation of FSP is quite similar to the one used for the CSP, with only a change in the optimization objective and the inequality sign in the constraint

$$m - \sum_{j=1}^{m} x_{s_j^i j} \geq d, \qquad i = 1, 2, \ldots, n.$$

Thus, to solve the problem using an ILP formulation, one can use similar techniques to those employed for solving the CSP. In 2011 [38] and more recently in 2015 [39] proposed a few integer programming models for some variants of the farthest string problem and the closest string problem. The number of variables and constraints is substantially less compared with state-of-the-art integer linear programming models and the solution of the linear programming relaxation contains only a small proportion of noninteger values, which considerably simplifies both a subsequent rounding process and a branch and bound procedure.

The Far from Most String Problem (FFMSP)

A problem closely related to the farthest string problem is the far from most string problem (FFMSP). It consists in determining a string far from most of the strings in the input set Ω. This can be formalized by saying that, given a threshold t, a string s^* must be found maximizing the variable l such that

$$d_H(s^*, s^i) \geq t, \text{ for } s^i \in P \subseteq \Sigma \text{ and } |P| = l.$$

In [1], the FFMSP has been mathematically formulated as an ILP. In fact, by defining a Boolean variable x_{ck} for each position k ($k = 1, 2 \ldots, m$) of a possible solution and for each character $c \in \Sigma_k$ and a Boolean variable y_i ($i = 1, 2 \ldots, n$) for each of the n input strings provided in set Ω, the FFMSP can stated as the following ILP:

$$\textbf{max} \sum_{i=1}^{n} y_i \tag{15}$$

subject to:

$$\sum_{c \in \Sigma_k} x_{ck} = 1 \quad \text{for } k = 1, 2 \ldots, m \tag{16}$$

$$\sum_{k=1}^{m} x_{s_k^i k} \leq m - t \cdot y_i \quad \text{for } i = 1, 2 \ldots, n \tag{17}$$

$$x_{ck}, y_i \in \{0, 1\}$$

Constraints (16) ensure that for each position k of a possible solution exactly one character from Σ_k is chosen. Constraints (17) ensure that y_i can only be set to 1 if and only if the number of differences between $s^i \in \Omega$ and the possible solution (as defined by the setting of the variables x_{ck}) is greater or equal than t. Remember, in this context, that s_k^i denotes the character at position k in $s^i \in \Omega$.

Despite the similarity, it can be shown [20] that the FFMSP is much harder to approximate than the FSP, due to the approximation preserving reduction to FFMSP from the independent set problem, a classical and computationally intractable combinatorial optimization problem. In particular, [20] demonstrated that for strings over an alphabet Σ with $|\Sigma| \geq 3$, approximating the FFMSP within a polynomial factor is **NP**-hard.

The first attempt in the direction of the design of heuristic methods to efficiently solve the FFMSP was done in [26, 27], who proposed a heuristic algorithm consisting of a simple greedy construction followed by an iterative improvement phase. Later, [9] designed a simple GRASP, recently improved in [29]. Mousavi et al. noticed that the search landscape of the FFMSP is characterized by many solutions having the same objective value. Consequently, local search is likely to visit many sub-optimal local maxima. To efficiently escape from these local maxima, Mousavi et al. devised a new hybrid heuristic evaluation function and used it in conjunction with the objective function when evaluating neighbor solutions during the local search phase in the GRASP framework.

Ferone et al. [7, 8] designed the following pure and hybrid multi-start iterative heuristics:

- A pure GRASP, inspired by [9]
- A GRASP that uses forward path-relinking for intensification
- A pure VNS
- A VNS that uses forward path-relinking for intensification
- A GRASP that uses VNS to implement the local search phase
- A GRASP that uses VNS to implement the local search phase and forward path-relinking for intensification.

The algorithms were tested on several random instances and the results showed that the hybrid GRASP with VNS and forward path-relinking always found much better quality solutions compared with the other algorithms, but clearly with higher running times as compared to the pure GRASP and the hybrid GRASP with forward path-relinking. The best objective function values found by GRASP and its hybrids were when the construction phase was more greedy than random. The integration of forward path-relinking as an intensification procedure in the pure metaheuristics was beneficial in terms of solution quality. A further investigation, studying the empirical distributions of the random variable *time-to-target-solution-value*, revealed that, given any fixed amount of computing time, GRASP with forward path-relinking has an empirically higher probability than all competitors of finding a target solution.

In [1], besides the first linear integer programming formulation for the FFMSP described above (15)–(17), a hybrid ant colony optimization approach has been proposed. This hybrid approach consists of two phases. A first phase applies ant colony optimization until the convergence of the pheromone values is reached. After this first phase, the algorithm possibly applies a second phase in which the hybridization with a mathematical programming solver takes place. Both the linear integer programming formulation and the hybrid ant colony algorithm have been compared to the most performing hybrid GRASP with path-relinking and computational results on a large set of randomly generated test instances have indicated that the hybrid ACO is very competitive.

Blum and Pinacho-Davidson [2] proposed the application of a recently introduced version of ant colony optimization—negative learning ant colony optimization—to the FFMSP. The proposed algorithm makes use of negative learning in addition to the standard positive learning mechanism in order to achieve better guidance for the exploration of the search space. The outcomes of the experimental experience showed that this new algorithm is especially successful for instances with specific characteristics and that none of the existing state-of-the-art methods is best for all problem instances. What achieves excellent performance on average on each type of instance is an algorithm afterwards designed by [32]. Here, the authors proposed a LEARN_CMSA, i.e., a hybrid method that combines a population-based algorithm with a CMSA (construct, merge, solve, and adapt). CMSA in its pure version does not make use of any explicit learning mechanism. Instead, in LEARN_CMSA explicit learning has been introduced to CMSA, so achieving superior performance when compared to current state-of-the-art solvers.

A Simple ILP-Based Heuristic

In the following, we present the results of a quite simple ILP-based heuristic that can be applied to all four problems described before: the closest string problem (CSP), the close to most string problem (CTMSP), the farthest string problem (FSP), and the far from most string problem (FFMSP). The heuristic is based on the ILP models of the four problems. It works as follows. Given a fixed computation time limit (t_{limit}), maximally half of this computation time is given to an ILP solver for tackling the mixed integer linear problem (MILP) that is obtained by relaxing the x_{ck}-variables involved in all four ILP models. The used ILP solver returns the best solution found in the given computation time. Note that this solution may or may not correspond to the optimal MILP solution. The fractional values of the x_{ck}-variables after termination of the solver are henceforth denoted by x'_{ck}. In the second phase of the heuristic, the corresponding ILP models are solved in the remaining computation time, with the following additional constraints:

$$x_{ck} = 1 \quad \text{for } k = 1, \ldots, m, \; c \in \Sigma_k, \; x'_{ck} = 1. \tag{18}$$

In other words, whenever a variable x_{ck} in the best-found MILP solution has a value of 1, this value is fixed for the solution of the ILP model.

Experimental Evaluation

In the case of all four problems, the heuristic described above is compared with the application of the ILP solver to the original ILP models. Moreover, a simple greedy algorithm was applied. This greedy algorithm generates a solution by selecting for each position of the solution string the letter which, in the case of the CSP and the CTMSP, has the least number of appearances at this position in the set of input strings and which, in the case of the FSP and the FFMSP, has the highest number of appearances at this position in the set of input strings. The greedy algorithm is henceforth denoted by GREEDY. As (M)ILP solver, we used IBM ILOG CPLEX V22.1. The experimental results were obtained on a high-performance computing cluster equipped with machines with Intel® Xeon® 5670 CPUs having 12 cores of 2.933 GHz and at least 32 GB of RAM. Moreover, CPLEX was configured for single-threaded execution. Depending on the problems, we used two different computation time limits: $t_{\text{limit}} = 200\,\text{s}$ and $t_{\text{limit}} = 3600\,\text{s}$ per problem instance. The different applications of CPLEX, respectively the ILP-based heuristic, are named accordingly: CPLEX-200, CPLEX-3600, HEURISTIC-200, and HEURISTIC-3600.

All the algorithms described above were applied, in the context of all four problems, to a set of benchmark instances that was originally introduced in [7] for the FFMSP. This set consists of random instances of different sizes. More specifically, the number of input strings (n) is in {100, 200}, and the length of the

input strings (m) is in $\{300, 600, 800\}$. In all cases, the alphabet size is four, that is, $|\Sigma| = 4$. For each combination of n and m, the set consists of 100 random instances. This makes a total of 600 instances. Note that, in the context of the CTMSP and the FFMSP, a value for parameter t must be specified before running the algorithm(s). However, a sensible choice of t is not trivial. For example, in the context of the CTMSP, the lower the value of t, the easier it should be, for example, for CPLEX to solve the problem to optimality. To be able to choose meaningful values for t, the following experiments were executed. In the case of the CTMSP, CPLEX was applied to each problem instance with a CPU time limit of 3600 s for each value of $t \in \{0.6, 0.61, \ldots, 0.79, 0.8\,\text{m}\}$. In the case of the FFMSP, CPLEX was applied to each problem instance with a CPU time limit of 3600 s for each value of $t \in \{0.7, 0.71, \ldots, 0.89, 0.9\,\text{m}\}$. The corresponding optimality gaps (averaged over 100 problem instances) and the number of instances (out of 100) that were solved to optimality are graphically presented in Fig. 1. The results reveal that, in the case of the CTMSP, the problem becomes difficult for approx. $t \leq 0.72$ m. In the case of the FFMSP, the problem becomes difficult for approx. $t \geq 0.78$ m. Therefore, the following values for t were chosen for the final experimental evaluation: $t \in \{0.65, 0.7, 0.75\,\text{m}\}$ in the case of the CTMSP and $t \in \{0.75, 0.8, 0.85\,\text{m}\}$ in the case of the FFMSP.

The numerical results for the CSP are shown in Table 1. They are presented as averages over the 100 instances for each combination of n (the number of input strings) and m (the length of the input strings). For all three algorithms we provide the values of the best found solutions (averaged over 100 problem instances) and the computation time at which these solutions were found. In the case of CPLEX-200 the average optimality gap is additionally provided. The results show that HEURISTIC-200 significantly outperforms GREEDY and—with the exception of case ($n = 200, m = 800$)—produces slightly better results than CPLEX-200. Similar observations can be made concerning the results for the FSP provided in Table 2.

In the case of the CTMSP, both the ILP-based heuristic and CPLEX were applied with computation time limits of 200 and 3600 CPU seconds. Therefore, Table 3 contains results for HEURISTIC-200, HEURISTIC-3600, CPLEX-200, and CPLEX-3600. The following observations can be made:

Table 1 Numerical results for the CSP

		GREEDY		HEURISTIC-200		CPLEX-200

- Both CPLEX and the ILP-based heuristic greatly outperform GREEDY.
- When the problem is rather easy—that is, for a setting of $t = 0.75$ m—CPLEX has usually slight advantages over the ILP-based heuristic. This is the case especially for the instances with a larger number of input strings ($n = 200$).
- With growing problem difficulty, the ILP-based heuristic starts to outperform CPLEX. In particular, for a setting of $t = 0.65$ m, the differences in the qualities of the obtained solutions between the ILP-based heuristic and CPLEX are significant.

Not surprisingly, the same observations can be made in the context of the FFMSP, for which the results are provided in Table 4. As the considered benchmark instances were originally used for the FFMSP, we are able to compare them to current state-of-the-art results for this problem (see [3]). This comparison is graphically presented in Fig. 2 for all instances concerning the interesting cases $t = 0.8$ m and $t = 0.85$ m. The results show that, for $t = 0.8$ m, HEURISTIC-3600 is generally outperformed by the other state-of-the-art methods, especially for what concerns ACO_NEG. However, note that when the instance size (in terms of the number of input strings and their length) grows, HEURISTIC-3600 starts to produce better results than some of the competitors. In the case of $t = 0.85$ m, which results in more difficult instances than $t = 0.8$ m, HEURISTIC-3600 is clearly able to compete with the current state-of-the-art methods.

Conclusions

The goal of this chapter was to provide an overview of some string selection and comparison problems, with special emphasis on the optimization and operational research perspective. Besides mathematical models that can be used to find exact solutions only up to a certain instance size, there are many approximate techniques, proposed by researchers from several heterogenous communities, which are more or less efficient, depending on the input data and the type of information they make use of. Not surprisingly, generally there is no single best approach that wins in every

aspect. Therefore, we proposed a simple ILP-based heuristic that can be used for any of the four considered problems. We have shown that this heuristic outperforms both a general greedy algorithm and the application of an ILP-solver (CPLEX) to the original ILP models. In the case of the far from most string problem, we were even able to show that this simple heuristic is able to produce state-of-the-art results for instances that are intrinsically difficult to solve.

Abstract

Vehicle routing problems (VRPs) are challenging combinatorial optimization problems that, given their significant impact on distribution logistics, continue to attract considerable research efforts to develop efficient and effective solution

methods. As the instance size grows, the combinatorial nature of these problems makes traditional approaches unable to find adequate solutions within a reasonable computing time. Large problem instances typically require the use of specialized scalability techniques that, coupled with the raw computing power of modern machines, make their heuristic resolution possible. This chapter reviews some of the most effective techniques for designing heuristics for large-scale VRPs.

Keywords

Vehicle routing problems · Large-scale instances · Scalability techniques · Heuristics

Introduction

Vehicle routing represents a family of fundamental combinatorial optimization problems. In essence, a vehicle routing problem (VRP) requires the identification of some routes to serve a set of geographically distributed customers so that the overall cost of the solution is minimal and all relevant constraints are satisfied [51].

Since the seminal proposal of the truck dispatching problem by [18], VRPs have attracted the attention of many researchers, given the challenges they pose and their significant impact on the efficiency of distribution logistics. Due to their practical relevance, various VRPs have been defined to properly model complex and realistic scenarios [56]. The ability to solve increasingly challenging problems that more closely model company requirements is thus of utmost importance from both a scientific and an application point of view.

A crucial factor in determining the empirical difficulty of a VRP is also the scale of problem instances that should be solved in practical applications. In fact, the larger the instance, the greater the search space, and thus the more challenging its effective exploration.

Currently, research on large VRPs is mostly related to the capacitated vehicle routing problem (CVRP), as it is the canonical variant of the VRP family from which more complicated problem variants are usually derived. The CVRP will thus be the main focus of this chapter. However, most of the techniques described in the following sections are largely problem independent and can, with additional implementation effort, be extended to more constrained variants.

The definition of an instance's scale is clearly problem dependent. For a CVRP, instances with several hundreds of customers are usually classified in the literature as *large scale* [52]. Larger instances, containing several thousands of customers, are generally called *very large-scale* instances [6, 33, 59]. Finally, instances with hundreds of thousands of customers are usually designated as *extremely large scale* [4]. In the remainder of the chapter, we will often not distinguish among the different scale nuances but rather just use the large-scale term with a broad meaning.

Recently, there has been renewed interest in expanding the frontier of VRPs by devising techniques to solve larger problem instances. Some applications, such as

those arising in waste collection and parcel delivery (and collection) problems, in fact, require the solution of such large-scale VRPs. A relevant example is given by [33], who proposed a set of CVRP instances with up to twelve thousand customers, some of which were derived from real-life waste collection problems in Finland. Similarly, [59] proposed a CVRP instance dataset, which has up to three thousand customers, provided by a logistics company, which contains the coordinates of customer locations within four major Greek cities. Additionally, [6] proposed a dataset of large-scale CVRP instances based on real-world parcel delivery problems in Belgium, where the largest instance includes thirty thousand customers. Finally, in [12], Cavaliere et al. extended the Belgium instances to model a VRP with simultaneous pickups and deliveries, as this is especially relevant for e-commerce applications in which the rapid increase in deliveries may co-occur with the collection of a large amount of returned goods. A complementary goal is pursued by [4], where the authors tackle extremely large-scale CVRP instances with up to one million customers (see Fig. 1) as a pure research exercise to promote insightful ideas possibly applicable and beneficial to smaller-sized instances.

Research on VRPs falls mainly into one of two categories: exact algorithms or heuristics. Despite recent advances in exact methods [17, 40, 41], large-scale instances are still the domain of heuristic approaches. The variance in the computing time of an exact method is, in fact, considerably high, and instances encountered in real-life settings should usually be solved quickly and with predictable computing time. This chapter thus overviews the most relevant techniques found in the literature that enable the scalability of heuristics for VRPs.

This chapter is organized as follows. In section "Scalability," we emphasize the importance of scalable solution approaches. Section "Problem Definition and Notation" provides a formal description of the CVRP, which is our reference problem, and introduces the common notation used throughout the other sections. In section "Decomposition," we review decomposition strategies, which are among

Fig. 1 Instance Emilia-Romagna proposed in [4] containing 900k customers

the fundamental tools for managing instances as their size grows. Section "Speeding Up Local Search" introduces local search acceleration and pruning techniques, as they have been shown to be essential components of many successful algorithms for large-scale VRPs. In section "Additional Design and Implementation Challenges," we discuss additional design choices and implementation details regarding scaling to large VRPs. Lastly, we conclude with section "Conclusions," where we provide some final remarks.

Scalability

The evaluation of heuristics is governed by several principles as discussed, for example, in Chap. 4 of [51]. The quality of the solutions found and the required computing time are among the most commonly used criteria. However, a solution approach may also have other desirable and often conflicting properties, such as being conceptually simple or flexible enough when it comes to extending it to other problem variants.

Another desirable property is the *scalability*, defined as a heuristic's capability to effectively find good-quality solutions in relatively short computing time across a wide range of instance sizes, up to large-scale ones.

This chapter reviews techniques that make VRP heuristics scalable. These techniques enable algorithms to approach large-scale instances by encouraging the usage of memory-efficient data structures and computationally efficient procedures. In addition, they can often be tuned to achieve the desired trade-off between computing time and search exhaustiveness, which is frequently correlated to solution quality.

The literature shows how techniques originally devised for tackling large-scale instances can often also be beneficial when solving smaller-scale ones, concurring in finding improved quality solutions [22, 45]. Designing methods explicitly targeting large-scale instances would thus often simply enlarge the set of approachable instances, possibly without (or with just modest) performance worsening on smaller-scale ones.

However, these benefits may come with additional design and implementation challenges. In particular, implementing some of these techniques may not be as straightforward as implementing their naive and less-scalable counterpart. Moreover, their adoption often gives rise to additional design choices, which may increase the overall complexity of the approach by requiring careful validation and possibly tuning of extra parameters.

Problem Definition and Notation

As mentioned in section "Introduction," we use the CVRP as a reference problem to describe the most relevant scalability techniques in the following sections.

The CVRP is defined on an undirected and complete graph $G = (V, E)$. The set of vertices is $V = \{0\} \cup V_c$, where 0 denotes the depot and $V_c = \{1, 2, \ldots, N\}$ is a set of N customers. We denote by E the set of edges. Each edge $(i, j) \in E$ is

associated with a cost c_{ij}, typically defined as the Euclidean distance between i and j. We assume that the costs are symmetric and satisfy the triangle inequality, that is, $c_{ij} \leq c_{ik} + c_{kj} \forall, i, j, k \in V$.

For a subset $V' \subseteq V$, we denote by $\mathcal{N}_i^k(V')$ the ordered list of the k nearest-neighbor vertices $j \in V'$ of vertex i with respect to costs c_{ij}. Whenever $k = |V'|$, we refer to the ordered list of neighbors with $\mathcal{N}_i(V')$.

Each customer $i \in V_c$ requires an integer quantity $q_i > 0$ of homogeneous goods from the depot, and for the depot, we have $q_0 = 0$.

The customers are served by an unlimited fleet of homogeneous vehicles, each with capacity Q, which is based at the depot. Recalling that a Hamiltonian circuit is a closed cycle that visits a set of customers exactly once, a CVRP solution S is made up of a number $|S|$ of Hamiltonian circuits, called routes, starting at the depot, visiting a subset of customers, and returning to the depot. Given a vertex $i \in V$, we denote by π_i and σ_i the predecessor and successor of i, respectively, in a given solution.

A solution is feasible if all customers are visited exactly once and the load of all routes in S does not exceed the capacity Q of the vehicles. The cost of a solution S is given by the sum of the edges' costs defining its routes and is denoted as $c(S)$. The goal of CVRP is to find a feasible solution with the minimum cost.

Decomposition

Decomposition is of fundamental importance for modern heuristics approaching large-scale VRP instances. In addition, it can also concur to find improved solutions when it is used to solve smaller instances [22]. We refer to [45] for a thorough analysis of decomposition techniques applied to VRPs.

The concept of decomposition is rooted in the *divide-and-conquer* principle. First, the original (large-scale) problem is split into several subproblems. The resulting subproblems are typically tailored to fit the resolution algorithm, but in general, they are considerably smaller than the original one so that they can be solved much more efficiently, possibly without the need for specialized scalability techniques. Once the subproblem solutions are available, they are collected and composed to obtain an overall solution to the original problem.

Therefore, decomposition strategies make resolution algorithms disregard the size dimension, enabling them to work on several smaller and more tractable problems. However, their usage also brings additional design questions that must be properly addressed to obtain an overall effective algorithm.

The first decision relates to the nature of the resulting subproblems. In a *homogeneous* decomposition, subproblems have the same characteristics of the original problem. This happens for VRPs created considering a fraction of the original customers. These subproblems can be solved using the same approach that theoretically could solve the original large problem. On the other hand, in a *heterogeneous* decomposition, the subproblems require the application of a specialized resolution algorithm, as they may differ significantly from the original problem. For example, consider a multilevel optimization approach with subproblems defined by

merging some of the original vertices into macro-vertices [13, 58]. In this scenario, the cost of an edge involving a macro-vertex clearly depends on the traversal order of vertices composing it, and an algorithm for the original problem cannot be directly applied.

As the original problem is decomposed into several subproblems, their dependencies must be defined. When the subproblems are *independent*, solving one of them does not affect the resolution of others. This, for example, happens when they are created from a partitioning of the original problem, and thus the cost and feasibility of a subproblem solution are unrelated to the resolution process of other subproblems. An independent decomposition is often the most desirable, as it easily enables the usage of parallel approaches by providing a straightforward way to combine the resulting subproblem solutions into a solution for the original problem.

Subproblems are instead *dependent* when some customers are assigned simultaneously to several of them [24]. In addition, dependencies also arise when the VRP has constraints on the whole or on a subset of customers, such as workload balancing between routes, levels of service for subsets of customers [11], consistency constraints [23], or a limit on the maximum number of usable vehicles. Ruin-and-recreate approaches [47] also perform a form of flexible instance decomposition with dependent subproblems [3, 14, 42]. In fact, the ruin step typically destroys a limited portion of the solution while keeping the remaining unchanged. Then, the recreate step repairs the ruined portion, often without the rigid boundaries that may be imposed by a classic partitioning decomposition. The working areas of subsequent ruin-and-recreate applications may overlap, thus enforcing dependencies between resolutions.

Finally, the definition of subproblems can be guided by several criteria. The routes of a high-quality solution are often used as a reference for partitioning customers [45]. This approach is closely related to the partial optimization metaheuristic under special intensification conditions [44, 49], which suggests optimizing subparts of a solution a posteriori, once a solution is available. Finding an appropriate way to decompose a problem a priori is, in fact, not a trivial task. Alternatively, customers frequently served together in high-quality solutions can be assigned to the same subproblems [36]. Generally, the vertices selected to belong to the same subproblem should be somehow related. For example, they may be geographically close, have similar service time windows, or have been observed together in good-quality solutions.

Speeding Up Local Search

Local search is among the most effective, yet computationally expensive techniques to improve the quality of solutions to combinatorial optimization problems [1]. It is a general heuristic approach that, given a starting solution S, explores a set of neighbor solutions S' obtained by performing a move that produces a local change to S. Virtually all successful metaheuristic approaches for VRPs and other problems have local search as their main building block.

The set $\mathcal{N}$ of solutions S' reachable from the current solution S is called the *neighborhood* of S for the local search procedure. Most of the effort in running a local search usually involves scanning the neighborhood. The neighbor solutions are evaluated for their feasibility and cost, and according to the selected search strategy, a feasible neighbor solution S' is selected to replace S. Typically, S' is either the first or the best-improving neighbor in the neighborhood. The process is then repeated until no improving solution is found, which implies that S is a *local optimum* for the neighborhood.

The number of neighbors in a neighborhood determines the computational complexity of its exploration. However, it should be noted that checking the feasibility or computing the cost of a given neighbor solution may not always be possible in constant time, thus adding complexity to the overall search process; see also section "Resources Processing."

There are some widely used VRP neighborhoods that have proven to be effective in practice. An example is the k-opt neighborhood that replaces k edges of the solution with k other edges [43]. The complexity of fully examining the k-opt neighborhood is $\mathcal{O}(|V|^k)$; thus, in practice, the special case with $k = 2$ is often used for intra- and inter-route optimization, given its quadratic computational complexity. The CROSS-exchange is another commonly used local search neighborhood [48]. It consists of replacing a contiguous sequence of n vertices with another one of length m that may belong to the same route or a different one. The computational complexity for given n and m is quadratic. The overall complexity to search the neighborhood for all possible values of n and m is therefore $\mathcal{O}(nm|V|^2)$. Finally, the ejection chain is another extensively used local search operator with exponential complexity [20]. It consists of performing a sequence of relocations, i.e., a special case of CROSS-exchange with $n = 1$ and $m = 0$, typically involving several routes, to improve the quality of the solution while seeking its feasibility.

Due to its effectiveness in improving the quality of solutions, several techniques have been developed to speed up local search executions. On the one hand, local search *acceleration techniques* can be used to explore the neighborhoods more efficiently without compromising the exhaustiveness of the search. On the other hand, local search *pruning techniques* can arbitrarily reduce the cardinality of a neighborhood, reaching the desired trade-off between speedup and quality by heuristically skipping the exploration of what are considered unpromising search areas. Finally, these techniques can be combined to obtain powerful tools for the design of scalable algorithms.

Acceleration Techniques

Some methods have been proposed to speed up local search execution by redesigning the exploration of neighborhoods compared to a naive for-loop implementation. These techniques retain the original search exhaustiveness, but better exploit the locality of local search changes to minimize the number of evaluations of neighbor

solutions. Thus, they are potentially beneficial not only to large-scale instances, but to instances of any size.

Sequential Search

Sequential search was originally independently proposed by [29] for the graph partitioning problem and by [15, 34] for the traveling salesman problem. It was then generalized and formalized by [28] for the CVRP and later applied to more constrained VRPs in [26].

Unlike traditional lexicographic search, sequential search efficiently explores local search neighborhoods by systematically decomposing moves into basic blocks called *partial moves*. This decomposition allows for early pruning of unpromising moves based on *gains* associated with partial moves.

The key aspect of sequential search is the decomposition of a local search move m into a sequence of k partial moves $p_k \circ \ldots \circ p_2 \circ p_1$. The neighbor solution S^k is then obtained by applying these partial moves to a starting solution S^0, i.e., $m(S^0) = p_k(\ldots(p_2(p_1(S^0)))) = S^k$. At stage $1 \leq i \leq k$, applying the partial move p_i to the solution S^{i-1} generates a not necessarily feasible solution S^i. In general, a move's decomposition is not unique; several decompositions of the same move exist and may differ in the number of stages and the structure of the partial moves.

For several traditional VRPs, the gain $g(m, S)$ of a move m applied to a solution S to obtain a neighbor solution S' only depends on the added and deleted edges and is defined as $g(m, S) = c(S) - c(S')$. Similarly, given a decomposition of m into $p_k \circ \ldots \circ p_2 \circ p_1$, it is possible to associate a partial gain $g(p_i, S)$, $1 \leq i \leq k$ with the partial moves composing move m in such a way that these partial gains depend only on the starting solution S.

Traditional VRP neighborhoods allow for the definition of *cost-independent* and *cyclic-independent* decompositions. In a cost-independent decomposition, the gain of a move m is given by the sum of the gains of partial moves $p_i, 1 \leq i \leq k$ composing m, that is, $g(m, S) = \sum_{i=1}^{k} g(p_i, S)$. A cyclic-independent decomposition is such that a move $m = p_k \circ \ldots \circ p_2 \circ p_1$, applied to a solution S, generates the same neighbor solution S' for every cyclic permutation of partial moves $p_1, p_2, \ldots, p_k$.

It is widely recognized that if a sequence of numbers has a positive sum, there is a cyclic permutation of these numbers such that every partial sum is positive [34]. Consequently, all improving moves described by a cost- and cyclic-independent decomposition can be constructed as a sequence of partial moves, where the sum of the partial gains is positive for all subsequences. Thus, when searching for an improving neighbor of a solution S with a move $m = p_k \circ \ldots \circ p_2 \circ p_1$, at stage 1, only partial moves p_1 such that $g(p_1, S) > 0$ need to be considered, while at a general stage ℓ, the search can be restricted to those partial moves p_ℓ such that $g(p_\ell, S) + \sum_{i=1}^{\ell-1} g(p_i, S) > 0$. Considering just this subset of moves may dramatically reduce the possibilities when looking for an improving neighbor solution by scanning only a fraction of the entire neighborhood.

The partial moves p_{ij}^{add} and p_{ij}^{rem} are the building blocks of moves that describe the VRP neighborhoods. More precisely, p_{ij}^{add} is the partial move that adds the edge (i, j) to the solution, while p_{ij}^{rem} removes it.

For example, consider a starting solution S and a swap move m_{ij}^{swap}, a special case of the CROSS-exchange operator, replacing vertex i with vertex j in S. A possible cost- and cyclic-independent decomposition of m_{ij}^{swap} is $p_{ij} \circ p_{ji} = p_{ji} \circ p_{ij}$ where p_{ab} is a compound partial move defined as $p_{ab} = p_{\pi_a a}^{rem} \circ p_{a\sigma_a}^{rem} \circ p_{\pi_b a}^{add} \circ p_{a\sigma_b}^{add}$ with π_t and σ_t denoting the predecessor and successor of the vertex t in solution S, respectively. The partial gain of p_{ab} is defined as $g(p_{ab}, S) = c_{\pi_a a} + c_{a\sigma_a} - c_{\pi_b a} - c_{a\sigma_b}$. When searching for an improving swap move, we can thus restrict the focus to first partial moves p_{ab} with a positive gain. First, all $i \in V$ are considered as initial candidate vertices to swap. Next, fixed i, promising vertices $j \in V \setminus \{i\}$ can be identified by considering neighbor vertices $t \in \mathcal{N}_i(V \setminus \{i\})$. To this end, we define the contribution associated with the choice of vertex i as $F = c_{\pi_i i} + c_{i\sigma_i}$ and the constant B as $B = F/2 = (c_{\pi_i i} + c_{i\sigma_i})/2$. The gain $g(p_{ij}, S)$ can thus be rewritten as $g(p_{ij}, S) = 2B - c_{\pi_j i} - c_{i\sigma_j}$. Looking for a first partial move with a positive gain $g(p_{ij}, S) > 0$ is equivalent to $(c_{\pi_j i} - B) + (c_{i\sigma_j} - B) < 0$, which implies $c_{\pi_j i} < B$ when $t = \pi_j$ or $c_{i\sigma_j} < B$ when $t = \sigma_j$. A single neighbor vertex $t \in \mathcal{N}_i(V \setminus \{i\})$ then identifies two swap moves, see Fig. 2. One in which $t = \pi_j$ and another one in which $t = \sigma_j$. The actual swapped vertex j is then selected accordingly, allowing the swap move gain and feasibility to be evaluated. The definition of constant B combined with the availability of the sorted list of neighbors $\mathcal{N}_i(V \setminus \{i\})$ allows the pruning of the search for a starting vertex i as soon as $c_{it} \geq B$. Moreover, the list of neighbors can heuristically be restricted to include only a fraction of vertices to further speed up the search process.

According to the instance and the local search operator under examination, [28] report a speed increase ranging from 5 to more than 10,000 when the neighborhoods are explored using sequential search compared to a traditional lexicographic search. Finally, this technique is also successfully used in [6] to solve very large-scale instances.

Static Move Descriptors

Static move descriptors (SMDs), originally introduced by [59], enable the efficient exploration of local search neighborhoods by exploiting the locality of changes induced by local search moves. In fact, a local search move application performs a very limited change, leaving most of the solution unaffected, especially when dealing with large-scale instances.

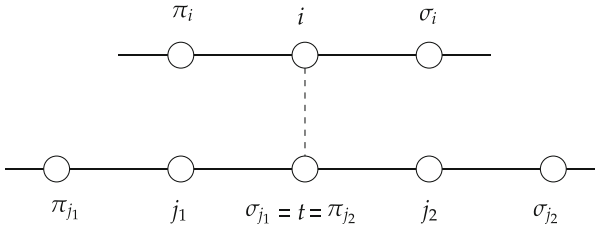

Fig. 2 Vertex t, neighbor of i, identifies the moves in which i is swapped with j_1 or with j_2

An SMD is a data structure that describes a unique local search move, generating a neighbor solution S' from a source solution S, and the associated change in the value of the objective function $\delta(S, S') = c(S) - c(S')$, called the δ-tag. The neighborhood exploration is redesigned around these data structures as follows. First, in the *initialization* stage, the δ-tag of the available SMDs is computed with respect to the current solution S. Then, a sequence of *search*, *execution*, and *update* stages is performed until no more improving solutions can be found in the neighborhood.

The search stage looks for a feasible and improving SMD, that is, an SMD describing a local search move that generates a feasible and improving neighbor solution. When such an SMD cannot be found, a local optimum is reached, and the neighborhood exploration is concluded. The local search move described by the SMD found during the search stage is then applied during the execution stage. Because the move application causes a local change to the solution, most of the SMDs will still hold a valid δ-tag even though the solution has been partially changed. The δ-tag of a constant and neighborhood-dependent number of SMDs affected by the change is finally updated during the update stage. See Fig. 3 for a possible pseudocode.

Improving SMDs can be efficiently retrieved using a heap data structure in which they are organized according to their δ-tag. The heap also ensures good performance during the update stage. The feasibility of an SMD is usually not included in its description; thus whenever an improving SMD is retrieved, its feasibility has to be checked before its possible execution. To obtain a best-improvement exploration strategy, all the most improving but infeasible SMDs are removed from the heap until a feasible one is retrieved. Then, after the move application, previously removed SMDs are reinserted into the heap, as they may now describe a feasible change. An alternative approach, proposed in [8], which assumes storing SMDs

```
begin APPLY(S)
1   H ← INITIALIZE(S);
2   L ← ∅;
3   while H is not empty do
4       Get the most improving move m from H;
5       if m does not produce a feasible change to S then
6           L ← L ∪ {m};
7           continue;
8       end-if;
9       Determine the set A of vertices affected by the application of m to S;
10      S ← EXECUTE(S, m);
10      Insert moves m ∈ L back into H;
11      L ← ∅;
12      UPDATE(H, A);
13  end-while;
end APPLY.
```

Fig. 3 Pseudocode of an SMD-based local search operator

into a binary heap implemented with a data structure using contiguous memory, consists of linearly scanning the heap to find the first feasible SMD. Given that in a binary heap entries are roughly sorted according to the used key, this results in a rough-best-improvement strategy.

Note that only improving SMDs can be stored in the heap to further speed up the interactions with the data structure. In fact, the computational complexity of its operations depends on the number of stored entries.

Compound neighborhoods can also be described in the framework. Extending the SMD definition to include a neighborhood identifier is sufficient to allow efficient exploration of several neighborhoods at once. However, note that the update stage would need to consider all the different local search operators included, making the process more expensive.

Consider again the swap local search operator already mentioned in section "Sequential Search." Given a starting solution S, the SMDs that describe a swap move are defined by the two swapped vertices $i, j \in V$ and the associated δ-tag. The execution of a move that swaps two generic vertices k and ℓ requires the update of the SMDs identified by the vertices i or j having one of the values in the set $\{\pi_k, k, \sigma_k, \pi_\ell, \ell, \sigma_\ell\}$, as some of the edges incident on these vertices have changed due to the swap. In addition to being stored in a heap, SMDs can also be indexed according to their defining vertices to quickly retrieve those requiring an update.

The SMD framework has been successfully used in [59] and [3] to solve very large-scale instances, and in [4] to deal with extremely large-scale instances.

Pruning Techniques

Contrary to acceleration techniques that preserve the original search space, pruning techniques heuristically trade the exhaustiveness of its exploration for faster execution. Despite restricting the search, because of the complex interactions among the algorithm components, they experimentally prove to be particularly effective in speeding up the overall algorithm execution without excessively harming the solution quality, especially in iterative approaches.

Granular Neighborhoods

As the size of the instance increases, fully exploring a local search neighborhood can become extremely time-consuming. In addition, only a small fraction of the explored neighbors will turn out to be improving.

A *granular neighborhood* [50] only includes a subset of the original neighbor solutions. In particular, the idea is to limit neighborhood exploration to the most promising subset of neighbors, ignoring the others. Indeed, a granular neighborhood can be seen as an effective implementation of *candidate-list* strategies [21].

These promising neighbor solutions are obtained by applying a *move generator* to a source solution S. A move generator $(i, j) \in \vec{E}$ is an arc used to uniquely identify a move for a local search operator, with $\vec{E}$ being the directed version

of the set of edges E. Indeed, even though the underlying graph is undirected, (i, j) and (j, i) can identify different local search moves. Finally, the set T of all move generators can be used to define a granular neighborhood, thus reducing the complexity of the neighborhood exploration to $\mathcal{O}(|T|)$.

The move generators are identified using *sparsification rules*. A common approach is to define, for a move generator (i, j), a local search change that inserts the edge (i, j) into the solution. For example, a swap move described by a move generator (i, j) would indeed swap vertices i and π_j. Note then the slight asymmetry of the move induced by the twin move generator (j, i).

Typical sparsification rules proxy the quality of neighbor solutions on the candidate edge (i, j) cost c_{ij}. In [2, 50], arcs are chosen as move generators if their cost is below a given cost threshold t, that is, $T = \{(i, j) \in \vec{E} : c_{ij} < t\}$. If the cost does not fully capture all problem characteristics, e.g., when there are time windows, the reduced costs obtained from a linear relaxation can be used for the same purpose [46].

An alternative to a cost-based approach consists in using a nearest-neighbor rule that guarantees a minimum number n_{gs} of the most promising move generators for every vertex [3]. Thus, $T = \cup_{i \in V}\{(i, j), (j, i) \in \vec{E} : j \in \mathcal{N}_i^{n_{gs}}(V \setminus \{i\})\}$. A cost-based rule may, in fact, not be the best model for scenarios where the standard deviation among edge costs is high, e.g., in clustered instances, leaving several vertices without local search moves directly involving them.

A *sparsification factor* $\gamma \in [0, 1]$ can be used to further filter the set of move generators and identify a fraction of the most promising ones. These *active* move generators are the only ones considered during local search procedures, i.e., $T^\gamma = \{(i, j) \in T : idx_{(i,j)} \leq \gamma \cdot |T|\}$, where $1 \leq idx_{(i,j)} \leq |T|$ is the position of move generator (i, j) in the list of all move generators sorted according to the chosen selection criteria, for example, the associated edge cost. The sparsification factor γ can be adjusted according to the algorithm's search trajectory, defining a so-called *dynamic* granular neighborhood. In particular, γ is increased when the local search struggles to find improving neighbor solutions. Instead, it is reduced to speed up exploration when several improving neighbors are often found. Typically, all move generators are identified once in a preprocessing step and stored in a list that is sorted according to the likelihood of identifying an improving solution, making changes to the fraction of currently active ones very efficient.

Varying a single sparsification factor globally increases and reduces the move generators for the whole instance. An alternative approach consists of using a *vertex-wise* sparsification factor $\gamma_i \in [0, 1], i \in V$ to achieve a more fine-grained management of the move generators [3]. The resulting sparsification vector $\bar{\gamma} = [\gamma_0, \gamma_1, \ldots, \gamma_{|V|}]$ allows for more precise control over the move generators, possibly tailoring the local search differently on different solution areas, at the cost of more complex management of such parameters, i.e., $T^{\bar{\gamma}} = \cup_{i \in V}\{(i, j) \in T_i : idx_{(i,j)} \leq \gamma_i \cdot |T_i|\}$, with T_i being the set of move generators related to the vertex i.

In the original proposal, [50] suggested including in the set of move generators all arcs incident to the depot. As noted in [7], whether this is always effective is still an open question. However, [3] report that including all such move generators may

not be appropriate when solving very large-scale instances. Their usage, even when dynamically managed, considerably slows down the local search execution without relevant improvements to the quality of final solutions.

Granular neighborhoods can be easily combined with the acceleration techniques described in section "Acceleration Techniques." In particular, the list of neighbors of vertex i used in the sequential search can be replaced by active move generators (i, j). Moreover, in the static move descriptor framework, only SMDs associated with active move generators can be initialized and later updated as a result of the application of an improved move [3, 59].

Limited Reoptimization

A key factor of successful implementations of VRP heuristics is to track instance or solution elements that are considered highly relevant to the current algorithm's state and focus the optimization procedures around them, possibly ignoring the other elements.

The first approaches in this line date back to the 1970s on research related to the traveling salesman problem (TSP). Lin and Kernighan [34] design the notorious Lin-Kernighan algorithm for the TSP, whose core is an effective search method for tentatively performing possibly long sequences of tour flips, starting from a given vertex, leading to an improved final tour. Initially, all vertices are marked as candidate starting points for searching such sequences. If the search initiated from vertex v is unsuccessful, v is unmarked, and the approach continues with another marked vertex. If, on the other hand, the search is successful, then it is possible that previously unmarked vertices may now allow for successful searches. Thus, all vertices are marked again before continuing with the next search. Applegate et al. [5] report that marking all vertices again was appropriate for the small problems instances faced by [34], having at most 110 vertices, but becomes extremely time-consuming for larger ones. Indeed, the likelihood that unmarked vertices far away from improving sequences of flips may lead to successful searches experimentally shown to be extremely low. Thus, a variation is proposed, based on the observation of [9] in the context of 2-opt, in which only vertices at the end of the flips in improving sequences are marked again. This generally results in slightly worse final solutions but greatly enhances the overall running time.

Martin et al. [37] apply a similar approach to solve the TSP in what we would classify today as an iterated local search metaheuristic [35]. In their approach, local search applications, performed using 3-opt and Lin-Kernighan, interleaved with perturbations, based on the double-bridge 4-opt move. In particular, only vertices sufficiently close to those involved in the double-bridge move are marked again as promising starting points for subsequent local search applications.

The approach is formalized in [39] through a local search framework with searches starting from a limited set of promising vertices. This set is initialized by a user-defined limitation strategy and possibly updated in light of move execution results. After initialization, an improving move is searched for each vertex v in the set. If such a move is found, the customers associated with it are optionally added to the set. On the other hand, the vertex v is optionally removed from the set if an

improving move cannot be found. Several limitation and update strategies are tested for the CVRP by using a memetic algorithm [38]. These strategies include limiting the search to endpoints of edges changed during crossover and mutation, restricting to vertices belonging to routes in children having at least a change compared to the parents, or only considering vertices from which an improving move is found.

Similarly to [37], [3] use a technique called *selective vertex caching* in an iterated local search metaheuristic where the perturbation is performed in a ruin-and-recreate fashion. The idea is to mainly re-optimize the area disrupted by the ruin-and-recreate application. To this end, a cache tracks the vertices involved in the disruption process. Then, subsequent local search procedures start only from the vertices in such a cache. In addition, whenever a change is applied to the solution, for example, due to the execution of an improving move, related vertices are added to the cache. However, instead of removing vertices that do not lead to improving changes, the cache is limited in size and managed with a least recently changed eviction policy that constantly keeps the optimization focused on more recently successfully changed areas. The cache is combined with the static move descriptor framework described in section "Static Move Descriptors" by initializing only SMDs identified by vertices belonging to the cache at the beginning of the neighborhood exploration.

Additional Design and Implementation Challenges

In this section, we briefly overview some additional technical challenges that arise when working with very large-scale instances, and we provide practical solutions described in the literature, for implementing scalable VRP heuristics. A common theme consists of using efficient data structures with a small memory footprint. Particular care should also be given to routine operations such as copying solutions, identifying neighbor nodes, or retrieving edge costs. Indeed, as the instance size grows and the optimization procedure becomes more efficient, these operations may turn out to contribute significantly to the overall computing time, while being accessory but still critical algorithm components. Overall, careful and reasonably good implementations are considerably more important here than when approaching smaller instances, as trivial inefficiencies are greatly amplified.

Memory Usage

Despite the great availability of random access memory (RAM) in modern computers, dealing with very large-scale VRPs may still require extra care in this regard, because of the super-linear growth of the memory use with respect to the instance size. The cost matrix and the list of neighbors of every vertex are typically among the most memory-consuming data structures, as their dimension grows quadratically with the instance size.

In [33], the authors developed their approach using a machine with the widely adopted 32-bit architecture, having a total addressable memory of 4 GB. To tackle very large-scale instances, they then proposed storing both the distance

(corresponding to the cost) and the travel time for each directed pair of vertices in a highly compressed format. First, they encoded both distance and travel time in a single word (2 bytes), thus halving the memory requirements. In addition, they noted that the travel time could be replaced with the average speed between two vertices, using fewer bits, and still achieving sufficient precision. This leaves more bits available for encoding the distance. Moreover, distances are not stored directly, but rather using twisty road curve factors. This representation allows storing for each pair of vertices their twisty road curve factor and average speed in a very compact way using 8 or 16 bits according to the required precision. Given that for common processors, memory accesses are much more expensive than executing calculations, original distances and travel times can be recomputed whenever required without significant performance penalties.

By analyzing near-optimal CVRP solutions with a gap smaller than 1%, [6] find that, for most instances, 95% of the vertices are connected to the 20 closest neighbors. Moreover, for 99% of the vertices, the two adjacent vertices in the route belong to the nearest 50 neighbors. There are, however, exceptions requiring long edges, for example, in instances with high variance in the demands or showing clusters of vertices. For the above reasons, the authors only store edge costs between a vertex and its 100 nearest-neighbor customers. The neighbors of a vertex are determined by sorting, for every vertex i, a list of tuples (j, c_{ij}) with $i, j \in V$. The selected number of tuples is then stored in a hash map for efficient cost retrieval. Whenever a cost is needed, the hash map is checked first, and if the value is not readily available, it is computed on demand.

In contrast to [6], in [4] all edge costs are always computed on demand. Their experiments show that, for costs corresponding to simple Euclidean distances, additional caching does not seem to be beneficial. In addition, every solution keeps track of the costs of edges composing it, allowing constant-time access to part of the costs required during algorithm procedures. Furthermore, given that local search procedures are designed according to the granular neighborhood principles described in section "Granular Neighborhoods," a local search move identified by a move generator (i, j) will always try to insert the associated edge into the solution. Thus, similarly to [25] for the TSP, the edge cost c_{ij} can be associated with the available move generators (i, j) for an additional constant-time retrieval. Finally, as in [6], a limited number of neighbors is computed and stored for every vertex. However, to avoid expensive sorting operations, neighbors are efficiently identified using a k-d tree data structure built on top of instance vertex coordinates [10]. Note that in [12], the authors identify neighbors using a radix sort and show that it can be an appropriate alternative to a more traditional comparison-based sorting approach for instances with several thousand customers.

Solution Management

A core component of a VRP heuristic is the representation and manipulation of the solution. Such an object should, in general, provide efficient ways to operate on its content according to the procedures performed by the algorithm.

A commonly used representation for large-scale VRPs is the so-called *next array* [33]. This representation combines the advantages of constant node insertion and removal given by linked lists with the data locality of contiguous memory storage. In particular, the solution is stored in a contiguous array with a size equal to the number of vertices, complemented by a separate auxiliary *start array* storing the first customer of each route. An optional *prev array* can also be used to represent a doubly linked list, if convenient.

Another popular representation is the *giant tour* [26, 28, 54, 57]. A giant tour encodes a VRP as a TSP with optional depot copies delimiting VRP routes. As an example, [28] suggest using two arrays with a length of the number of customers plus depot copies. The *node* array gives for each giant tour position the vertex that occupies it, while the *pos* array gives, for each node, its position in the giant tour. Route delimiters can be optimally placed using a dynamic programming-based linear split procedure based on dynamic programming [53], which makes this representation particularly useful in evolutionary algorithms, as it facilitates the combination of solutions with crossover procedures.

A common operation in metaheuristics involves copying solutions. For example, a copy is made to update the best found solution as soon as a candidate neighbor solution is found to be better, or to update the working solution in iterative approaches using specific acceptance criteria. According to the algorithm optimization pattern, it may not be worthwhile to perform a complete solution copy. In fact, despite being a linear-time operation, it may become extremely expensive when working with solutions of very large-scale instances. For this reason, in [4], the copy operation is replaced by an incremental synchronization between the best and the current working solutions. Initially, two identical solutions are created. Any change to the current working solution is stored in the so-called *do-* and *undo-lists*. The undo-list allows for the restoration of the working solution at any previous point in time by undoing part of the stored changes, for example, to backtrack to a better working solution. Similarly, the do-list can be used to update the best solution by applying all changes separating the best from the current working solution, for example, when the latter becomes better than the former. Synchronization between solutions is no longer a linear procedure, but it is more dependent on the algorithm optimization pattern. This mechanism has been shown to be effective in approaches for very large-scale instances that iteratively focus their optimization on localized and limited areas.

Initial Solution Construction

An initial solution is the starting point where further optimization procedures are applied. The main idea behind most approaches is to efficiently perform the preprocessing required by the construction algorithm, possibly trading its exhaustiveness with faster execution time and smaller memory requirements.

In [33], the initial solution is created using a cheapest insertion heuristic, where routes are created sequentially until all customers are routed. A new route is

initialized with a seed customer, and the unrouted customers are then added one at a time. To limit computational effort, only unrouted customers with the smallest insertion cost are considered for insertion on the current route. The next best customer to insert is identified with priority queues containing a limited and constant number of the smallest insertion costs and associated customers.

Another popular approach is the savings algorithm proposed by [16]. This construction heuristic computes an entry for every pair of customers, representing the savings that could be obtained by connecting the respective customers. These savings are then sorted and considered for application starting from the most improving one. The memory occupation as well as the savings computation grows quadratically with the instance size. Moreover, expensive sorting of all entries is required to apply the most promising savings first, making the algorithm unsuitable for very large-scale instances. Therefore, [6] propose a variation that only calculates a linear number of savings. In particular, for a vertex i, only savings connecting i to a limited set of k nearest neighbors $j \in \mathcal{N}^k(V \setminus \{i\})$ are considered. Observing that in most high-quality solutions, vertices are typically connected to other geographically close vertices, the authors propose $k = 100$ and show that this choice allows the construction of good-quality solutions in considerably short computing time and with small memory requirements. The same approach is successfully used in [12] in combination with resource extension functions [19, 27], to build an initial solution to a more constrained VRP, and in [4] to solve extremely large-scale instances.

Finally, optimizing the initial solution construction step should be weighed against the overall solution approach, as the subsequent improvement phases are typically considerably more computationally demanding than this initial step.

Resources Processing

For many constrained VRPs, the feasibility of candidate changes can be checked in constant time, provided that additional data are available. The *segment resource extension function* framework, proposed by [27], is a popular approach to formally describe how to treat common constraints. It combines ideas from resource extension functions proposed in [19] and information handling techniques introduced in [30], providing an excellent compromise between flexibility of use and efficiency of computation.

In this framework, the additional data are referred to as *resources*. Resources are typically associated with instance vertices and are computed on the basis of the position of the vertex in its route. The feasibility checks are then performed in constant time by combining the resources associated with sequences of vertices, also called *segment resources*, according to the candidate change.

For example, consider the CROSS-exchange move depicted in Fig. 4, swapping the sequences $(i_1, \ldots, i_n)$ and $(j_1, \ldots, j_m)$ between routes r_i and r_j. The feasibility assessment of such a move for route r_i can be performed by combining segment resources associated with the sequences $(0, \ldots, \pi_{i_1})$, $(j_1, \ldots, j_m)$, and $(\sigma_{i_n}, \ldots, 0)$. Similar reasoning applies to the route r_j.

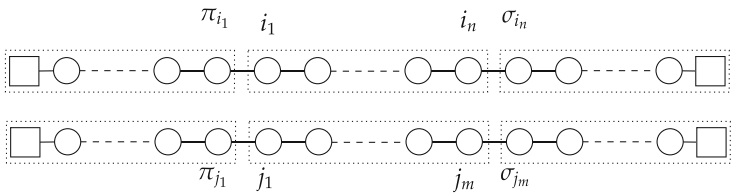

Fig. 4 Segments for the evaluation of a CROSS-exchange move swapping sequences $(i_1, \ldots, i_n)$ and $(j_1, \ldots, j_m)$ from routes r_i and r_j, respectively. The square denotes the depot

Segment resources must be computed and updated as the underlying solution changes. The two main opposite approaches consist in precomputing these resources or computing them on demand whenever required. The selection of one approach over the other depends on the balance between the number of moves evaluated and those leading to actual solution changes. Indeed, the higher the number of moves tested without application, the more efficient is having segment resources precomputed and readily available. On the other hand, having precomputed segment resources for a solution that constantly changes may incur in expensive update operations.

Irnich [26] propose a hierarchical approach that trades preprocessing effort with an increased number of combinations of segment resources required to evaluate a candidate change. In particular, this is proposed for constrained VRPs described by a giant tour representation; see also section "Solution Management." Instead of precomputing all segment resources between every pair of nodes, which would require both a quadratic procedure and memory occupation, the authors define a number of seed points to divide the vertices of the giant tour uniformly into sections. The segment resources are then computed only for every pair of nodes within a section, delimited by two seed points, and between all pairs of seed points. Using this approach, any arbitrary segment resource associated with a sequence from vertex i to j can be obtained by combining at most three already computed resources. In particular, if i and j lie in the same section, the associated segment resource is already available. If i and j are in two consecutive sections divided by a seed point s, then the desired segment resource can be computed combining resources associated with the sequences $(i, \ldots, s)$ and $(s, \ldots, j)$. Finally, when there are at least two seed points between i and j, with s_1 the first seed point after i, and s_2 the last seed point before j, the required segment resource can be calculated by combining the resources associated with $(i, \ldots, s_1)$, $(s_1, \ldots, s_2)$ and $(s_2, \ldots, j)$. This approach can be generalized to a hierarchy of segments by introducing multiple levels of seed points, trading a lighter preprocessing for an increased number of combinations. As an example, [32] successfully used a two-level approach to solve a VRP with time windows.

In [12], segment resources are used to efficiently perform constant-time feasibility checks for a VRP with simultaneous pickup and deliveries. For each route, segment resources are computed for sequences of increasing size starting from the depot, as well as from every customer to the depot. Initially, this is done for the entire

solution, and then whenever a route is changed, the associated resources are updated. Following the approach used in [55], the authors performed experiments in which all segments up to size three are precomputed for the current solution. The choice of such a size is dictated by having local search procedures that can swap at most three consecutive vertices. However, this additional preprocessing was not found to be beneficial because the maximum segment size was small enough to allow a quick computation of such resources. Moreover, for very large-scale instances, having this information associated with a solution greatly increases the cost of copy operations if such preprocessed resources are preserved. This is especially problematic for approaches that optimize a very limited portion of the solution at every iteration but still require a full solution copy to keep track of the current solution, as the generated neighbor where local search is applied may later be discarded due to the neighbor acceptance criterion [3, 12].

In [4], cumulative customer demands are used to efficiently perform inter-route 2-opt feasibility checks for extremely large-scale CVRP solutions. As in [12], segment resources are calculated for every route for the sequences from the depot to each customer and from each customer to the depot. However, these resources are computed on demand only when required and cached until there is a change to the associated route. In this case, as mentioned in section "Solution Management," the algorithm never makes solution copies. Instead, whenever a neighbor is rejected by the acceptance criterion, the current working solution is restored by undoing previously applied changes. Cached segment resources affected by this process are marked as no longer valid and recomputed when needed.

More Limitation Strategies

The recurring theme throughout the chapter is avoiding brute-force naive implementations by carefully limitating the options explored during the optimization process while still identifying good-quality solutions. So far, we have described what we consider to be the most relevant scenarios in which this idea has been applied. However, there are more areas where it can be successfully applied.

Consider, for example, a ruin-and-recreate approach. In very large-scale instances, evaluating all candidate reinsertions for unrouted customers removed during the ruin step can be extremely time-consuming. In practice, the likelihood of finding good insertion positions far away from the location of the removed customer is extremely low. A common approach, closely related to candidate lists and granular neighborhood concepts, consists of only considering a subset of promising insertion positions. For example, in [12], reinsertion of unrouted customers is limited only to positions before and after a fixed number of nearest neighbors. Similarly, in [4], all the positions in routes close to an unrouted customer are considered, although this may include distant positions for certain route shapes.

When performing local search procedures, it is often convenient to limit the exploration to reasonable sizes. As an example, [6] limit the maximum lengths of sequences exchanged during a CROSS-exchange procedure to three. In fact,

larger values seldom provide substantial improvement to the quality of solutions but greatly increase the overall running time. Similar findings have been reported for the length of ejection chains [3,6]. Exploring very long sequences of relocations is rarely useful and is extremely computationally expensive.

Sometimes, random sampling can be an alternative to complete evaluation. For example, [4] use a simulated annealing acceptance criterion to guide the algorithm's search trajectory [31]. To handle instances with significantly different edge costs, the simulated annealing temperature is defined to be proportional to the average edge costs of the instance. However, given the size of the extremely large-scale instances considered, and the underlying full graph representation, the exact temperature computation cannot be performed in a reasonable time. Instead, the temperature value is estimated randomly sampling a fixed number of instance edges. Experimental results show that, overall, this does not have a significant impact on the search trajectory of the algorithm.

Conclusions

This chapter reviews some of the most effective techniques that enable VRP heuristics to scale up to extremely large-scale problem instances. The underlying main idea is the usage of efficient procedures and data structures with acceptable memory requirements. Often, these techniques can be tuned to achieve the desired compromise between search exhaustiveness, execution speed, and memory usage. Local search plays a major role in most successful heuristics for VRPs. Therefore, acceleration and pruning techniques become essential components for successfully exploring neighborhoods that would otherwise be out of reach. Finally, routine operations should also be designed with extreme care to craft an overall efficient algorithm.

Abstract

Supply chain management (SCM) is related to the management of all activities along a network of organizations to provide a good or a service to final customers. The efficiency of these activities can have a great impact on customer's satisfaction and cost reduction. However, SCM is not just the sum of activities along the supply chain but, instead, it must consider the organization, supervision, and control of all activities in the chain from an integrated and collaborative perspective aiming to provide a competitive advantage. From this point of view, an increase in the dimension and complexity of the decision problems involved is expected, as several actors with different goals must be considered to administrate efficiently the activities within the supply chain.

This chapter briefly reviews the main concepts of SCM, identifying relevant decision and optimization problems and discussing possible solution approaches. Heuristics and metaheuristics are two of the best optimization tools to be used in solving and providing business insights for the SCM problems. This chapter also describes some successful metaheuristic approaches to SCM and it examines future research trends. A large number of applications of metaheuristics to SCM integrating new subjects, such as open and big data, smart cities, and online decision-making, just to mention a few, are foreseen.

Keywords

Supply chain management · Optimization problems · Metaheuristics

Introduction

Supply chain management (SCM) consists in integrating processes by linking major business functions from a particular company as well as across companies with business relationships. SCM is more than just summed up of a series of interconnected activities among business; it consist of integrated and collaborative processes within a clear business model that leads to a more cohesive and efficient performance of companies and better customer services. Being able to optimize the activities and processes along a supply chain is strategical for most businesses.

The activities and processes in the supply chain management include topics like location and network design, sourcing and inventory strategies, manufacturing and resource strategies, sustainability and green strategies, and also transportation and distribution strategies. At the operational level, we can find different topics as for example customer service management, demand management, returns management etc. To efficiently manage these areas, in many situations large-scale complex combinatorial optimization problems must be solved in a very effective way to be able to answer the increasingly demanding market.

Companies like INDITEX, AMAZON, DELL, etc. (just to mention some) have used and applied the concept of supply chain management to improve their processes and customer service with great success. These companies manage all activities along the supply chain in a collaborative way with the final objective to serve efficiently the final customer.

This chapter argues that metaheuristics can be an outstanding tool to help in the SCM decision-making. On the one hand, problems associated with SCM are becoming more complex and bigger causing greater impact on business performance. On the other hand, metaheuristics have attributes (as accuracy, speed, simplicity, and flexibility [1]) that can help dealing with problems that have arisen in SCM.

The objective of the chapter is to emphasize previous and potential metaheuristic's applications to SCM problems. We also revised some of the most relevant work in the literature that combines and apply metaheuristics to problems in the area of supply chain management.

The chapter is organized as follows: The first two sections describe main concepts and decision-making problems in SCM. Next, relevant applications of metaheuristics to different decision-making problems in SCM are presented and discussed. Relevant current and future topics in SCM where heuristics and metaheuristics can have a significant impact on the management of a supply chain are also examined. Finally, conclusions are drawn.

What Is Supply Chain Management?

Supply chain management has been a very popular topic in the last decade not only in business but also in academia. However, it is still possible to find some ambiguity in the concept and definition of SCM [2]. In this section, the most relevant definitions are presented and discussed to clarify SCM concepts. This definition will help us to identify the optimization problems within SCM and consequently the applications of Metaheuristics to this area.

A supply chain is a set of organizations, activities, people, resources, and products that interact to provide a service or a good to a customer, from the raw material initial stages to the end users and backward when reverse logistics is relevant. Therefore, it is a network of elements interacting with each other with the objective of satisfying customers while minimizing costs. The management of all activities along the supply chain is known as supply chain management. These activities include logistics, manufacturing and operations, sourcing, distribution, sales and marketing, accounting and finance, product design, and information technology activities among others that can be specific for each type of industry. The supply chain is related to the flow of products and goods along the chain, but information flow also plays a relevant role in its efficient management. Another related matter in SCM is the collaboration and integration of the activities in the chain since decisions in one element affect directly the whole supply chain. Thus, decision based on suboptimization approaches may lead to enormous inefficiencies in the chain. Consequently, the decision-making problems in SCM are usually more complex and have greater dimensions than other decision problems in traditional individual businesses.

In the literature, several definitions can be found. However, in this chapter, only two of the most commonly mentioned are analyzed.

The Council of Supply Chain Management Professionals (CSCMP) defines SCM as: "Supply Chain Management encompasses the planning and management of all activities involved in sourcing and procurement, conversion, and all logistics management activities. Importantly, it also includes coordination and collaboration with channel partners, which can be suppliers, intermediaries, third-party service providers, and customers. In essence, supply chain management integrates supply and demand management within and across companies" [2].

Simchi-Levi et al. [3] describes SCM as: "... a set of approaches utilized to efficiently integrate suppliers, manufacturers, warehouses, and stores, so that merchandise is produced and distributed in the right quantities, to the right locations,

and at the right time, to minimize system-wide costs while satisfying service level requirements."

Janvier-James [4] presents a discussion on the lack of consensus in the definitions of SCM, a list of definitions found in the literature, and review on the theory and practice of SCM. In Chap. 2 of [5], it can be found a history of SCM and also a discussion on its definition.

When focusing on the common aspects of these definitions, it is possible to see that a supply chain can be understood as a set of interconnected entities and activities which are concerned with the plan, coordination, and control of materials, parts, and finished goods from suppliers to customers. An essential aspect of a successful management of these activities is the integration, cooperation, and coordination of the decision-making processes as well as in the sharing of information throughout the entire supply chain. Integrated decisions in SCM are related to cross functional planning. SCM coordination attempts to maintain an efficient and smooth flow of products and services. An effective SCM is not just a sum of management individual activities, but it must take into account the effect of their interrelation, seeking collaborative actions among the chain. But the importance of concepts as performance and quality service cannot be ignored. The ideas around integration and collaboration arise to improve the customer service and the performance by taking advantages of the synergies among the elements of a supply chain and to have a common objective and align the targets to satisfy the final customer.

In the literature, there is still some uncertainty about the definitions of SCM and Logistics Management (LM). Although, these two areas have a serious overlap; LM is a functional area of business while SCM crosses the businesses borders including relationships and interactions from different entities, as providers and customers for example. The CSCMP defines Logistics Management as follows: "Logistics management is that part of SCM that plans, implements, and controls the efficient, effective forward and reverses flow and storage of goods, services and related information between the point of origin and the point of consumption to meet customers' requirements" [2].

Other similar definition can be found in Johnson et al. [6]: "Logistics define the entire process of materials and products moving into, through, and out of a firm. Inbound logistics covers the movement of materials received by the suppliers. Material management describes the movements of materials and components within a firm. Physical distribution refers to the movement of goods outwards from the end of the assembly line to customers. Finally, SCM is a larger concept than logistics, dealing with managing both the flow of materials and the relationships among channel intermediaries from the point of origin of raw materials through to the final consumer."

Supply chain management gives a particular emphasis on the integration of the entire supply chain, including the logistics, marketing, operations and other activities within the organization, and with suppliers, suppliers of suppliers, customers, and customers of customers, etc. Therefore, in this chapter, we focus on cross functional aspects of the business collaboration and integrated activities as well as the decisions in SCM.

Decision-Making Problems in SCM

The decision-making in SCM is very complex as it may involve a large number of elements and processes, different businesses, or economic functions within each business. This section presents some general and relevant decision-making problems in SCM and relates them to optimization problems. Depending on the segment of the economy or industry sector, the SCM may have specific characteristics, sharing common difficulties. However, this chapter focuses on problems dealing with integration and collaboration issues along the supply chain.

The decision-making problems may be categorized into two groups: planning (long-term decision-making) and execution (tactical and short-term decision-making).

In planning, the most relevant decisions relate to the following areas: network design, sourcing and inventory strategies, manufacturing and resource strategies, sustainability and green strategies, transportation and distribution strategies, information strategies, and global supply chain strategies [7–10].

In execution, it is possible to identify several processes related to supply, manufacturing, logistics and distribution, and post-sale [11]. The problems that arise from these processes share cross functional issues along the chain.

How should the supply chain efficiency be evaluated? The main criteria mentioned in the literature are speed, reliability, cost, and customer satisfaction [4]. Other authors suggest resources measures (cost), output measures (customer related), or flexibility measures [10]. Therefore, the decision problems that can occur in SCM are in general related to finding solutions that perform well for the mentioned criterions.

Next, some examples of decision-making problems in a supply chain are described, emphasizing the ones where metaheuristics have been or can be applied. Please note that there is no intention to make an exhaustive list of problems but exemplify some important problems in SCM where heuristics and metaheuristics can be successfully applied. Some of these problems are already well known in the operations research literature; however very few of them have considered the integration and coordination aspect of SCM.

In SCM planning, two of the most relevant subjects are network design and facility location problems. Location problems have been extensively studied in operations research, and there is a large amount of applications of heuristics and metaheuristics to this area. However, the problems in this chapter on *location and network design* are problems from an integrated and collaborative perspective within a supply chain. For a survey on managerial issues in supply chain and network design, see [11]. The authors describe the main issues in network design, as determining its size, number and locations of the facilities, integration with tactical decisions as distribution, transportation, and inventory policies, as well as fulfilling customers' demand. They also evaluate supply chain network design where competition among supply chains is taking into account in the design phase. For the optimization point of view, the authors mention interesting objectives that should be considered in the network design problem as social, environmental,

economical, agility, and uncertainty considerations. Melo et al. in [12] presented a literature review of facility location models within a SCM context. One interesting aspect of this work is the identification of the key features that these models should capture in the strategic planning of the supply chain. They consider not only the common objectives and constraints of standard location problems but also its integration with other decision aspects of the chains as capacity, production, inventory, transportation, procurement, and routing. All of them received little attention in the literature. Other problems still very relevant in network design problems are globalization and internationalization of the supply chain, financial and taxation factors, risk factors, and multiobjective models (due to the consideration of multiple actors).

The *sourcing and inventory strategy* in SCM refers to several elements, for example, inventory positioning in the network, inventory objectives balancing cost and product availability, pull versus push systems, and inventory policies as VMI (vendor management inventory) or restock policies. Inventory and sourcing represent a large percentage of the supply chain's cost, thus the optimization of these elements is of critical importance. Notice that some decisions related to sourcing and inventory must be taken considering the whole supply chain including the production, transportation, and distribution decisions. These problems are well studied in the literature [13–17]. However, less attention has been done to strategic problems considering a collaborative and integrated point of view. There are few studied problems in inventory and sourcing from SCM perspective, the inventory-routing problem [18, 19] and the vendor-managed inventory [20] are a few examples.

The *manufacturing and resource strategies* are associated with the process of producing a good or a service. Most problems and relevant decisions are related to the production planning and scheduling, global production assignment, postponement strategies, resource utilization, and resource investments. Also, related issues as market forecasts and product design make a great impact on the manufacturing and resource strategies. Once again, many problems can be defined within this subject; however, only recently the supply chain perspective has been considered when defining business strategies for manufacturing and resource use. This broad strategy leads to larger and complex problems if compared with the traditional single business perspective. Production planning within a supply chain can be a very challenging problem, as its solution may affect several elements of the chain, horizontally and vertically. For example, job scheduling has been mostly applied to deal with operational decision problems, but its integration with the production planning decision [21] and among different production plants is not commonly considered. Their integration with the availability of raw materials, the global forecasting, and distribution decisions can also be of great interest in the SCM. An overview of production and scheduling problems in the supply chain can be found on [22, 23].

Sustainability SCM must be taken into consideration from product design and production to transportation and waste management. Good decisions in *sustainability and green strategies* have a significant impact on the economics and market value

of the business. For a literature review on the implications and interrelationships of SCM, sustainability, and lean management, we refer to [24]. The environmental and waste costs are often quite significative. Thus it should be taken into account in almost all SCM decisions mentioned in this chapter, for example, the impact of carbon dioxide emissions in transportation strategies. The design of green and lower environmental impact routes is attracting many researchers [25]. The sustainability or green strategies and returns management should also be considered in network design strategies, the latter is known as closed-loop network design, for example, Devika et al. in [26] apply metaheuristics to solve a similar type of problem successfully.

Transportation and distribution strategies are key elements in SCM. The connections among the elements are based on transportation activities or information interchange. Transportation elements not only permit to connect components in the chain but also it represents in many cases a substantial overall cost to the organizations in the chain. Therefore, managers need to have a good understanding of the transportation system and develop good transportation strategies. To the development and design of these strategies, several elements must be taken into account, i.e., transportation costs and performance, transit time and variability, loss and damage costs, transportation mode, international issues, transportation outsourcing, and collaborative transportation, just to mention a few. From the metaheuristic literature, a potential application is the study of the impact of transportation decisions in the SCM.

Today's information technologies allow companies to collect vast amounts of data related to several activities in the supply chain: from demand data to stock levels data, from the location of the transportation vehicle data to order delivery status, etc. Information strategies should be carefully considered since the impact on the business' performance is significant [27]. In reality, it is difficult to discuss SCM without mentioning information technologies. The capability of integration, collaboration, and coordination along a supply chain will not be possible without the information flow along the network. It should also be easy to understand that a good use of this information may lead to improvements in the decision-making and consequently on the overall performance of the business and customer satisfaction [3]. SCM strategic decisions on information are related to where and which data should be collected, accessed, storage, analyzed, and shared with other supply chain elements [3]. Notice that these decisions can affect all optimization problems, since all of them have the need for high-quality input data [28]. Other significant problems raised in this activity are related to how to deal with the enormous amount of available data. Feature selection and classification problems, as well as other data mining difficulties, must be formulated and solved to improve the information quality. Thus, metaheuristic techniques are usually an appropriate method to solve such large problems in a reasonable amount of time, avoiding suboptimizations, poor data aggregation, and other simplifications procedures. The availability of huge quantities of data will probably lead to a widespread use of metaheuristics and better decisions on SCM.

Several businesses have a worldwide presence, so global supply chain strategy is a relevant topic in SCM. Companies frequently produce globally but with some local personalization to improve sales numbers. So, strategic decisions related to marketing, financial, logistics, distribution, production, and postponement within a global supply chain can represent high complexity but at the same time make a great impact on the performance of the elements of the supply chain. Some of these SCM strategic decisions are, for example, where to produce or store the goods or how to distribute globally produced products and always considering: global market characteristics, technological aspects, global costs, and economic and political scenes [29]. The consideration of all these issues usually leads to very complex problems and eventually with nonlinear objective functions, where again, the use of metaheuristics can be extremely useful.

The characteristics of metaheuristics [1] make them one of the best tools to evaluate different scenarios during strategic decision-making processes. Managers face complex, integrated, and stochastic problems, and being able to obtain relevant insights by using optimization methods certainly provides them with a competitive advantage.

In the SCM execution area, the well-established supply chain processes as defined in Croxton et al. [30] are considered. These processes are:

- Customer relationship management
- Customer service management
- Demand management
- Order fulfillment
- Manufacturing flow management
- Supplier relationship management
- Product development and commercialization
- Returns management

Many other processes are suggested in the literature. However, they are quite similar since all include functional processes in supply, manufacturing, logistics and distribution, and post-sales.

Next, some examples of decision problems that occur in the abovementioned processes are briefly described. It is important to remember that the list of problems is not exhaustive, as the goal is to mention relevant examples with a focus on the use of metaheuristics.

Customer relationship management (CRM) is a well-established area in SCM and closely related to marketing. The objective of CRM is to identify target markets and implement marketing programs with key customers. Most of the literature has a focus on the marketing area. However, recently, there is an increase number of applications of operations research and metaheuristics to marketing and CRM processes. The main reason of this interest is due the increased complexity and dimensions of the decision problems, as for example: identification and segmentation of target customers and optimization of product portfolio, recommendation systems, and characteristics of the potential clients.

Customer service management (CSM) is the coordination structure for managing the business' relations with current and future clients. It includes the management of the sales department and information providers and it must deal with the communication among all departments and companies within the supply chain that provide products or services to customers. This process has a strong component of information systems, and different processes, from inventory problems, assignment of the corresponding customer support or representative, to optimize the sales team's organization. Most examples of applications of metaheuristics in CSM are found in inventory management, as [31, 32], and also in staff scheduling [33].

The main objective of the demand management process is to meet the customer's demand and balance their requirements with the capacities of the organizations in the chain. This is a crucial process, and one of its essential elements is the synchronization between the procurement, production, and distribution function to satisfy customer's demand and orders. Forecasting plays a major role in this process, as well as its integration into the resource planning and allocation [34].

The *order fulfillment* process provides for timely and accurate delivery of customer orders. One of the most relevant decisions in this process is the well-known *capacitated vehicle routing problem* (CVRP) [35]. The CVRP has been extensively studied in operations research area and is one of the problems with the largest number of applications of metaheuristic algorithms [36–39]. But from the SCM perspective, it is important to go beyond the classical CVRP and extend this problem to take into consideration more aspects within the supply chain. For example, the collaborative CVRP, that is, where several distribution companies collaborate to deliver their products [40, 41]. Another example is the CVRP with environmental and reverse logistics considerations [42, 43]. An important area of research is also the consideration of inventory constraints and costs in the routing decisions [18] or rich routing problems as in [44, 45], where metaheuristics have already been successfully applied.

The *manufacturing flow management* process is related to the production of the goods and services to serve the customers, including the moving of products through the plants and businesses. Within an SCM context, the production planning must take into account providers and customers, as well as the production capacity of the organization, differing significantly from the usual individual standpoint. Aspects as the production flexibility, batch size, cycle time, postponement, make to order, make to stock, customer order forecast, production scheduling, etc. must be considered when setting the production flow. Examples of applications of metaheuristics in this process can be found on [46, 47].

The *supplier relationship management* is associated with the relationships upstream in the supply chain and can be seen as a minor image of the CRM. Some of the important decision problems in this process are the selection of the right suppliers, cross docking systems, inventory coordination, and planning between providers and customers. The *product development and commercialization* process integrates all necessary activities to develop new products or services as their introduction to the market. The decision problems in this process are related to activities in the CRM and fulfillment; therefore issues such as market

and promotion planning, sales force training scheduling, make or buy decisions, inventory decisions, transportation planning, or commercialization planning are relevant. One example is the application of genetic algorithms to design different product structures considering different product parts, production processes, and green strategies [48].

The process of *returns management* is related to the reverse logistics and closed-loop supply chain processes. Over the last decade, business and academia have been increasing their attention to this issue due to three main reasons: impact on the environment and laws forcing the right disposal of products, recognition of the sustainable issues by the society, and social responsibility by the businesses. The forward logistics activities are already difficult to plan and optimize. The returns activities have an increased difficulty due to the stochastic aspect of the "demand." For example, if a company uses reused/recycled components in their production, the collection of these components can vary significantly along the time horizon, leading to an increased complexity of the production planning. Some applications of metaheuristics to design closed-loop supply chains have been addressed by [49].

The metaheuristics have already being applied to SCM at the operational level as it will be discussed in more detail in the next section. However, the need to consider integration and coordination aspects still exists, and future applications of metaheuristics to SCM must examine these issues as well as its computational efficiency and flexibility.

Metaheuristic Algorithms for SCM Problems

In the last years, there have been several applications of heuristics and metaheuristics to SCM decision problems. The reasons are quite clear, the increase in complexity due to the horizontal and vertical integration and the need for quick and flexible algorithms granted to metaheuristics, a special place in the methodologies applied to SCM.

In this section, we review relevant publications of heuristic algorithms applied to SCM problems. Note that the literature review is not exhaustive and readers are also referred to a recent survey on this topic [50].

In [51], the problem of distribution planning of a network of manufacturing plants, depots, and customers is analyzed. A heuristic based on an evolutionary algorithm approach (▸ Chap. 22, "Genetic Algorithms") is proposed where the solution consists in deciding which depots should be considered and how the product should be distributed from depots to clients minimizing fixed and delivery costs. The approach considers a bi-level structure; the upper level decides how the customers are supplied from the depots. The lower level decides on the manufacturing process.

The problem of coordinating the production schedule and the transportation of orders is analyzed in [52]. The problem aims to establish the best allocation of orders specifying, at the same time, their production sequence and completion times with the objective of minimizing the total cost of the supply chain. Two genetic algorithms (▸ Chap. 22, "Genetic Algorithms") are proposed with different

integration strategies, where the best approach allocate more CPU time in solving the scheduling problem.

Considering a seven-layer recovery network, including primary customers, collection/redistribution centers, recovery, recycling and disposal centers, and secondary customers, the problem of recovering products is analyzed in [53]. A mixed integer linear programming model is proposed to determine the collection and recycling centers for the logistic of recovered products, minimizing the total cost. To deal with real-sized instances, the authors propose heuristic approach based on Tabu search (▸ Chap. 31, "Tabu Search"), to design and select the best recovery option while minimizing fixed and variable costs.

Considering the same type of problem, but on a multiobjective approach, Devika et al. [26] analyzes a general closed-loop supply chain network with six echelons. They consider the minimization of total costs, the minimization of environmental impacts, and the maximization of social benefits. Considering two metaheuristics, adapted imperialist competitive algorithm (AICA) and variable neighborhood search (VNS) algorithm (▸ Chap. 18, "Variable Neighborhood Search"), three hybridization approaches are designed and tested against benchmark algorithms and on a case study. Other examples of quantitative approaches to green SCM can be found on [54–57].

There are few studies considering the transportation and distribution decisions at the strategic level. Lourenço and Ribeiro [58] explore the impact of considering logistics and marketing issues in the design of distribution strategies. Schmid et al. in [44] describe basic models for extensions of vehicle routing problems in the context of SCM. These extensions consider other elements in the supply chain as scheduling, packaging, batching, intermodality, etc. They also describe an important extension where inventory is considered. The inventory and routing interconnectivity is a well-known area in the operations research literature; see for example [18, 59, 60].

Considering a two-echelon supply chain, Cardona-Vales et al. [61] work on a bi-objective optimization problem, minimizing the cost for opening warehouses and the expected value of transportation costs and the maximum traveling time through the whole supply chain. Locations for warehouses and the assignment between warehouses and distribution centers have to be decided by the actual value of the demand. To deal with this stochastic problem, a hybrid heuristic based on Tabu search and GRASP (▸ Chap. 23, "GRASP") is designed to consider a multiobjective approach.

The design and evaluation of cooperative purchasing strategies for healthcare supply chains are evaluated in [62]. The authors propose hybrid heuristic algorithms based on *variable neighborhood search* and *Tabu search*. Considering a set of hospitals, they want to determine the best cooperation arrangements, to foresee global and individual savings and organize their joint supply chain to take advantage from cooperation.

Regarding *customer relationship management,* several examples of applications of metaheuristics can be found on market basket analysis [63, 64], product portfolio optimization [65], store operation within CRM systems [66], or data mining appli-

cations in CRM [67]. The CRM process is receiving more attention from the SCM point of view; however, we could observe few publications using metaheuristics. We identify that there is great potential to apply these techniques to complex problems in CRM.

Although it is possible to see an increased number of metaheuristic applications to SCM, there are still several problems to be mathematically formulated. As a consequence, there is a lack of proper benchmarks and test beds leading to a deficiency in algorithm comparison and analysis.

Current and Future Research Trends in SCM

Supply chain management will continue to be a relevant topic in the following years, and the decision-making problems will be growing in quantity, dimension, and complexity. In this section, current and future research trends in metaheuristics applied to SCM are discussed. Many of them have not been yet extensively considered in the metaheuristic research literature.

Main topics:

- Greater integration and collaboration, horizontal and vertical, along with the supply chain
- Uncertainty decision-making in SCM
- Multiobjective approaches
- E-commerce and SCM
- Online decision-making in SCM
- Open and big data in SCM
- Smart cities and SCM

One of the main characteristics of SCM is the relevance of integration and collaboration between the elements of the chain. If this integration is not taken into account, there is not a truly SCM setting. However, most current works do not always consider these aspects. We conjecture that the main problem is that incorporating objectives and constraints to model the integration and collaboration of processes lead to very complex and in many cases nonlinear problems. Still, models and algorithms in the SCM decision-making must consider these aspects to obtain a real impact and add value to the business in general.

As previously mentioned, an increase in the dimension and complexity of the problem is expected. Thus, metaheuristics are certainly a clear option to deal with this new problem profile, especially when accurate solutions are needed in fast time. High-performance computing and hybrid methods are clear options to deal with this increased size and complexity. From the application point of view, cloud computing algorithms seem to be a good option for medium-sized companies willing to have access to low-cost distributed algorithms.

Efficient decisions in SCM must take into account an important element: *uncertainty*. Uncertainty is present all over the supply chain: uncertainty demand, travel

times, cost, resource availability, etc. The uncertainty parameters make it difficult to optimize the system-wide costs and performance in SCM. The consideration of scenario strategies, robust methods to deal with the parameter's uncertainty, will play a major role in helping the decision-making. For example, a new line of research called simheuristics [68, 69] extends metaheuristic capabilities through simulation for solving problems with uncertainty parameters.

The need for integration of different elements of the supply chain often leads to optimization problems where many different objective functions must be assessed. Therefore, metaheuristics once again present themselves as an excellent option to efficiently deal with multiobjective problems in a complex environment.

E-commerce is already a reality, and with this new form of commerce had appeared new decision problems [70]. The e-commerce will be shortly a central part in many businesses, and this involves not only the retailing companies but also many other elements integrated into a supply chain, as production and logistics companies. The need to a fast response in e-commerce is also a reality, so the decision-making in a supply chain presents a different set of problems than the traditional ones.

The availability of technology and online data, as well as the need for flexibility and immediate responses, pushes the decision-making processes from an offline to an online perspective. In this new perspective, we do not count with the whole instance data but rather a sequence of input portions that must be solved as they arrive. Thus, online algorithms must take into account the current state of the system and react as a new portion of information arrives. Once again, the trade-off of computer efficiency and solution quality has to be carefully analyzed, but due to the complexity of the problems and the size of real scenarios, metaheuristic approaches are again promising in this new context.

Open email accounts, Internet search browsers, and mobile phones are just some of the new ways to capture online consumer's habit information. This incredible big amount of data represents an excellent opportunity to find commercial advantages. The problem is now how to extract good-quality information from these vast databases that usually cannot fit in regular servers and lacks proper structure [71]. The fact that these databases are relatively open in today's business increases the potential of the impact of this information in the SCM. Due to the characteristics of metaheuristics, these methods have an enormous potential to be applied in SCM decisions involving big and open data.

Although there are several different definitions of a smart city, the main concept behind the idea is to consider a city as an integrated system. The available information from its infrastructure and dynamical systems are continuously analyzed for the improvement of all the systems as energy, transport, healthcare, buildings, etc. [72]. The large amount of sensors and available data have a great impact on urban supply chain management. The availability of the resources of smart cities can provide substantial improvements in mobility, sustainability, distribution, and many other SCM activities. Notice that in a smart city environment, the decision problems in SCM will become more complex, with a need for a faster and online response. For example, retailing companies can identify the closest transportation vehicles and make collaborative distribution decisions online.

These issues are only some of the actual and future relevant topics that must be addressed in SCM. Metaheuristics, as one of the available optimization tools, can provide better quality insights to these important issues in a faster time, improving significantly the decision making.

Conclusions

An efficient supply chain management is of critical importance in today's businesses; if we take into account the market's globalization and the increasing demand for flexibility and quality, a good SCM will be vital for the survival of any company.

This chapter reviews the main concepts and decision problems of SCM. The challenges for obtaining relevant business insights and decisions are associated with methods in the area of heuristics and metaheuristics.

Decision problems that have arisen in SCM are becoming more complex and larger; the need for integrating all the elements of the supply chain is an enormous challenge, as it relates to different objective functions, online decisions, big databases, and uncertainty data. Thus, this chapter argues that heuristics and metaheuristics are the most promising tools to solve the decision problems in SCM. The attributes of metaheuristics, as well as the successful cases mentioned in this work, support the argument that these methods can address the main challenges of the actual and future SCM problems.

A larger number of applications of heuristics in metaheuristics to problems in SCM are foreseeing shortly. The vast amount of available data, the need for more integration and coordination, the need for online solutions, the consideration of uncertainty, and many other new constraints will produce a significant amount of complex decision problems with the need for a fast and efficient solution method. The use of metaheuristics may provide a significant contribution in SCM from a theoretical and practical perspective.

Abstract

In this chapter, we review heuristic approaches for two classical and closely related problems of finding a maximum clique and an optimal vertex coloring. Both problems have a wide variety of practical applications, and due to their computational intractability, a significant effort has been focused on developing heuristic methods. This chapter discusses construction heuristics, local search strategies, and metaheuristics designed and/or adapted for the maximum clique and vertex coloring problems.

Keywords

Maximum clique · Vertex coloring · Chromatic number

Introduction

Given a simple, undirected graph $G = (V, E)$, a *clique* is defined as a subset $C \subseteq V$ of pairwise adjacent vertices. A graph is called *complete* if the set of its vertices forms a clique. A *maximal clique* is a clique that is not a subset of a larger clique. The *maximum clique problem* asks for a clique of the greatest possible cardinality in G. The size of such a clique is known as the *clique number* of G, denoted by $\omega(G)$.

An *independent set* (or *stable set*) is a subset $I \subseteq V$ of vertices with no edge between them. It is easy to see that a *clique* in G is an *independent set* in the *complement graph* of G, $\bar{G} = (V, \bar{E})$, where $\bar{E} = \binom{V}{2} \backslash E$, and vice versa. Finding a maximum clique in G is equivalent to finding a maximum independent set in $\bar{G}$. The cardinality of a maximum independent set in G is called the *independence* or *stability number* of G, denoted $\alpha(G)$, and $\alpha(\bar{G}) = \omega(G)$.

A *proper vertex coloring* (also referred to as a coloring for simplicity) is an assignment of a color (or a label) to each vertex in a graph such that no adjacent vertex has the same color. More formally, given a set of colors $\{1, 2, \ldots, k\}$, a *proper k-coloring* is a mapping $f : V \to \{1, 2, \ldots, k\}$, where $f(v_i) \neq f(v_j)\ \forall \{i, j\} \in E$. Then the vertices with the same value of f belong to the same *color class*. The *chromatic number* of a graph G, denoted $\chi(G)$, is the minimum number of colors necessary to color G. An *optimal coloring* of a graph is a proper coloring that uses exactly $\chi(G)$ colors.

It is easy to see that the vertices that belong to the same color class form an independent set, and the vertices of a clique all belong to different color classes. Then it follows that for a given graph G:

$$\chi(G) \geq |V|/\alpha(G),$$

and

$$\chi(G) \geq \omega(G).$$

The maximum clique and vertex coloring problems often arise in similar applications, where they play complementary roles. For example, let the vertices in the graph represent elements of a system and the edges between them—the incompatibility between those elements. Then a maximum clique will represent a set of mutually incompatible elements of the largest size in the system, whereas the color classes will correspond to sets of mutually compatible elements.

Both problems have numerous real-world applications across diverse domains. Some of the earliest and best-known applications of the maximum clique problem

are in computer vision, experimental design, information retrieval, coding theory, fault diagnosis, social network analysis, and computational biochemistry and genomics, among other areas [36, 158, 191]. As for the coloring, it is commonly used for scheduling [131, 147], timetabling [182, 183, 187], frequency assignment [78, 185], circuit board testing [80], register allocation [42, 46], and various problems in transportation [39, 186]. A discussion of both clique and vertex coloring applications in telecommunications is presented in [15].

The maximum clique and vertex coloring problems are both well-known NP-hard problems [79, 124] that are hard to approximate within a factor of $n^{1-\epsilon}$ for any $\epsilon > 0$, where $n = |V|$ [9, 10, 63, 64, 101, 196]. Such intractability results, along with the practical interest, have led to a considerable effort in devising numerous heuristic approaches. Almost all known types of heuristic methods have been applied to these problems. Some of the early surveys on heuristic methods for the vertex coloring problem can be found in [159, 184] and more recent in [45, 75, 77, 139, 161], among which [45, 75] review just the local search methods and [77] focuses on the recent approaches. As for the maximum clique problem, the first extensive surveys date back to the 1990s [25, 158], while the more recent one [191] focuses mostly on local search techniques. Other brief discussions on heuristic approaches for the maximum clique problem can be found in [158, 161]. It should be noted that most of these surveys also discuss exact algorithms, many of which take advantage of heuristics to enhance their performance.

The remaining sections of this chapter are organized as follows. The most common construction heuristics for the maximum clique and vertex coloring problems are discussed in section "Construction Heuristics." In section "Local Search," we briefly outline the local search strategies used for both problems. Section "Metaheuristics" covers various metaheuristic approaches. It is followed by sections "Heuristics Based on Continuous Formulations," "Other Heuristics," "Computational Results," and "Conclusion," respectively.

Construction Heuristics

Construction heuristics are used to build an initial feasible solution. The most intuitive and common construction heuristics are *sequential* ones, which recursively update the current, partial (and not necessarily feasible) solution one step at a time. Based on how the next step is selected, most of these heuristics can be classified as either greedy, random, or a combination of both. Greedy selection rules often aim to ensure the highest level of flexibility (i.e., the largest possible "candidate set") in the future steps.

The most common sequential greedy heuristics for the maximum clique problem are *best in* and *worst out*, as named by Kopf and Ruhe [128]. Best-in algorithms are those that start with an empty set as an initial solution and iteratively add a vertex with the largest degree among the candidate vertices, whereas worst out are the ones that start with a whole graph and recursively delete vertices with the lowest degree

until the remaining graph is complete. The best-in heuristic applied for finding a maximal independent set yields a solution of size at least $\frac{|V|}{\delta+1}$, where $\delta = \frac{2|E|}{|V|}$ is the average degree of a vertex [62]. The best-in heuristic was also shown to be "provably best" for the maximum clique problem in [120]. A heuristic is called provably best if no other polynomial-time algorithm can guarantee a better solution whenever one exists (assuming $\mathcal{P} \neq \mathcal{NP}$).

As for the vertex coloring problem, any heuristic that finds a coloring using at most $\Delta(G)$ colors (referred to as Brooks' coloring), where $\Delta(G)$ is the maximum vertex degree in G, is provably best [120]. According to Brooks' theorem [27], a simple, connected graph G that is neither complete nor an odd cycle satisfies $\chi(G) \leq \Delta(G)$. Brooks' coloring can be obtained using several heuristics [89, 95, 121, 123, 134, 171].

Many popular heuristics for the vertex coloring problem are based on sequential construction approaches. Sequential construction heuristics usually iteratively assign each vertex with the smallest feasible color such that no conflicts with already colored vertices occur. The order in which vertices are colored is either static and determined beforehand (preorder) or dynamic and updated on the fly. It is easy to see that the quality of the solution depends entirely on how the vertices are ordered and that there exists such vertex ordering that produces an optimal coloring [184]. Hence, considerable attention has been devoted to studying and designing various ordering schemes.

Two examples of preorder sequential coloring heuristics are the *largest first* (LF) [182] and the *smallest last* (SL) [146]. LF sorts the vertices in decreasing order of their degree, and the ordering $(v_1, \ldots, v_n)$, produced in such manner, results in the coloring with at most $1 + \max_{1 \geq j \geq n} d_j(v_j)$ colors, where $d_j(v_j)$ is the degree of vertex v_j in the induced subgraph $G_j = G[\{v_1, \ldots, v_j\}]$. SL is similar to LF, but it sorts the vertices in the reverse order. First, a vertex of the minimum degree in graph G is selected and labeled v_n. Then, iteratively for each $j = n-1, \ldots, 1$, a vertex of the minimum degree in G_j is selected and labeled v_j.

A notable sequential coloring approach that does not preorder vertices is the DSATUR [26] heuristic. A decision on what vertex to color next is based on the value of the vertex *saturation degree*—a number of the differently colored neighbors of this vertex. A vertex with the maximum saturation degree is selected. Another example of a heuristic that does not preorder vertices is the *recursive largest first* (RLF) [131]. This heuristic generates a color class one at a time and does not proceed to another color class until no more vertices can be assigned to the current class. This assignment proceeds as follows: When a new color class is generated, set U_1 contains all uncolored vertices, and set U_2 is empty. Iteratively, a vertex $v \in U_1$ is selected, assigned to the current color class, and removed from U_1. If v has any neighbors in U_1, they are removed from U_1 and placed in U_2. The vertex assignment proceeds, while U_1 is not empty. The very first vertex to be assigned to the new color class is the one with the maximum degree in $G[U_1]$, and all the rest are the ones with the maximum degree in $G[U_2]$. When U_1 becomes empty, the next color class is generated, and the process repeats.

In another study [23], a maximal independent set is iteratively extracted from the set of uncolored vertices, and all the vertices forming this independent set are assigned the same color. The process repeats until the whole graph is colored. Similar technique is used in the algorithm called XRLF [119], which is a version of RLF [131]. Several independent sets are first constructed, and then the one whose removal yields a residual graph with the smallest edge density is selected as a new color class. This process is repeated until a threshold number of uncolored vertices are left, which are then colored using an exhaustive search. Independent set extraction approach has been used to construct initial colorings within various metaheuristic frameworks [43, 70, 77, 103, 150]. In addition, a few enhanced approaches based on independent set extraction were proposed. Namely, in [188], the authors suggest to preprocess large graphs by iteratively extracting a maximal number of pairwise disjoint independent sets of the same size. Such strategy was shown to assign more vertices to the same number of color classes than that with a one-at-a-time independent set extraction. This yields smaller in size residual graphs of uncolored vertices, which are easier to color. In [100, 190], the authors observe that an independent set extracted may not necessarily define a color class in an optimal coloring and that removing such sets during preprocessing may prevent one from reaching an optimal solution. To mitigate this drawback, the authors of [100, 190] suggested a framework that reconsiders a certain number of the removed independent sets and allows some of the vertices forming those sets to change a color. Different strategies on how many and which extracted sets to reexamine were studied, and the experiments on some large and hard graph instances reported in [100, 190] demonstrate an encouraging performance of the proposed approach.

To improve the quality of solutions generated by the greedy sequential methods, different techniques ranging from randomization, multiple restarts, and local search (section "Local Search") to sophisticated metaheuristic frameworks (section "Metaheuristics") can be used. We will cover here a few simple strategies and discuss the rest in the later sections.

For the maximum clique problem, Jagota and Sanchis [114] proposed several enhancements to a basic greedy sequential heuristic, which include randomization, multiple restarts, and an adaptive mechanism. A randomization is embodied by a probabilistic greedy vertex selection rule. Three kinds of adaptation are studied: an update of the initial state (AI), an update of the probability distribution used by a selection rule (AW), and no adaptation at all (NA). The corresponding updates take place at each restart and are based on the information obtained in the previous restart. NA heuristic was shown to perform poorly compared to AI and AW. Grosso et al. [91] used similar techniques and developed a two-phase heuristic, called a *deep adaptive greedy search* (DAGS). In the first phase of DAGS, the modified variant of a sequential greedy heuristic is applied for all the vertices in the graph. The modification consists of allowing to swap already added vertices with the better candidates. The second phase is used for diversification purposes. It is a restart-adaptive greedy heuristic performed on a set of vertices that appear less frequently

in the cliques obtained during the first phase. Each vertex is assigned a weight associated with its quality as a potential candidate for a solution. Such weight is updated at each restart by means of a learning-like mechanism.

For the vertex coloring problem, an improvement procedure called an *iterative greedy* (IG) heuristic was proposed in [50, 51]. It is based on the observation that given a feasible coloring and an ordering in which vertices belonging to the same color class are grouped together, applying a sequential greedy heuristic to such an ordering will produce a solution at least as good as the previous one.

Local Search

In this section, we outline common local search strategies for both the maximum clique and vertex coloring problems and discuss their defining features.

Local search is an approach that iteratively refines a current solution by examining its local neighborhood and moving to higher-quality neighbors until no further improvement is possible. A solution's local neighborhood is defined by a *neighborhood function*, which maps a feasible solution to a set of "close" feasible solutions (neighbors). Local search methods vary in how they define this neighborhood function, the choice of search strategy, and the objective or evaluation function used to measure solution quality.

As suggested in [191], local search strategies for the maximum clique problem can be categorized into *legal* and *k-fixed penalty* ones. A legal strategy is a traditional local search, where a search space consists of legal (feasible) solutions, cliques; an evaluation function is the size of a clique; and a neighborhood function is a list of vertex operations to be performed to move from one clique to another. The most common neighborhood functions are (a, b)-interchanges, where a is the number of vertices removed from the current solution and b is the number of added vertices, with a usually smaller than b to ensure that such interchange increases the size of the solution by $(b - a)$.

A k-fixed penalty strategy, on the other hand, can be thought of as a technique that solves the decision version of the problem that answers the question "is there a clique of size k?" This type of a local search deals with infeasible solutions, sets that are not necessarily cliques. An evaluation function is defined as the number of edges in the set. By moving to sets with a larger number of edges, a local search attempts to eventually reach a feasible solution—a clique. For this type of a local search, a (1,1)-interchange is usually used, where a vertex to be removed is usually the one with the smallest number of neighbors in the solution and a vertex to be added is the one adjacent to the largest number of solution members. Such a technique does not guarantee finding a feasible solution; therefore, it is usually used as a part of a more sophisticated local search framework (section "Metaheuristics").

For the vertex coloring problem, the local search strategies can also be categorized into legal and k-fixed ones. Moreover, as discussed in [75], they can be

further grouped into *legal*, *k-fixed partial legal*, *penalty*, and *k-fixed penalty* ones. Here, the legal and the k-fixed penalty strategies, similarly to the local search strategies for the maximum clique problem, are the local searches on either feasible (proper) colorings or infeasible k-coloring, respectively. For the legal strategy, the local neighborhood is explored in an attempt of finding a feasible coloring with a fewer number of colors. An infeasible coloring is such that it contains at least one pair of adjacent vertices assigned the same color. An edge connecting a pair of such vertices is referred to as *conflicting*. For this strategy, a local search aims at performing moves resulting in the minimization of the number of conflicting edges in the solution.

Under a k-fixed partial legal strategy, the search space contains partial feasible k-colorings. A partial feasible k-coloring corresponds to a coloring of a subset of vertices $V' \subset V$ that uses k colors and is feasible with respect to already colored vertices in V'. The rest of the vertices in $V \setminus V'$ are not yet colored. The local neighborhood is explored in an attempt to find a complete feasible k-coloring. For a pure penalty strategy, the search space contains infeasible colorings, and the number of colors used is unfixed. The local search under this strategy tries to detect a feasible coloring with the minimum number of colors used. The quality function usually combines both the number of conflicting edges and the number of colors used.

The most common neighborhood functions for coloring are also interchanges [146]. They are performed by moving vertices from one color class to another, in an attempt of emptying one of the classes and, thus, reducing the number of colors used. Under the penalty and k-fixed penalty strategies, such interchanges are allowed to result in infeasible solutions.

Local search approaches also vary based on the rules of determining when to move to a better solution. By the *best improvement strategy*, the entire local neighborhood is explored, and the best neighbor is selected as a new solution, whereas the *first improvement strategy* updates the current solution with the first found neighbor of a better quality. However, with either of these strategies, a local search can get trapped in local optima of poor quality. To overcome this drawback and explore more regions of a search space, different techniques, e.g., allowing non-improving moves and recording the search process to direct the future exploration, have been devised and will be discussed in the following section.

Metaheuristics

In this section, we will review the most common metaheuristics for the maximum clique and vertex coloring problems. The metaheuristics can be classified with respect to various criteria [22]. Based on the number of solutions maintained at the same time, the algorithms can be divided into single-point search ones, encompassing most local search-based heuristics (section "Local Search-Based Methods"), and population-based ones (section "Population-Based Methods"), which deal with a pool of solutions at a time and perform evolution-like search processes.

Local Search-Based Methods

The most successful techniques to enhance local search have proven to be the ones that allow non-improving moves in the process of local neighborhood exploration. One of them, *simulated annealing* (section "Simulated Annealing"), allows moving to a worse solution with a certain probability, while another one, *tabu search* (section "Tabu Search"), records the moves and forbids (tabu) their future usage for a certain number of iterations to prevent cycling. Other successful local search-based methods have been devised and will be discussed in section "Other Local Search-Based Methods."

Simulated Annealing

Simulated annealing (SA) method is a randomized neighborhood search introduced by Kirkpatrick et al. [126] and covered in a separate chapter of this book. SA is analogous to a physical annealing—a process of heating up a solid material and slowly cooling it down in order to obtain a low-energy configuration. The main idea of SA is to iteratively select random candidate solution in the local neighborhood and, if it is of better quality, move to the candidate solution; otherwise perform the move with a certain probability of acceptance. Such probability is usually defined as $\exp(-\Delta)/T$, where Δ is a difference between the objective function values of the new and the current solutions and T is a parameter called the *temperature*. As the heuristic progresses, the probability is being decreased, ensuring fewer random walks and directing the search toward improvement. The rate at which the probability decreases is usually referred to as a "cooling schedule." The cooling schedule that follows the logarithmic law guarantees the convergence of the algorithm to a global optimum [22]; however, it may result in an exponential running time. Hence, faster cooling schedules are usually used in practice.

The most influential papers devoted to application of SA to the maximum clique problem date back in the late 1980s and mid-1990s and are all covered in [25]. Since, to the best of our knowledge, no novel SA methods for the maximum clique problem have been designed since then, we will follow [25] and briefly review here the same studies.

An application of SA to the maximum clique (independent set) problem was first described by Aarts and Korst in 1988 [1]. Without providing any experimental results, they proposed a *penalty function* method (k-fixed penalty strategy), for which a possible solution can be any set, not necessarily independent, and the quality of the solution is determined by the function $f(V') = |V'| - \lambda|E'|$, where V' and E' are the vertex and edge sets of the solution and λ is a certain weighting factor. A few years later, Jerrum [116] has theoretically proven a poor performance of SA application to the maximum clique problem. In particular, they studied a variant of SA with the temperature parameter fixed and a solution space consisting of legal cliques (legal strategy). Feo et al. [68] implemented SA for the maximum independent set problem utilizing the penalty method and observed that it was inferior to the greedy randomized adaptive search procedure (GRASP)

they proposed. However, the computational experiments presented by Homer and Peinado [108, 118] in the Second DIMACS Implementation Challenge showed that SA can be very effective. In their work, Homer and Peinado used the idea of penalty method described by Aarts and Korst and implemented it for the maximum clique problem. The results of the experiments on large graphs, reported in [108, 118], were quite promising, and SA was ranked one of the best heuristics in the Second DIMACS Implementation Challenge.

One of the first attempts to apply SA to the vertex coloring problem dates back to 1987, when Chams et al. [43] considered the following variant of the method. The neighborhood structure consists of k-colorings that are not necessarily legal (k-fixed penalty strategy), and the objective function to be minimized is defined by the number of conflicting edges. According to the experimental results reported in [43], the pure SA did not perform as strongly as when it was combined with other methods. In particular, when SA was combined with RLF [26], where RLF was used to generate color classes and SA to color the rest of the uncolored vertices, the performance of such combined method dominated all other methods tested in the paper (DSATUR and RLF). In 1991, Johnson et al. [119] conducted a detailed study of different schemes of SA adopted to the vertex coloring problem. The first scheme tested is a penalty function method, where the neighborhood structure is defined by infeasible solutions (penalty strategy), i.e., colorings with conflicting edges. The number of colors used in a particular solution is not fixed. Let C_i denote a color class, let E_i be an edge set in the subgraph induced by C_i ($i = 1, \ldots, k$; $1 \leq k \leq |V|$), and let $\Pi = (C_1, \ldots, C_k)$ be a solution. Then the cost (penalty) function associated with Π is defined as follows:

$$f(\Pi) = \sum_{i=1}^{k} 2|C_i| \cdot |E_i| - \sum_{i=1}^{k} |C_i|^2.$$

The first component of $f(\Pi)$ favors independent sets, while the second one favors large color classes. Minimization of $f(\Pi)$ results in eliminating the conflicting edges and reaching a legal coloring and also, as the authors argued, in potentially reducing the number of color classes as a side effect. The second scheme is by Morgenstern and Shapiro [151], and it utilizes the so-called *Kempe chains*, which are defined in [119] as the connected components of the subgraph induced by the union of two disjoint independent sets. In this method, the same cost function as in the penalty function method is retained, but the search space contains legal k-colorings. The new candidate solution is generated as follows. Two color classes C_i and C_j ($i \neq j$) are picked at random, and a Kempe chain defined by a set $H \subset C_i \cup C_j$ is constructed. Next C_i is replaced by $C_i \Delta H$ and C_j by $C_j \Delta H$, where $X \Delta Y$ denotes a symmetric difference $(X \backslash Y) \cup (Y \backslash X)$ between X and Y. The third scheme uses the same strategy as in [43], where the number k of colors is fixed and the objective is to minimize the number of conflicting edges in an attempt to find a feasible k-coloring. According to the results of the experiments reported by Johnson et al., none of the three methods was found dominant over the other.

A simplified version of SA with the temperature parameter remaining fixed was used by Morgenstern [118, 150] for the Second DIMACS Implementation Challenge. In this chapter, a new neighborhood structure, called *impasse neighborhood*, was defined. It turned out to be very effective, and many approaches have used it thereafter. This neighborhood structure operates with a fixed number k of colors and aims to improve a partial coloring, in which not all vertices are colored, to a complete coloring with k colors. A feasible solution is a partition of the set of vertices into $k + 1$ subsets $\{V_1, \ldots, V_k, V_{k+1}\}$, where $V_1, \ldots, V_k$ are independent sets representing a partial k-coloring and V_{k+1} is the set of uncolored vertices that needs to be eventually emptied in order to obtain a proper k-coloring of all vertices. A neighbor of a solution is obtained by moving a vertex v from V_{k+1} to one of the k independent sets, say V_i, and then moving to V_{k+1} all vertices from V_i that are adjacent to v.

Tabu Search

Tabu search was developed by Glover [85] and, independently, by Hansen and Jaumard [97]. See ▸ Chap. 31, "Tabu Search," for more details. It is a modified local search which allows performing moves yielding worse quality solutions, thus diversifying the search path. The algorithm uses the so-called *tabu lists* to store certain information about the previously visited solutions to forbid future local search moves that can result in cycling. The length of the tabu lists, called *tabu tenures*, allows to control the level of diversification and intensification of the search. Sometimes the tabu restriction is relaxed if a solution meets certain *aspiration-level* condition.

In 1989, Friden et al. [72] used tabu search ideas to construct a heuristic called STABULUS for finding stable (independent) sets. STABULUS is based on the k-fixed penalty local search strategy (see section "Local Search"), where the search space consists of the sets of size k, and the algorithm tries to minimize the number of edges in the set. To find an independent set of the largest cardinality, STABULUS is applied iteratively, incrementing k each time an independent set of size k is detected. Three tabu lists were used in STABULUS, one for storing visited solutions, and the other two contained added and deleted vertices.

A few years later, Gendreau et al. [82] proposed two simple variants of tabu search for the maximum clique problem, deterministic and probabilistic, where in the former, at each iteration, the entire set of the solution neighbors is explored and, in the latter, the sampling of the neighborhood is applied. In both variants the legal local search strategy was exploited, where the search space contains the feasible cliques and the objective is to find a clique of the maximum size. In the deterministic approach, it is allowed to remove only one vertex per iteration, while in the probabilistic it is a few at a time. Later these heuristics were enhanced with the diversification strategies [174], such as greedy restart and continuous diversification. The first one is a very simple approach of restarting the algorithm with the new solution after a certain number of iterations without improvement have been performed. A new solution is constructed from vertices that have not been visited yet or have been visited less frequently. The continuous diversification

works in "on-the-fly" mode. It guides the search path by evaluating each vertex addition/removal using the information on how frequently the vertex has been added to the solution and how long it has stayed in the solution. Both diversification techniques and their combination have proven to be beneficial if used along with the simple basic search. The more efficient and sophisticated the search is, the less improvement the diversification is able to add to it. It also did not appear to work well with the probabilistic version of the tabu search heuristic. The heuristics were tested on DIMACS instances, and the results were reported in [175].

A similar idea of prohibiting the future moves in order to prevent cycling was used in reactive local search (RLS) [17]. However, contrary to the traditional tabu search, where certain parameters (tabu tenure, depth of the search, etc.) are determined by the user through numerous preliminary experiments and are usually sensitive to certain specific structures of the instances, RLS determines all of this information dynamically within its execution. The length of tabu lists is adjusted based on previously stored information on how often the algorithm cycles, etc. Also, the algorithm is equipped with a memory-influenced restart procedure to provide additional long-term diversification. RLS showed excellent performance on DIMACS instances and is considered one of the best local search-based heuristics for the maximum clique problem.

Further efforts of applying tabu search to the maximum clique (independent set) problem include works by Wu et al. [117, 189, 192]. In [189], the authors developed an adaptive multistart tabu search approach that uses a k-fixed penalty local search strategy. The exploration of a search space is performed by moves that swap a vertex from the current solution with a vertex from the solution-constrained neighborhood. The algorithm employs a restart strategy, under which a new solution is constructed from the vertices that were less frequently used throughout the algorithm, that way visiting unexplored search space regions. The algorithm showed excellent performance when compared against several other state-of-the-art algorithms. The study of the relationship between the number of restarts and the quality of the evaluation function performed by the authors suggested that for structured instances, more frequent restarts yield better results, while the reverse holds for random graphs.

For the vertex coloring problem, tabu search techniques were first applied by Hertz and de Werra [103]. In their proposed algorithm, named TABUCOL, the search space consists of the complete k-colorings, where k is fixed. Some colorings might have conflicting edges, and, hence, the algorithm's goal is to move to the solutions with a smaller number of conflicting edges by changing the color assignment of the endpoints of conflicting edges. The tabu lists store these color assignments. The algorithm uses the same local search strategy as in [43] but yields better results than those obtained by SA in [43].

Blöchliger and Zufferey [21] designed several variations of the tabu search framework for the vertex coloring problem. The main ingredients they used were the partial k-coloring local search strategy and reactive tabu tenure, adjusted based on the fluctuations of the objective function.

Tabu search has also been applied to both the maximum clique and vertex coloring problems as a part of more complex metaheuristics, such as evolutionary

algorithms, yielding the so-called *hybrid algorithms* (discussed in section "Population-Based Methods").

Other Local Search-Based Methods

The greedy randomized adaptive search procedure (GRASP) [66, 67], described in the ▸ Chap. 23, "GRASP," is a simple metaheuristic that combines a constructive heuristic, a local search, and a restart policy. Its construction part uses both greedy and random selection rules. More precisely, the initial solution is built by randomly selecting a vertex from a so-called *restricted candidate list* (RCL), which consists of a certain number of the best candidates. This number ranges between 1 and the size of the candidate list, where the closer it is to 1, the greedier the selection rule is, and the closer it is to the candidate list size, the more randomness is involved. Every time a solution is constructed, an attempt to improve it is made using an appropriate local search technique (see section "Local Search"). The algorithm restarts a certain number of times, and the best-found solution is recorded. GRASP has been successfully applied to the maximum clique (maximum independent set) [2, 68, 169] and the vertex coloring problems [129].

Variable neighborhood search (VNS) [98, 149] is a metaheuristic that systematically explores different neighborhood structures of the same problem in the search for a better solution. This method is introduced in the ▸ Chap. 32, "Variable Neighborhood Search." VNS approach was applied to the maximum clique problem in [99]. For the vertex coloring, an algorithm based on VNS was proposed in [11]. It uses more than ten different neighborhoods and utilizes tabu search techniques. An extension of VNS, called *variable space search* (VSS), was proposed for the vertex coloring problem by Hertz et al. in [105]. In VSS, when the search is trapped in a local optimum, the entire search space, including the neighborhood searched and the objective function, is changed. The proposed algorithm, called VSS-Col, explores three different search spaces for the vertex coloring problem and yields excellent results. An *iterated local search* (see the ▸ Chap. 26, "Iterated Local Search" in this handbook for more information), which upon reaching a local optimum perturbs it so that the local search can keep going, was applied to the vertex coloring problem in [44, 156]. In [44], the authors analyzed the performance of different types of solution perturbations.

An algorithm based on *variable depth search* for the maximum clique problem, based on *k-opt* local search (KLS), was proposed by Katayama et al. [125]. The k-opt search is essentially an (a, b)-interchange with $a > b$ and $a + b = k$, where a vertices are removed from the current clique and b vertices from the local neighborhood are added to the solution yielding a clique of a larger size. The value k is determined dynamically throughout the execution of the algorithm. The reported results on selected DIMACS instances show the algorithm's competitiveness with RLS [17].

Pullan and Hoos [167] introduced a dynamic local search (DLS) algorithm for the maximum clique problem. DLS is based on alternating between a clique expansion phase, during which vertices are added to the current clique, and plateau search, during which vertices of the current clique are swapped with vertices outside of

the current clique. The selection of vertices is based on the penalties assigned to them dynamically during the search in a similar way used in DAGS [91]. When no more expansion or swapping is possible, a perturbation mechanism is applied to overcome search stagnation. The algorithm achieves substantial improvements over some state-of-the-art algorithms on many DIMACS instances. However, the algorithm has a disadvantage of being sensitive to the penalty delay parameter, which controls the frequency at which vertex penalties are decreased and needs to be determined beforehand by preliminary experiments and thorough calibration. This issue has been addressed in [166], where a modified algorithm, called a Phased Local Search (PLS), was proposed. Similarly to DLS [167], the algorithm is a combination of a clique expansion and a plateau search. Moreover, it operates three sub-algorithms, which differ in their vertex selection rule: random selection, random selection within vertex degree, and random selection within vertex penalties. In the latter one, the parameter responsible for the frequency of penalty decreases does not have to be fixed and defined externally as in DLS but is modified adaptively. PLS has shown to have a comparable and sometimes improved performance to DLS. Grosso et al. [92] performed a detailed computational study of the main components of DLS, such as usage of vertex penalties as a selection rule, plateau search, etc., in an attempt to design simple and efficient iterated local search techniques for the maximum clique problem. Another study that analyzes the key ingredients of RLS and DLS was performed by Battiti and Mascia in [16] and yielded several enhanced modifications of the mentioned algorithms.

Pullan et al. [168] introduced a parallelized hyper-heuristic algorithm for the maximum clique problem, called a cooperating local search (CLS). Hyper-heuristics [32] are heuristic search methods that manage the low-level heuristics. In particular, CLS is a methodology that controls the four PLS-based heuristics and dynamically reconfigures their allocation to cores, based on information retrieved from a trial in order to ensure the appropriateness of selected heuristic for a particular instance. In [5], Andrade et al. introduce efficient implementations of $(1, 2)$ and $(2, 3)$-interchange legal strategy local searches for the maximum independent set problem. These two local searches are integrated into an iterated local search metaheuristic, which according to the results reported in [5] yield great results, especially on large and difficult instances. Benlic and Hao [18] devised an algorithm, called breakout local search (BLS). BLS is an iterated local search, which, when a local optimum is discovered, applies a certain diversification strategy to perturb the current solution, so it can be used as a starting point to explore another region of the search space. The magnitude of perturbation is adapted dynamically according to the current search state. The results of the experiments showed that BLS competes favorably with RLS [17], VNS [99], and PLS [166].

Population-Based Methods

As opposed to local search algorithms, where one solution is maintained at each iteration, the population-based algorithms deal with several solutions (a *population*)

at a time. The new population is produced by certain interactions between the members of a current population. Namely, the population generation techniques in *evolutionary* and *genetic algorithms* (section "Evolutionary and Genetic Algorithms") are based on imitating the mechanisms of evolution, whereas in *ant colony algorithms* (section "Ant Colony Optimization"), the solution construction is inspired by the behavior of ants seeking paths to food sources.

Evolutionary and Genetic Algorithms

Evolutionary and genetic algorithms [86, 107] (see also the corresponding chapters in this volume) are inspired by the evolution and natural selection and are based on the following evolution principles: "the fittest survives," "two fit parents will have even fitter offsprings," and mutation. In the genetic algorithms, these principles are embodied with the help of respective mechanisms: *reproduction*, *crossover*, and *mutation* operators. At each iteration (in evolutionary terminology—*generation*) of an algorithm, the population of solutions (*individuals*) is subjected to all or some of those operators. Reproduction operator selects the "fittest" solutions, where the fitness level is represented by a *fitness function* (or objective function in optimization terms). Then, with the help of the crossover operator, the "offspring" solutions are produced as a result of merging one or several parts of one parent solution with one or several parts of another parent solution. The mutation operator changes a small part of a solution to provide randomization.

For the maximum clique problem, the most intuitive way to encode a solution is to use a binary array of the size equal to the cardinality of the given graph's vertex set, where an entry contains 1, if the corresponding vertex is included in the current solution, and 0, otherwise. The definition of the solution fitness function can vary. A fairly simple fitness function assesses the size of a vertex subset if it is a clique, or equals 0, otherwise. It can also be a little more complex. For example, it can combine several terms, such as the density of the induced subgraph and its size. It can also include a term to penalize the infeasible solutions.

The early work on adapting genetic algorithms to the maximum clique problem is covered in great detail in [25]. We will review in the following the same studies and also discuss several more recent advancements.

One of the earliest studies on the effectiveness of genetic algorithms at solving the maximum clique problem was done by Carter and Park [41]. The authors showed that the pure genetic algorithm performs poorly and designed several modifications, including an annealed fitness function and the modified crossover operators, to improve its performance. However, their results were still not satisfactory and led to a conclusion that genetic algorithms have to be significantly customized to be able to perform well and that they are very computationally expensive. Their later studies in [160] report that genetic algorithms are ineffective for solving combinatorial optimization problems and are inferior to other heuristics, such as simulated annealing. However, in another study [12], Back and Khuri showed quite the contrary results. They designed a genetic algorithm called GENEsYs with a fitness function which included a component for penalizing infeasible solutions. The performance of GENEsYs for the maximum independent set problem on graphs

with up to 200 vertices was promising and suggested that with the right fitness function, genetic algorithms are capable of yielding satisfactory results. In another approach, Murthy et al. [154] introduced a new crossover mechanism, called a *partial copy crossover*, and suggested to split a mutation operator into *deletion* and *addition* operators. The results presented in the paper are based on experiments with small graphs (up to 50 vertices), making it difficult to evaluate the algorithm's effectiveness.

In [71], Foster and Soule developed two variations of genetic algorithms for the maximum clique problem. One of them uses a different problem-encoding approach, referred to as a *grouping representation*, which instead of encoding each solution as a binary string uses an array that stores information about all the solutions in the current population. Such encoding scheme showed to increase effectiveness of the crossover operation. The other variant of the algorithm uses the time-weighted fitness function, which showed to improve the algorithm's performance. Hifi [106] adopted a genetic algorithm for solving the maximum weighted independent set problem. The necessary algorithm modifications included an introduction of a so-called *two-fusion crossover operator* and a replacement of a mutation operator by a *heuristic-feasibility operator*. The two-fusion crossover operator takes into account both the structure and the fitness of two parent solutions and produces two children, while the heuristic-feasibility operator transforms infeasible solutions into feasible ones. The main contribution of the designed approach is that it is easily parallelizable.

Aggarwal et al. [4] designed an optimized crossover mechanism (inspired by a heuristic CLIQMERGE proposed in [13] by Ballas and Niehaus) and applied it to the maximum independent set problem. The new crossover operator exploits the structure of the solution rather than its encoding. More precisely, when a crossover operator is applied to two solutions from the population, one of the new solutions is generated in such a way that it has the best fitness function value, while the other one is constructed in a way that ensures the diversity of the search space. Promising results of the proposed mechanism inspired authors of CLIQMERGE, Balas and Niehaus, to examine this strategy even further [14]. The authors also considered a different way of population replacement called a *steady-state replacement* and a different selection method. The results of the experiments reported in [14] were even more encouraging than those by Aggarwal et al. in [4].

Since most of pure genetic algorithms have shown to be not very effective for solving hard combinatorial optimization problems, they are usually enhanced by incorporating different techniques. Bui and Eppley [29] designed a hybrid strategy with vertex preordering phase and a local optimization at each iteration of the genetic algorithm. The authors claim that the performance of their hybrid algorithm is comparable to a continuous-based approach by Gibbons et al. [83] but inferior to tabu search- and simulated annealing-based approaches. Fleurent et al. [69] used tabu search and other techniques as alternative mutation operators. The performance of their approach was satisfactory with respect to the quality of the obtained solutions but rather disappointing with respect to the computational effort. Marchiori [143] developed an approach that combines a genetic algorithm

and a greedy heuristic, referred to as HGA. At each iteration of genetic algorithm, the greedy heuristic is applied to each member of the population to extract maximal cliques. That way, the genetic part of the approach provides exploration of the search space, while the greedy heuristic provides exploitation. Despite its simplicity, the approach has shown very good results [143, 144]. Zhang et al. [195] developed an approach called EA/G which uses similar techniques as HGA but also incorporates a guided mutation operator. The results of the experiments indicated that the algorithm was superior to HGA. Singh and Gupta [170] designed a framework which consists of two phases: generation of cliques by a steady-state genetic algorithm and extending them to maximal cliques by a heuristic which combines a randomized sequential greedy approach and the exact algorithm of Carraghan and Pardalos [40]. The results of the experiments show that the algorithm outperformed three other evolutionary algorithms, of Balas and Niehaus [14], Marchiori [144], and Fenet and Solnon [65], but its performance is inferior to that of one of the most effective local search-based techniques (RLS) of Battiti and Protasi [17].

Guturu and Dantu [94] designed an approach that combines an impatient evolutionary algorithm and a probabilistic tabu search. Brunato and Battiti [28] presented a hybrid algorithm similar to EA/G by Zhang et al. in [195]. In the proposed algorithm, which they refer to as R-EVO, the new solutions are initialized according to an estimated distribution which is based on knowledge extracted from the previous generations of the population. The solutions are then evolved through a simplified version of RLS technique.

Despite such a significant effort in studying and designing different variations of evolutionary and genetic algorithms, these approaches are still considered to be far less effective for the maximum clique problem than the local search-based ones. Perhaps, their inability to compete with the simple local search techniques lies in the fact that there is no intuitive relationship between the crossover operator and a discovery of improved cliques, and no such a meaningful operator has been devised yet [191].

For the vertex coloring problem, the solutions are usually encoded either as permutations of the vertices and referred to as *order-based encoding* or as color partitions and referred to as *direct encoding*. The direct encoding can further be categorized into the *assignment based* and *partition based*. Under the former one, a solution is represented as an array, where each entry is associated with a certain vertex and contains an index of the class the corresponding vertex belongs to. The latter one, on the other hand, represents a solution as a partition of the vertices into the color classes. Even though more satisfactory results have been achieved using direct encoding techniques, the order-based encoding has a powerful advantage of always corresponding to a feasible solution. Hence, it has been somewhat exploited as well [52, 61, 153].

One of the first attempts to apply evolutionary algorithms for vertex coloring problem is by Davis [52]. The author used order-based encoding, and a solution was evaluated using a greedy sequential heuristic, which colors the vertices in the order defined by the permutation. The algorithm yielded unsatisfactory results, as was also shown in [70]. All of the later efforts of applying evolutionary algorithms

to the vertex coloring problem involved the incorporation of other techniques, such as local search. The pioneers of this direction were Costa et al. [48] and Fleurent and Ferland [70], replacing the mutation operator by a simple descent method in the former and tabu search in the latter, respectively. In both papers the uniform crossover operator or its slightly enhanced modification [70] is used. The algorithms yielded slightly better results than their pure counterparts; however, the importance of designing better crossover operators was concluded in [70].

In later developments, the focus shifted to designing more advanced crossover operators tailored to the specifics of the problem of interest. More precisely, Dorne and Hao [56] used a specialized crossover based on the notion of the union of independent sets, which, with the combination of tabu search, led to a simple yet very powerful algorithm. Galinier and Hao [74] devised a new class of crossover mechanisms based on the partition of vertices into color classes rather than assignment of colors to vertices. The crossover operator called *greedy partition crossover* (GPX) transmits the subsets of color classes from parent solutions to the offspring solution. The power of this operator lies in its ability to retain some of each parent's structure in the offspring solution. The hybrid algorithm that uses this crossover operator and a tabu search was tested on large and difficult DIMACS instances and showed to be one of the best performing compared to other coloring algorithms [74]. A few years later, Glass and Prügel-Bennett [84] examined the hybrid algorithm of Galinier and Hao [74] by replacing the tabu search part of the algorithm with a steepest descent. The results of the experiments showed that the algorithm still remained powerful, which led to a conclusion that its success is due to the crossover operator. Hamiez and Hao [96] presented a *scatter search algorithm* devised for the vertex coloring problem. A scatter search is a subclass of evolutionary approaches, where replacements of the population are based not only on the improvement of the fitness function but also on the improvement of the population diversity; see the corresponding chapter in this handbook for more detail. The algorithm proposed in [96] was able to obtain results similar to the best-known approaches, but it was more expensive computationally.

Galinier et al. [76] proposed an *adaptive memory algorithm*, called AMACOL, where portions of solutions (color classes) are stored in a central memory and are then used to build new solutions. The algorithm uses a tabu search and yields results comparable to those obtained by an algorithm proposed in [74]. Malaguti et al. [140] designed a two-phase metaheuristic algorithm, called MMT, for the vertex coloring problem. The first phase is a combination of an evolutionary algorithm with a crossover similar to GPX from [74] and a tabu search with an impasse neighborhood, proposed in [150]. The second phase of MMT is a post-optimization procedure based on the set covering formulation of the problem. The algorithm yields promising results.

Ant Colony Optimization

Ant colony optimization, discussed in more detail in a separate chapter of this book, was originally introduced by Dorigo [55] and was inspired by the way the ants use pheromone to communicate with each other and search for better paths to a source

of food. As they search for food, each ant leaves a pheromone trail. All subsequent ants will follow the path with stronger pheromone. Since the pheromone evaporates over time, it will last longer on better (shorter) paths. This way, these paths will be followed by more ants and will subsequently have more pheromone laid. Eventually all the ants will follow one single best path. The main idea of ant colony optimization algorithms is to mimic this process. Each ant is thought of as a constructive heuristic, which builds a solution step by step using a greedy force and a *trail* information on the history of the search obtained from other ants.

First attempt to investigate ant colony capabilities to tackle the maximum clique problem was by Fenet and Solnon [65]. They introduced an algorithm, called Ant-Clique, that generates maximal cliques by repeatedly adding vertices to partial solutions, where each vertex is chosen according to the probability that depends on the level of pheromone. The pheromone deposition is proportional to the quality of previously constructed cliques. The performance of the algorithm was compared to that of [144] and showed that on average Ant-Clique is capable of reaching better solutions on the majority of tested instances. Youseff and Elliman [193] introduced an algorithm that combines the capabilities of ant colony optimization and local search techniques with prohibition rules. The algorithm was compared to the genetic local search of [144] and has shown to be somewhat competitive. Incorporation of local search techniques into the ant colony algorithm has also been addressed in [173] and has shown to improve the solution process.

One of the first ant colony algorithms for the vertex coloring problem was designed by Costa and Hertz [47]. Their algorithm, called ANTCOL, considers each ant as a constructive heuristic derived from DSATUR [26] and RLF [131]. Even though the algorithm was not superior of the best graph coloring heuristics of that time, its performance was still promising enough to encourage more research in this direction. Dowsland and Thompson further applied the same algorithm for examination scheduling [57] and later enhanced it by strengthening the construction phase and incorporating it with a tabu search improvement phase [58].

Hertz and Zuffrey [104] argued that an algorithm, where each ant has only a minor role, is still competitive with the other ant algorithms. Namely, in their proposed algorithm, each single ant does not build an entire solution but only colors a single vertex. A similar idea was explored by Bui et al. [30]. In their algorithm, instead of coloring the entire graph, each ant colors only a portion of the graph. The performance of the algorithm seemed to be rather encouraging. Plumetta et al. [163] proposed an ant local search algorithm, where each ant is considered as a local search, rather than a constructive heuristic. The algorithm showed to be competitive with other evolutionary methods available at that time.

Zufferey [197] conducted an analysis of importance of different ant roles, ranging from insignificant ones, used to make a minor decision, to more crucial ones, by performing a refined local search. It was shown experimentally that the ant algorithms are more efficient when ants have strong roles like local search procedures.

Heuristics Based on Continuous Formulations

A remarkable result by Motzkin and Straus [152], which provides an elegant connection between maximum cliques and a certain quadratic program, has been extensively explored to devise efficient heuristics for the maximum clique problem. Some of the early methods are discussed in detail in [25].

Given a graph $G = (V, E)$, let A_G be the adjacency matrix of G. Consider the following quadratic problem:

$$\max_{x \in \Delta^n} g(x) = \sum_{\{i,j\} \in E} 2x_i x_j,$$

where $\Delta^n = \left\{ x \in R^{|V|} \mid \sum_{i \in V} x_i = 1, x_i \geq 0, i \in V \right\}$ is the standard simplex in $R^{|V|}$.

Motzkin and Straus [152] showed that the size of a maximum clique in G is equal to:

$$\omega(G) = \frac{1}{1 - g(x^*)},$$

where x^* is a global maximizer of the above problem.

One perceived drawback associated with the Motzkin-Straus quadratic program is that its solution does not always correspond to a clique in the graph; hence, some postprocessing is required to obtain clique's vertices based on a solution to the continuous problem. Bomze [24] proposed a regularization of the Motzkin-Straus formulation by adding $\frac{1}{2} x^T I x$ to the objective, where I is the corresponding identity matrix. He has shown that every local maximum of the modified formulation corresponds to a maximal clique in the graph as follows: C is a maximal clique of G if and only if x^*, such that $x_i^* = 1/|C|$ if $x_i \in C$ and $x_i^* = 0$ otherwise, is a local maximum of the regularized Motzkin-Straus formulation. Hungerford and Rinaldi [110] established more general conditions on the regularization term that guarantee the one-to-one correspondence between the local maxima of the regularized Motzkin-Straus formulation and maximal cliques in the graph.

One of the early approaches based on the Motzkin-Straus result was an iterative clique retrieval procedure [157], which turned out to be of very high computational cost and was only able to solve instances on less than 75 vertices. Gibbons et al. [83] proposed to modify the Motzkin-Straus formulation so that it becomes a problem of optimizing a quadratic function over a sphere. Even though such problem is polynomially solvable, it, however, yields approximate solutions that need to be rounded. Similar approaches, with a few advances, can be found in [33, 34]. Simple heuristics based on formulations of the maximum independent set problem as maximization of polynomial functions over a unit hypercube were studied in [3].

Gruzdeva [93] proposed to add a non-convex quadratic constraint represented by the difference of two convex functions (DC contraints) [109] to a continuous formulation of the maximum clique problem. The author showed that the proposed approach is competitive with other methods based on continuous formulations.

Massaro et al. [145] transformed the Motzkin-Straus formulation of the maximum clique problem into its corresponding linear complementary problem (LCP) [49]. To deal with the inherent degeneracy of the derived LCP, the authors designed a variation of a classical Lemke's method [132] with an effective "look-ahead" pivot rule.

Butenko et al. [38] proposed variable objective search, a metaheuristic framework that performs a local search with respect to different alternative formulations of the same combinatorial optimization problems. To test their method, authors considered the maximum independent set problem and its equivalent non-convex programming formulations discussed in [3].

Recently, the Motzkin-Straus formulation was extended to a hierarchy of higher-order standard polynomial programming formulations in [35]. Namely, the authors of [35] showed that for all $k \in \{2, \ldots, \omega\}$, where $\omega \equiv \omega(G)$:

$$\binom{\omega}{k}\left(\frac{1}{\omega}\right)^k = \max_{x \in \Delta^{|V|}} \sum_{C \in \mathcal{C}_k} \prod_{i \in C} x_i,$$

where $\mathcal{C}_k$ is the set of all cliques of cardinality k in G. The above formulation is referred to as (P^k). They have shown that a local maximizer of (P^{k+1}) is also a local maximizer of (P^k), which establishes the hierarchical structure of the formulations. In particular, all local maximizers of (P^ω) are global. The support of a local maximizer of (P^k) was proved to correspond to a so-called strongly part-maximal multipartite clique in G (see [35] for the definition), which can be easily converted into a clique. To obtain the direct correspondence of local maximizers to maximal cliques, the authors proposed regularized versions of (P^k) in [138]. The numerical experiments exploring the performance of both the original and regularized formulations for $k \in \{1, \ldots, 5\}$ in conjunction with a first-order solver showed that the results improve with the increase in k and that the non-regularized formulations appear to perform slightly better than their regularized counterparts (since regularizations introduce poor-quality local maxima).

Another notable result—the "sandwich theorem" [127]— has inspired several heuristic algorithms for both the maximum clique (independent set) [31, 59] and vertex coloring problems [60, 88, 122]. For a given graph G, the sandwich theorem states that the following relationship holds:

$$\omega(G) \leq \theta(\bar{G}) \leq \chi(G),$$

where $\theta(\bar{G})$ is the Lovász theta, which can be computed in polynomial time [135].

In [31], the authors study rank-one and rank-two formulations of the semidefinite programming (SDP) formulation of the Lovász theta number. Based on the obtained further continuous formulations, they designed heuristics for the maximum

independent set problem. As for the vertex coloring problem, the proposed solution algorithms also used a semidefinite programming (SDP) formulation of the Lovász theta and were capable of obtaining near-optimal solutions for problems of medium sizes [60].

Other Heuristics

Many other interesting heuristic approaches have been devised to tackle the maximum clique and the vertex coloring problems. Balas and Niehaus [13] developed a heuristic, called CLIQMERGE, that generates large cliques by repeatedly finding a maximum clique in the subgraph induced by the union of two cliques. Such procedure is performed by finding the bipartite matching of the complement subgraph. A heuristic for the maximum independent set problem based on the operation of *edge projection*, which is a specialization of Lovász and Plummer's clique projection [136], has been designed in [142]. Goldberg and Rivenburgh [87] used a *restricted backtracking* for detecting cliques in graphs. DNA computing was applied to the maximum clique problem in [155, 194].

Neural network approach has been very popular in tackling the maximum clique problem since the mid-1980s. A detailed discussion on neural network-based methods applied to the maximum clique problem developed before 1999 is presented in [25]. The interested readers are also referred to [90, 111, 112, 115]. The recent success of deep learning applications has motivated the development of heuristics based on graph neural networks. However, their performance currently lags behind established approaches [6, 148].

For the vertex coloring problem, the neural network approach has also been applied in [19, 20, 81, 113, 162, 176, 177]. An algorithm which inherits ideas from quantum mechanics was proposed in [179]. Heuristics based on Douglas-Rachford algorithm were developed in [7, 8].

Since many large-scale real-world networks are sparse, with most vertices having a low degree, heuristics specifically designed for such networks effectively exploit these structural properties. These methods typically integrate scale-reduction or kernelization techniques with other heuristic approaches to enhance efficiency and solution quality [2, 130, 180, 181].

Computational Results

In this section, we summarize best computational results achieved by heuristic algorithms on selected hard benchmark instances for the problems of interest. We disregard running times and focus on the quality of the reported solutions. More specifically, we report only the best-found solutions for the instances with no known optima and list the methods that were able to attain these solutions.

The results for the maximum clique instances are presented in Table 1. First three columns contain information about the graph instance (name, the number of vertices $|V|$, and edges $|E|$). In the next columns, we report the size of the largest

detected clique (ω_{lb}) and list references of the methods that were able to attain such solution. Note that the first two graph instances in Table 1 are from the Second DIMACS Implementation Challenge [53], the next three instances are from the Tenth DIMACS Implementation Challenge [54], and the rest of them are from the so-called CODE family [172], which is a collection of challenging graph instances arising from the coding theory.

The computational results related to the coloring problem are contained in Table 2. Here, the first three columns are the same as in Table 1. The fourth and fifth columns contain the size of the lower (χ_{lb}) and upper (χ_{ub}) bounds on the chromatic number. The majority of the results related to the lower bound size is by [102]. The last column in Table 2 lists the references to the algorithms which have achieved χ_{ub}. The first 27 instances presented in this table are from the Second DIMACS Implementation Challenge [53]; the next 12 are from Stanford Large Network Dataset Collection [133], referred to as the SNAP; and the last 8 are from the Tenth DIMACS Implementation Challenge [54].

More detailed discussions on computational performance of various heuristics can be found in the surveys [77, 139, 191].

Conclusion

In this chapter, we discussed various heuristics for the maximum clique and the vertex coloring problems that were developed in the past several decades. Local search-based metaheuristics have demonstrated greater effectiveness compared to population-based approaches. Nevertheless, the latter continue to attract significant research interest. When combined with efficient local search techniques, population-based methods can achieve competitive results and offer the additional advantage of easy parallelization. Meanwhile, heuristics inspired by continuous optimization present a promising avenue for future research. In particular, refining continuous formulations by eliminating poor-quality local optima would facilitate the rapid computation of high-quality solutions using standard gradient-based solvers. Significant efforts are being devoted to the development of artificial intelligence and quantum computing-based methods. However, their effectiveness remains to be established.

Abstract

The lot sizing problem consists in determining lot sizes and their scheduling to meet the required demands. This chapter focuses on a multiplant lot sizing problem with a planning with multiple items, each plant with their own demands and multiple periods. In spite of not been widely investigated, their theoretical and practical importance are supported by applications from private and public sectors. The first part of this chapter pays special attention to the multiplant uncapacitated lot sizing problem (MPULSP). In particular, a novel network flow formulation is introduced, and some computational experiments were carried out to assess the performance of commercial solvers in solving a number of large instance problems. Moreover, a comparative analysis is performed by considering two other formulations for the MPULSP found in the literature. The second part of this chapter turns its attention to the multiplant capacitated lot sizing problem (MPCLSP) and some extensions that add flexibility to the production process. Mathematical formulations are presented and evaluated through computational results.

Keywords

Lot sizing · Mathematical formulations · Comparative analysis

Introduction

Lot sizing plays an important role in improving the profits of the companies in addition to other goal effects, as, for example, the environmental impacts. Many features and requirements of the companies influence and impose additional constraints and limitations on a lot sizing problem. As a consequence, a number of variants on this subject, each of them suitable for particular applications, can be found in the literature.

Buschkühl et al. [3] and Karimi et al. [11] defined, in a comprehensive literature review, the primary characteristics and existing variants of lot sizing problems. Nevertheless, Karimi et al. [11] do not mention lot sizing problems involving more than one plant, best known as multiplant lot sizing problems (MPLSP). Buschkühl et al. [3] briefly discuss the MPLSP, but because of the general scope of their review in dynamic lot sizing problems, they do not go into detail on this problem. Highly relevant in certain industry sectors such as mattress companies [17], the MPLSP has received a reasonable amount of attention in the last two decades even though a very small number of solution methods have been studied to approach it. This chapter, therefore, focuses on the MPLSP presenting the state-of-the-art solution methods and mathematical models.

There are two cases of the MPLSP in the literature: the capacitated case (MPCLSP) [17] and the uncapacitated case (MPULSP) [16]. The studies present in [4,5,17,20] approach two mathematical formulations for the capacitated case. To approach the uncapacitated case, it is enough to delete the capacity constraints of

the capacitated models. Both problems have been proved to be NP-hard [16]. The solution methods of the literature mostly focus on the MPCLSP [5, 14, 17, 18].

The Lot Sizing Problem

Lot sizing is a research topic widely studied due to its importance for the production planning. According to Karimi et al. [11], lot sizing belongs to the medium-term decision-making, when it is necessary to determine the timing and how much of the items to produce to meet the demands and minimize the total costs. This tactical planning is responsible for the productivity of the company, where the decisions must consider the requirements and limitations of the manufacturing process.

Many variants of the lot sizing problem and solution methods to solve them can be found in the literature. Among the numerous features that define the different variations of the problem, it is highlighted the finite planning horizon divided into periods, single or multiple production levels, single or multiple items, single or multiple machines in each plant, single or multiple plants, uncapacitated or capacitated, stochastic or deterministic demand, with or without setup time, and limited or unlimited inventory capacity or not. These characteristics define the primary traits of the classical lot sizing problems.

The next section further describes these features loosely based on [11].

Demands

The demand of an item is the required amount to produce in the desired production planning. This amount comprises the estimated value according to the history of the productive process or the quantity of the order of clients. The types of demands are stationary (static or dynamic). Stationary demands mean they do not vary over time. The values of dynamic demands may change over time [23].

Apart from being stationary or dynamic, the demands can be deterministic or nondeterministic. The determinism on demands means that they are known beforehand, and most of the existing studies in the literature consider this type of demand. The nondeterministic or stochastic demands depend on a probability function or an information subject to uncertainty.

Planning Horizon

Scheduling the production up to a certain time in the future is a relevant characteristic of lot sizing problems. In general, one defines this planning as finite, infinite, and rolling. The main characteristics regarding these types of planning horizon are enumerated as follows.

- The time interval of a finite planning horizon is limited.
- There is no time limit imposed in an infinite planning horizon. Demands, in this case, are generally stationary.
- The rolling planning horizon is a strategy that projects the actual planning horizon that has been scheduled to part of or to the entire next interval of time. This planning aims at keeping running the production of a firm based on past planning.

The lot sizing problems with rolling planning horizon are hard to evaluate as discussed in [8].

Items
The production system can have a single or multiple types of items to produce. In single-item systems, only one type of item is considered as the final product. Multi-item systems involve the production of more than one type of item as the final product.

Multi-item production may be an item independent problem. In problems with item dependency, an item can only be manufactured after the production of another item. Dependencies on items are usually found in problems with more than one level.

Levels
The dependence between tasks performed for the transformation of the raw material into a final product is modeled by levels in the production system.

- Single level: In a single-level production system, the transformation of the raw material into the final product (item) is direct. This means that there are no intermediate steps, that is, the production of items is independent.
- Multilevel: The production of some final product (item) depends on the operations performed at different levels of the production system. In other words, the production of an item depends on the availability of items produced at previous levels.

Plants
A production system must have a facility (plant) where the items are produced. There are problems in which there is more than one production facility. In these multiplant lot sizing problems, each plant has its own demand and capacity, and lot transfers between plants are possible subject to the transportation costs.

Machines
A production facility may have a single or multiple machines to produce items. Multiple parallel machines produce the same items. The problem can be uncapacitated and capacitated when the machine production is limited by an upper bound and is located at the same facility.

Setup Structure
A setup cost is incurred to produce an item type, and a setup time is required to prepare the machine. These two components characterize the machine setup structure in a production system, which can be classified as simple or complex. In the simple setup, the time and cost of preparation are not influenced by previous periods' production. In the complex setup, both time and cost of setup may be dependent on the sequencing of tasks and decisions taken in previous periods, as follows:

- Setup carry-over: If the preparation of the machine is ready at the end of a period for the production of a certain type of item, there is no need to re-prepare the machine in the beginning of the following period, if the same type of item is the first to be produced.
- Setup crossover: This type of setup enables a setup starting at the end of a period be interrupted and resumed in the beginning of the next period.
- Setup by similarity: The preparation is carried out taking into consideration the group of items to be produced. Similar items can be produced without additional preparation if they are produced in the sequence.
- Sequence-dependent setup: The preparation is dependent on the sequence determined for the production of the items.

Inventory and Backlogging
When the amount of production of an item exceeds the demand for the item in the period produced, the production stock may be subject to costs, and it may be restricted to the capacity of the storage warehouse, among other factors [17, 18]. In another case, a delay (backlogging) in the supply of demand is allowed, subject to some penalty costs.

Some additional characteristics for the MPLSP are presented as follows.

Flexibility
In the standard lot sizing problem with multiple plants, each item can be produced at any plant, incurring setup costs and time before production begins. This scenario assumes complete plant flexibility. However, in practice, installing plants with full flexibility can be prohibitively expensive, particularly if the products vary significantly. Consequently, it may be more practical to implement limited flexibility, where each plant is capable of producing only specific types of items.

Clients
The MPLSP involves producing various items across multiple plants. In a network of geographically dispersed plants and clients, distributing these items can be managed through direct shipments from the plants to the clients. This requires careful consideration of transportation costs to optimize the overall distribution efficiency.

On the Complexity

Wagner and Whitin [23] proved that the uncapacitated lot sizing problem with multiple items (or a single item), setup time, and deterministic demand can be solved in polynomial time by a dynamic programming algorithm. Bitran and Yanasse [1] proved that the capacitated lot sizing problem is NP-hard. Maes et al. [13] proved that to decide whether an instance of the capacitated lot sizing problem with setup times is feasible is NP-complete. The existing studies include new problems, reviews, and surveys and they present methods, their computational complexity, and

mathematical formulations [2,3,8,10,11,15]. The computational complexity of the different variants of the lot sizing problem depends on their features, such as limited capacity and existence of setup times.

Among the plethora of variants and possibilities to approach this problem, this chapter limits the attention to the description of the multiplant lot sizing problem with setup time and unlimited inventory.

Different from most uncapacitated lot sizing problems that, even with setup times have polynomial time solution, the MPULSP has been proved NP-hard [16].

The Multiplant, Multi-item Lot Sizing Problem

The multiplant lot sizing problem (MPLSP), where all plants produce the same items and have limited capacity, is known as multiplant capacitated lot sizing problem (MPCLSP). For this problem, the literature on mathematical formulations presents two different mixed integer programs. First, in this chapter, the formulation proposed in [16] is presented.

Let one define the following parameters of the problem.

n: number of items
m: number of plants
p: number of periods
cs_{ij}: setup cost for producing item i at plant j
c_{ij}: unitary production cost of item i at plant j
h_{ij}: unitary inventory cost of item i at plant j
r_{jk}: unitary transportation cost of items from plant j to plant k
d_{ijt}: demand of item i at plant j in period t
b_{ij}: processing time of item i at plant j
f_{ij}: setup time for preparing the machine for producing item i at plant j
C_{jt}: capacity of production at plant j in period t

To formulate the MPCLSP, Sambasivan and Schimidt [17] considered the following variables:

x_{ijt}: the quantity of item i produced at plant j in period t
y_{ijt}: binary setup variable that receives 1 if item i is produced at plant j in period t, and 0, otherwise
I_{ijt}: variable that controls the inventory of item i at plant j at the end of period t
w_{ijkt}: variable that specifies the amount of item i transferred from plant j to plant k in period t

$$\min \sum_{i=1}^{n} \sum_{j=1}^{m} \sum_{t=1}^{p} (cs_{ij} y_{ijt} + c_{ij} x_{ijt} + h_{ij} I_{ijt} + \sum_{k \neq j} r_{jk} w_{ijkt}) \tag{1}$$

subject to

$$x_{ijt} + I_{ij,t-1} - I_{ijt} - \sum_{k \neq j} w_{ijkt} + \sum_{l \neq j} w_{iljt} = d_{ijt} \qquad \forall i, j, t \qquad (2)$$

$$\sum_{i=1}^{n} (b_{ij} x_{ijt} + f_{ij} y_{ijt}) \leq C_{jt} \qquad \forall j, t \qquad (3)$$

$$x_{ijt} \leq L y_{ijt} \qquad \forall i, j, t \qquad (4)$$

$$y_{ijt} \in \{0, 1\}, x_{ijt} \geq 0, I_{ijt} \geq 0, w_{ijkt} \geq 0 \qquad \forall i, j, t; j \neq k \qquad (5)$$

The objective function (1) is the minimization of the sum of setup, production, inventory, and transfer costs. Constraints (2) balance inventory production transference and demand of items at each plant in each period t. Constraints (3) limit the time production capacity of plant-period (j, t). Constraints (4) ensure the production of item i at plant j in period t can occur only if the corresponding setup is performed. Finally, constraints (5) define the domain of the variables.

Silva [19] proposed a mathematical formulation for the MPULSP based on the study found in [9]. Carvalho and Nascimento [4] refined this integer program and the formulation, presented next.

This formulation possesses the following parameters:

$$\bar{c}_{ijtku} = \begin{cases} 0, \text{ if } u < t, \\ c_{ij} + \chi_{ijtku}, \text{ otherwise} \end{cases}$$

where

χ_{ijtku} is the inventory and transfer costs for producing one unit of item i at plant j in period t to meet the unitary demand of item i at plant k in period u. It is given by

$$\chi_{ijtku} = \min\{(u-t)h_{ij} + r_{jk}, \min_{1 \leq v \leq p} \{(u-t)h_{iv} + r_{jv} + r_{vk}\}, (u-t)h_{ik} + r_{jk}\} \qquad (6)$$

$\bar{c}_{ijtku}$ is the cost of producing one unity of item i at plant j in period t plus the least inventory and transportation costs of this unity of i from plant j to plant k from period u to t. In addition to y_{ijt} defined as previously, the following variables are used:

x_{ijtku} is the production of item i at plant j in period t to meet the demand of item i at plant k in period u.

The model of [4] for the MPCLSP is

$$\min \sum_{i=1}^{n}\sum_{j=1}^{m}\sum_{t=1}^{p}\sum_{k=1}^{m}\sum_{u=1}^{p}(\overline{c}_{ijtku}x_{ijtku}) + \sum_{i=1}^{n}\sum_{j=1}^{m}\sum_{t=1}^{p}(cs_{ij}y_{ijt}) \tag{7}$$

subject to

$$\sum_{j=1}^{m}\sum_{t=1}^{u} x_{ijtku} = d_{iku} \qquad \forall(i,k,u) \tag{8}$$

$$\sum_{i=1}^{n}\left(f_{ij}y_{ijt} + \sum_{k=1}^{m}\sum_{u=t}^{p} b_{ij}x_{ijtku}\right) \leq C_{jt} \qquad \forall(j,t) \tag{9}$$

$$x_{ijtku} \leq \min\left\{d_{iku}; \left\lfloor \frac{C_{jt} - f_{ij}}{b_{ij}} \right\rfloor\right\} y_{ijt} \qquad \forall(i,j,t,k,u) \tag{10}$$

$$x_{ijtku} \in \mathbb{N} \qquad \forall(i,j,t,k,u) \tag{11}$$

$$y_{ijt} \in \{0,1\} \qquad \forall(i,j,t) \tag{12}$$

The objective function aims at minimizing the total costs: production, setup, inventory, and transference between plants. Constraints (8) ensure that the demands of all plants are met; constraints (9) ensure the production capacity at each plant in every period is not violated. In constraints (10), if item i is produced at plant j in period t, then y_{ijt} assumes value 1, that is, a corresponding setup cost must be added to the total cost. Constraints (11) and (12), respectively, define the domain of the decision variables.

It is noteworthy that the number of variables of this formulation asymptotically grows faster with the size than the variables of the model of [17]. Consequently, there is a major influence on the performance of exact solution methods in solving the problems regarding different sizes of instances.

As some applications involving MPLSP have a large number of items, heuristics are solution methods that play an important role in this problem, as discussed in the next section.

Solution Methods

In the literature, one can find a few heuristic methods specially designed for solving both MPULSPand MPCLSP. They are a simple heuristic based on lot transfers [17], a Lagrangian heuristic [18], a Greedy Randomized Search Procedure (GRASP) with path relinking [14], and Lagrangian heuristics [4].

The Lagrangian heuristic proposed in [18] aims at finding a heuristic solution for the relaxed uncapacitated problem and posteriorly transfers lots of production of items as an attempt of achieving a feasible solution for the MPCLSP. The authors take into consideration the mathematical formulation proposed in [17] to develop their method. They evaluate the performance of the Lagrangian heuristic by using

artificial instances they generated. As a result of the experiments, the Lagrangian heuristic systematically achieved better results than the first heuristic proposed to solve the MPCLSP, found in [17].

Later, Nascimento et al. [14] besides proposing a novel hybrid metaheuristic set forth a new set of instances with a more diversified structure and classified them as indicated in the section of experiments of this paper. In their experiments using the set of instances introduced in [18], they show that the hybrid metaheuristic, GPheur, had a better performance than the Lagrangian heuristic [18]. In order to better investigate the performance of their metaheuristic, they carry out experiments with the set of instances they suggested. For these instances, GPheur could not find optimal solutions for the hard instances, even though the heuristic method achieved better results than CPLEX v. 7.5.

More recently, Carvalho and Nascimento [4] proposed a pair of Lagrangian heuristics that make use of CPLEX v.12.6 to find the optimal solution of the uncapacitated problem, by considering the model introduced in [19]. One is a Lagrangian heuristic, named by the authors as Lag, and the other is a hybrid version, referred to as LaPRe. For finding feasible solutions for the capacitated problem, both feasibility strategies, adapted for tackling the MPCLSP from [21] and the local search phase of the GRASP from [14], were embedded in the strategy. To enhance the quality of the solutions, the path relinking, also proposed in [14], was used to compose the hybrid Lagrangian heuristic. In experiments, the authors show that both LaPRe and Lag significantly outperformed GPheur achieving feasible solutions for the whole set of instances. However, for smaller instances, CPLEX v. 12.6 outperformed the Lagrangian heuristics on most of the classes of instances. On the other hand, when considering large instances, CPLEX could not find good solutions for all instances in a limit of 1800 seconds established by the authors to run each instance of the experiment, whereas the Lagrangian heuristics presented better lower and upper bounds.

Network Flow-Based Formulation

Because of the importance of the multiplant lot sizing problems, this chapter gives a new insight to the MPULSP. For this, it presents a network flow-based formulation for the MPULSP, different from the formulations proposed in the literature.

In unlimited capacity lot sizing problems, the production of items is independent. Therefore, the formulation will disregard item indices, without loss of generality.

In a network flow, consider the following parameters:

cs_j: setup cost of an item at plant j
d_{jt}: demand in plant j in each period t
h_j: inventory cost at each plant j
c_j: production cost of an item at plant j
r_{jk}: transfer cost between plants j and k
M: sum of the demands of every plant-period

Therefore, if a machine is ready to produce an item, the cost in producing at plant j in period t to meet the demand at plant k in period u is

$$\chi'_{jtku} = c_j + \min\{(u-t)h_j + r_{jk}, \min_{1\le v\le p}\{(u-t)h_v + r_{jv} + r_{vk}\}, (u-t)h_k + r_{jk}\}$$

In the most general case, other plants can be considered in the transfer of the produced item. To calculate the costs of the arcs, it is necessary to determine them by solving the minimum cost problem between the pair of vertices of the network. Consider a toy example with two plants and three periods as illustrated in Fig. 1.

In Fig. 1, node 0 is the source of the network. It receives the sum of the demands of all periods in each plant. The nodes represented as yellow rectangles are the setup nodes, whereas round blue nodes indicate the demands to be met. The labels of yellow nodes, s_{kt}, indicate the setup at plant k in period t. The labels of round nodes, kt, represent the planning in the plant k at period t. A sink node is associated with each blue node, to represent the addressing of the corresponding demand. Arcs with heads incident to demand nodes are only those with tails in setup nodes or with tails from the immediately previous period at the same plant. These conditions ensure the machine to be prepared for producing that item. Aggregated to such arcs are the aforementioned costs. Moreover, arcs with head in setup nodes have tails in the production or source nodes.

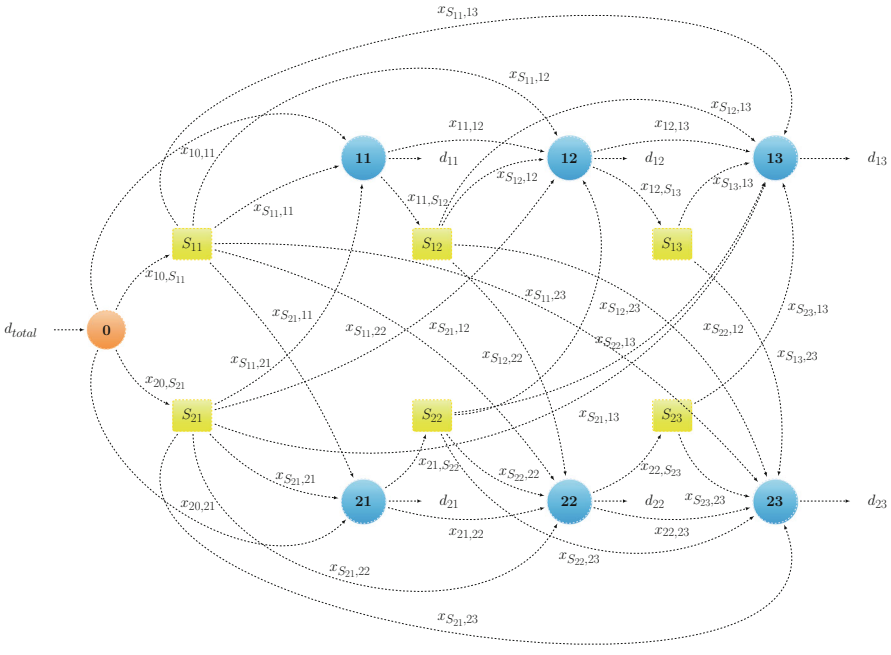

Fig. 1 Example with two plants and three periods

To formally introduce the network flow-based problem, referred to here as NYC, consider the following variables:

y_{jt}	is a binary setup variable that receives 1 if there is setup to produce demands at plant j in period t, and 0, otherwise.
$x_{jt-1,jt}$	is an arc that carries demands from plant j not produced up to period $t-1$.
$x_{jt-1,s_{jt}}$	is the amount of demand not met up to period $t-1$ to be produced at plant j in period t.
$x_{s_{jt},ku}$	is the amount of demand produced at plant j in period t to meet the demand of plant k in period u.

The domain of the indexes is the following: $j, k \in \{1, \ldots m\}$; $t \in \{1, \ldots, p\}$; $u \in \{t, \ldots, p\}$. The general formulation is, thus, the following:

$$\min \sum_{j=1}^{m}\sum_{k=1}^{m}\sum_{t=1}^{p}\sum_{u=t}^{p} \chi'_{jtku} x_{s_{jt},ku} + \sum_{j=1}^{m}\sum_{t=1}^{p} cs_j y_{jt} \tag{13}$$

subject to

$$\sum_{j=1}^{m}(x_{j0,s_{j1}} + x_{j0,j1}) = \sum_{j=1}^{m}\sum_{t=1}^{p} d_{jt} \tag{14}$$

$$x_{jt-1,s_{jt}} = \sum_{k=1}^{m}\sum_{u=t}^{p} x_{s_{jt},ku} \qquad \forall j, t \tag{15}$$

$$x_{jt,s_{j,t+1}} + x_{jt,jt+1} - x_{jt-1,jt} = 0 \qquad \forall j, t = 1, \ldots, p-1 \tag{16}$$

$$\sum_{j=1}^{m}\sum_{t=1}^{u} x_{s_{jt},ku} = d_{ku} \qquad \forall k, u \tag{17}$$

$$x_{jt-1,s_{jt}} \leq M y_{jt} \qquad \forall j, t \tag{18}$$

$$y_{jt} \in \{0, 1\} \qquad \forall j, t \tag{19}$$

$$x_{s_{jt},ku}, x_{jt-1,s_{jt}}, x_{jt-1,jt} \geq 0 \qquad \forall j, k, t \leq u \tag{20}$$

Constraints (14) define the set of source nodes assigning to them the sum of the demands of the plants. Constraints (15) refer to the flow conservation constraints of setup nodes. Constraints (16) ensure the flow conservation of production nodes. Constraints (17) ensure that the demands of all plants are met. Constraints (18) ensure the setup variables to be 1 if there is production in period t, whereas constraints (19) and (20) define the domains of the variables of the model.

In the next section, computational experiments were carried out to evaluate the performance of CPLEX v.12.6 with the three models discussed in this chapter.

Computational Experiments

For the analysis of the proposed network flow-based model, it was performed an experiment comparing its results with those achieved by CPLEX v.12.6 considering the formulations presented in [17] and [19] refined and introduced in [4].

All algorithms were implemented in C++ language and the experiments carried out in an Ubuntu Server 14.04, Intel core i7 with 3.4 GHz, CPU 500 MB and 16 GB DDR RAM.

For the experiment, it was employed a set of instances generated as suggested in [14]. It is a set of eight classes of datasets with 160 instances. The division into classes was due to three main characteristics of the instance: capacity, setup cost, and setup time. Accordingly, the instances were classified with tight (T) or normal (N) capacity. Considering $\beta = \sum_{t=1}^{p} \sum_{i=1}^{n} \frac{(d_{ijt} b_{ij} + f_{ij})}{p}$, instances with normal and tight capacities have their parameter C_{jt} set as $1 \times \beta$ and $0.9 \times \beta$, respectively.

Regarding the setup costs, instances were defined with low (L) or high (H). In the former, cs_{ij} was chosen randomly within interval [5.0; 95.0]. In the latter, instances were chosen randomly within interval [50.0; 950.0].

To define each f_{ij}, it was picked randomly a value within interval [10.0; 50.0] when considering an instance with low setup time (L) and from interval [15.0; 75.0] if it was a high setup time (H) instance.

The remainder parameters, c_{ijt}, h_{ij}, r_{jk}, b_{ij}, and d_{ijt}, were set selecting at random values from the respective intervals: [1.5; 2.5], [0.2; 0.4], [0.2; 0.4], [1.0; 5.0], and [0, 180.0].

Therefore, a class of instances of the type NHL has instances with normal capacity, high setup cost, and low setup time. In the first set of instances, generated in [14], each instance corresponds to a problem with 12 periods, 2 plants, and 100, 200, 300, or 400 items. For each combination, the set has 5 problems, totaling 20 instances in each class.

Setup of the Experiments

To describe the results of the experiments and computationally compare the models, the performance profiles of [7] will be employed. This profile consists in a graphic that displays the relation between the metric to be evaluated, in this case, the time to solve every instance, and the performance of each algorithm in solving the instances, being the reference the best solution times found among all algorithms. For this, consider the ratio in Eq. (21).

$$\rho_{a,\tau} = \frac{1}{|\mathscr{S}|} \{s \in \mathscr{S} : r_{sa} \leq \tau\} \tag{21}$$

The factor τ in Eq. (21) means specifically the factor that multiplied by the best solution found considering all algorithms results in a lower bound for the solution

found by algorithm a for instance s. Therefore, r_{sa} can be calculated as indicated in Eq. (22).

$$r_{sa} = \frac{t_{sa}}{\min\{t_{sa'} : a' \in \mathscr{A}\}} \tag{22}$$

In Eq. (22), t_{sa} corresponds to the metric used for evaluating the solutions, which must be minimized. Therefore, r_{sa} is the performance of algorithm a to solve instance s in comparison to every algorithm. Consequently, $\rho_{a,\tau}$ is the percentage of solutions of the set of instances solved by algorithm a that respects the bound τ.

Results of the Experiments

In this experiment, the network flow-based formulation, named NYC, the model presented in [17], SS02, and the formulation adapted in [4], named CN16, were compared. As mentioned before, the time to achieve the optimal solution is the object of assessment. For this, the first performance profiles displayed in Fig. 2

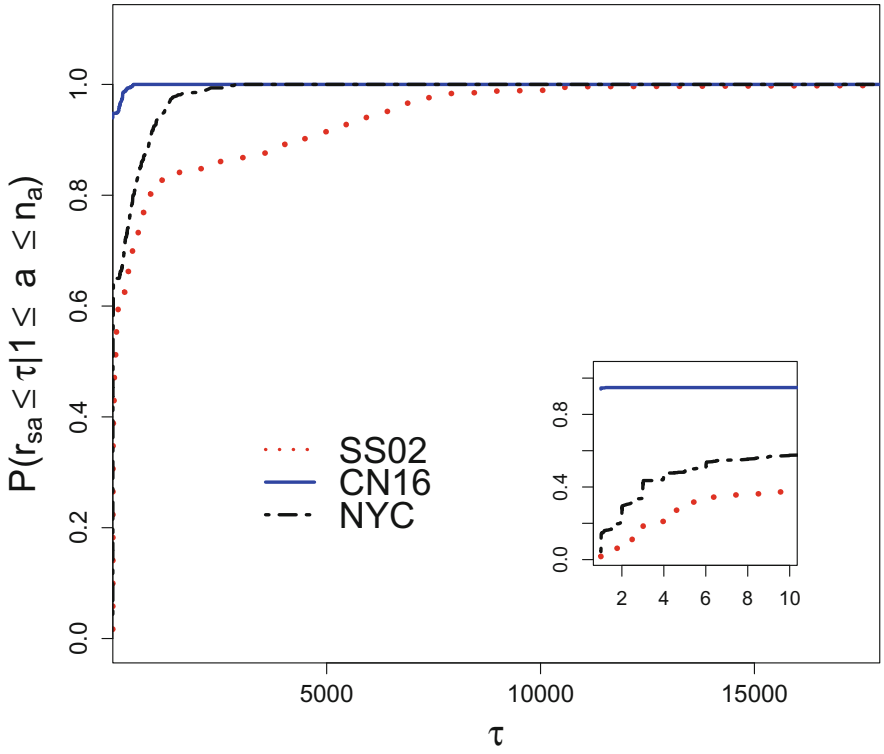

Fig. 2 This figure shows the performance profiles considering the two existing models in the literature, SS02 and CN16, and the formulation proposed in this chapter, NYC

assess only the small-sized instances (those with a number of items lesser than or equal to 50). In this case, it was possible to consider the time elapsed considering SS02, since it was comparable with NYC.

According to the results of the experiment, CN16 presents a clear advantage in performance in comparison to the other formulations. NYC achieves better results than SS02 even though their performance was very close. However, the difference between the performance profiles of NYC and SS02 becomes more evident with the increase in the number of items.

Figure 3 plots the performance profiles considering the larger instances (with a number of items larger than or equal to 100). This evaluation only takes into consideration the results achieved using models CN16 and NYC since to run instances modeled as SS02, it was very time-consuming.

Although the performance of NYC was poorer than CN16, it is noteworthy that their difference in performance fell in relation to the smaller instances. The value of τ for NYC to have at least half of the instances with results comparable to CN16 is 6. On the other hand, for larger instances it was approximately 2.

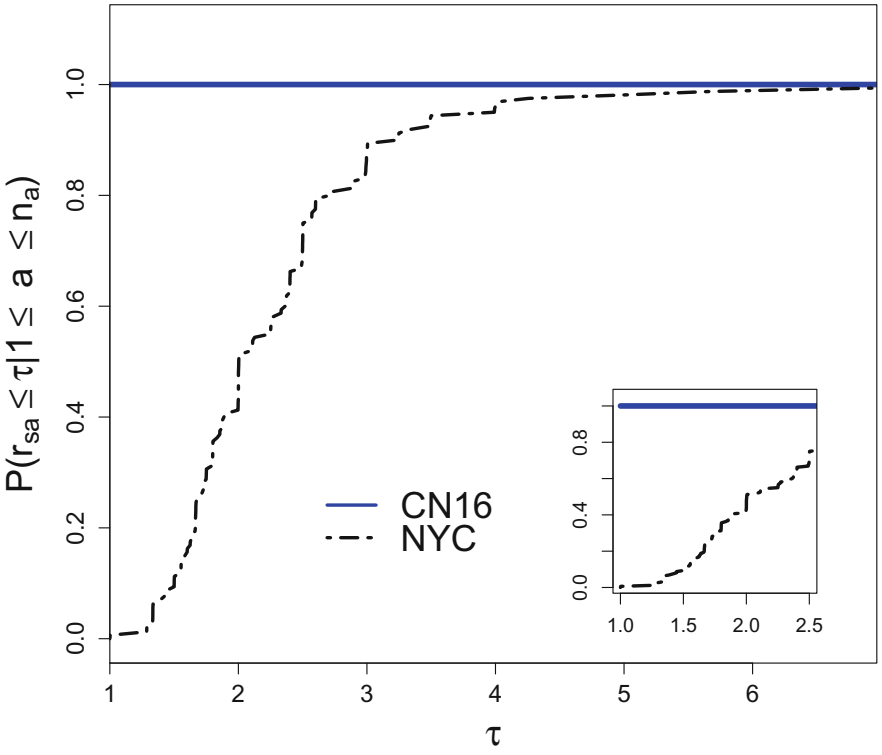

Fig. 3 This figure shows the performance profiles considering the existing model in the literature CN16 and the formulation proposed in this chapter, NYC

Extensions for the Capacitated Problem

In [6], the authors address the Multiplant Capacitated Lot Sizing Problem with Process Flexibility and Transportation Costs (MPCLSP-PFT), which extends the model (1)–(5). Specifically, they examine a lot sizing problem incorporating limited process flexibility, where each plant is capable of producing only certain types of items. Furthermore, the model includes a network of plants and clients, taking into account the transportation costs from each plant and each client. Below, one of the mathematical models proposed by Carvalho et al. [6] is presented, which is based on the classical formulation (1)–(5).

Extended Classical Formulation for the MPCLSP-PFT

Initially, it is important to consider additional parameters and decision variables based on the classical formulation of the multiplant lot sizing problem as proposed by [16].

Additional Parameters

c:	number of clients
d_{itk}:	demand of client k for item i in period t
sd_{itu}:	sum of the demands of item i, from period t to period u
b_{ij}:	processing time of item i at plant j
f_{ij}:	setup time for producing item i at plant j
bc_{itk}:	unit backlog cost of item i for client k in period t
tc_{ijk}:	unit transportation cost of item i from plant j to client k
fc_{ij}:	flexibility investment cost for item i at plant j
$Fmax$:	maximum budget to invest in flexibility

Additional Decision Variables

tr_{ijkt}:	amount of item i to be transported from plant j to client k in period t
B_{itk}:	amount of backlog for item i and client k in period t
z_{ij}:	binary variable that assumes value 1, if plant j is configured to produce item i, and 0, otherwise

The capacitated lot sizing problem with multiple plants, process flexibility, and transportation costs (MPCLSP-PFT) is modeled as follows:

$$(M1): \quad \min \sum_{i=1}^{n}\sum_{j=1}^{m}\sum_{t=1}^{p}\left[\left(cs_{ij}y_{ijt}+c_{ij}x_{ijt}+h_{ij}I_{ijt}\right)+\sum_{k=1}^{c}\left(tc_{ijk}tr_{ijkt}\right)\right]$$
$$+\sum_{i=1}^{n}\sum_{t=1}^{p}\sum_{k=1}^{c}\left(bc_{itk}b_{itk}\right) \tag{23}$$

subject to

$$I_{ijt} = x_{ijt} + I_{ij,t-1} - \sum_{k=1}^{c} tr_{ijkt} \qquad \forall\ (i, j, t) \tag{24}$$

$$d_{itk} = \sum_{j=1}^{m} tr_{ijkt} + B_{itk} - B_{i,t-1,k} \qquad \forall\ (i, t, k) \tag{25}$$

$$x_{ijt} \leq \min\{sd_{i1p}, (C_{jt} - f_{ij})/b_{ij}\} y_{ijt} \qquad \forall\ (i, j, t) \tag{26}$$

$$\sum_{i=1}^{n} \left(b_{ij} x_{ijt} + f_{ij} y_{ijt}\right) \leq C_{jt} \qquad \forall\ \ (j, t) \tag{27}$$

$$y_{ijt} \leq z_{ij} \qquad \forall\ (i, j, t) \tag{28}$$

$$\sum_{i=1}^{n} \sum_{j=1}^{m} f c_{ij} z_{ij} \leq Fmax \tag{29}$$

$$y_{ijt} \in \{0, 1\},\ z_{ij} \in \{0, 1\},\ x_{ijt} \geq 0,\ tr_{ijkt} \geq 0 \qquad \forall\ (i, j, t, k) \tag{30}$$

$$I_{ijt} \geq 0,\ I_{ij0} = 0,\ I_{ijp} = 0,\ B_{itk} \geq 0,\ B_{i0k} = 0 \qquad \forall\ (i, j, t, k) \tag{31}$$

The objective function (23) minimizes the total of setup, production, inventory, backlog, and transportation costs. Constraints (24) ensure flow balance at the plants, while constraints (25) maintain flow balance at the client locations. At the client sites, early fulfillment is not allowed, meaning no inventory is permitted; however, backlogging is allowed when demand cannot be met on time. Constraints (26) require that a plant setup operation is performed in order to produce a specific item. Capacity constraints (27) take into account production and setup at each plant for each period. Constraints (28) ensure that a setup cannot be executed if the plant is not configured to produce a specific item in a specific period. Constraint (29) imposes a limit on the budget invested in flexibility. Finally, constraints (30) and (31) define the domains of the decision variables. In addition to the formulation (23)–(31), the authors in [6] proposed a reformulation based on the facility location problem, along with an additional formulation that combines elements of both the original and the facility location-based formulations.

Facility Location Reformulation for the MPCLSP-PFT

In Krarup and Bilde [12], the authors propose a facility location reformulation for the classical version of lot sizing problem. In the present chapter, such reformulation for the MPCLSP-PFT is adapted.

Additional Parameters

$Cost_{ijtuk}$ represents the unit cost for production, inventory, and transportation of item i, produced at plant j during period t, to meet the demand of client k in period u, and is calculated as follows: $Cost_{ijtuk} = c_{ij} + tc_{ijk} + (u-t)h_{ij}$, for all $(i, j, t, u \geq t, k)$.

$Costb_{ijtuk}$ represents the unit cost for production and transportation of item i, produced as backlog at plant j in period t, to fulfill the demand of client k in period u, and is determined as follows: $Costb_{ijtuk} = c_{ij} + tc_{ijk} + \sum_{l=u}^{t-1} bc_{ilk}$, for all $(i, j, t, u < t, k)$.

Additional Decision Variables

x'_{ijtuk}: amount of item i to be produced at plant j in period t to satisfy the demand of client k in period u

B'_{ipuk}: amount of item i backlogged at the end of the planning horizon (i.e., period p), necessary to fulfill the unmet demand of client k in period u

The facility location reformulation for the MPCLSP-PFT problem is modeled as follows:

$$(M2): \quad \min \quad \sum_{i=1}^{n}\sum_{j=1}^{m}\sum_{t=1}^{p}(cs_{ij}y_{ijt}) + \sum_{i=1}^{n}\sum_{u=1}^{p}\sum_{k=1}^{c}\left[\left(\sum_{t=u}^{p} bc_{itk}\right)B'_{ipuk}\right] + \sum_{i=1}^{n}\sum_{j=1}^{m}\sum_{t=1}^{p}\sum_{k=1}^{c}\left[\left(\sum_{u=t}^{p}(Cost_{ijtuk}x'_{ijtuk})\right) + \left(\sum_{u=1}^{t-1}(Costb_{ijtuk}x'_{ijtuk})\right)\right] \tag{32}$$

subject to

$$\sum_{j=1}^{m}\sum_{t=1}^{p} x'_{ijtuk} + B'_{ipuk} = d_{iuk} \qquad \forall\ (i, u, k) \tag{33}$$

$$x'_{ijtuk} \leq \min\{d_{iuk}, (C_{jt} - f_{ij})/b_{ij}\}y_{ijt} \qquad \forall\ (i, j, t, u, k) \tag{34}$$

$$\sum_{i=1}^{n}\left(\sum_{u=1}^{p}\sum_{k=1}^{c} b_{ij}x'_{ijtuk} + f_{ij}y_{ijt}\right) \leq Cap_{jt} \qquad \forall\ (j, t) \tag{35}$$

$$y_{ijt} \leq z_{ij} \qquad \forall\ (i, j, t) \tag{36}$$

$$\sum_{i=1}^{n}\sum_{j=1}^{m} fc_{ij}z_{ij} \leq Fmax \tag{37}$$

$$y_{ijt} \in \{0, 1\},\ z_{ij} \in \{0, 1\} \qquad \forall\ (i, j, t) \tag{38}$$

$$x'_{ijtuk} \geq 0,\ B'_{ipuk} \geq 0 \qquad \forall\ (i, j, t, u, k) \tag{39}$$

Objective function (32) minimizes the total costs, including setup, production, inventory, backlog, and transportation. Constraints (33) model the flow balance at both the plants and the clients, where no inventory is permitted, but backlogging is allowed. In these constraints, the additional variable B'_{ipuk} is used to account for the possibility that part of the demand may remain unmet by any production at the end of the planning horizon in cases where backlogging occurs. Constraints (34) ensure that if an item is produced at a specific plant, a setup must occur. Constraints (35) limit the available capacity for production and setup in each plant and period. For each plant j, item i, and period t, constraints (36) enforce that a setup cannot be performed unless the plant j is configured to produce the specific item i. Constraints (37) restrict the total budget allocated to flexibility investments. Lastly, the domains of the decision variables are defined by constraints (38) and (39).

In [6] the authors analyzed the lower bounds obtained with both the formulations $M1$ and $M2$ to determine the best approach for solving the problem. Their analysis revealed that for problems with tight capacity, $M1$ provides better bounds, while $M2$ achieves better bounds for problems with normal capacity. Based on these findings, they proposed a third formulation, ($M3$) to the MPCLSP-PFT, which consistently produces lower bounds that are equal to or better than those obtained with formulations $M1$ and $M2$. The formulation $M3$ consists in minimizing the objective function value $\zeta \in \mathbb{R}$, subject to constraints (24)–(31), (33)–(35), and (39)–(42).

$$\zeta \geq \sum_{i=1}^{n}\sum_{j=1}^{m}\sum_{t=1}^{p}\left[\left(cs_{ij}y_{ijt} + c_{ij}x_{ijt} + h_i s_{ijt}\right) + \sum_{k=1}^{c}\left(tc_{ijk}tr_{ijkt}\right)\right] + \sum_{i=1}^{n}\sum_{t=1}^{p}\sum_{k=1}^{c}(bc_{itk}B_{itk}) \tag{40}$$

$$\zeta \geq \sum_{i=1}^{n}\sum_{j=1}^{m}\sum_{t=1}^{p}(cs_{ij}y_{ijt}) + \sum_{i=1}^{n}\sum_{u=1}^{p}\sum_{k=1}^{c}(bc_{ipk}B'_{ipuk}) + \sum_{i=1}^{n}\sum_{j=1}^{m}\sum_{t=1}^{p}\sum_{k=1}^{c}\left[\left(\sum_{u=t}^{p}(\text{Cost}_{ijtuk}x'_{ijtuk})\right) + \left(\sum_{u=1}^{t-1}(\text{Cost}b_{ijtuk}x'_{ijtuk})\right)\right] \tag{41}$$

$$\sum_{u=1}^{p}\sum_{k=1}^{c}x'_{ijtuk} = x_{ijt} \qquad \forall\ (i, j, t) \tag{42}$$

Constraints (40) and (41) impose a lower bound on the value of the objective function, ensuring that ζ is at least as large as the objective function values of $M1$ and $M2$, respectively. For each item, plant, and period tuple, constraints (42) ensure consistency between the two types of production decision variables.

Computational Experiments for the MPCLSP-PFT

This section compares the proposed mathematical models using a set of instances provided by Carvalho et al. [6]. The experiments were conducted on a computer equipped with two Intel Core i5-9300H processors running at 2.4 GHz and 16 GB of DDR3 RAM. Each instance was solved using a single thread with a time limit of 3600 seconds, utilizing the commercial solver CPLEX v. 12.10.

The instances used involve four and five plants (f); five and eight items (n); five periods (p); and four and six clients (c). The parameter $Fmax$, appearing in constraints (29), represents the total budget available for investment in flexibility. It is assumed that $fc_{ij} = 1$, meaning the total budget corresponds to the maximum number of production-plant links. Observe that a flexibility level of 100% means that all plants can produce all items, that is, there is total flexibility. In computational tests, the value considered for the parameter $Fmax$ is 75% and will be represented by $Flex3$ in the next tables, meaning it is considered that 75% of the total possible links ($n \times m$) can be used.

The available capacity levels per period, as defined in constraints (27), vary based on a factor μ, which is multiplied by the total average capacity $ACap$, which is calculated as $\left(\left(\sum_{i\in\mathscr{I}}\sum_{k\in\mathscr{K}}\sum_{t\in\mathscr{T}} d_{ikt}b_i + f_i\right)/(m \times p)\right)$. Values $\mu = 0.6, 0.9, 1.3$ are considered to encompass a broad range of problems, ensuring that the solutions exhibit varying levels of backlog.

To generate the transportation costs (tc_{ijk}), a pair of coordinates, bounded between 0 and 1, is uniformly assigned to each plant and client within a square on the Cartesian plane. The costs are then calculated using the Euclidean distance between each plant and client. Specifically, for each item i, the transportation cost tc_{ijk} is obtained by multiplying the Euclidean distance between plant j and client k by a scalar value $\beta = 0.3$.

Table 1 outlines the general parameters defined for the MPCLSP-PFT, which are based on a subset of instances proposed in [22].

Table 1 Parameter definitions designed for the MPCLSP-PFT. Each row presents a set or a value used to define their parameters where U[a, b] represents the uniform distribution

Parameters	All classes of instances
d_{itk}	U[0, 180]
f_{ij}	U[10, 50]
b_{ij}	1
cs_{ij}	U[400, 1000]
h_{ij}	U[1, 5]
bc_{jtk}	300
bc_{jpk}	600
c_{ij}	0
fc_{ij}	1

Results of the Experiments

By comparing the upper bounds and the gaps obtained by each model, it is possible to observe that the values are quite similar. Specifically, the results are:

- Model $M1$: upper bound = 1,285,413 and gap = 0.2%
- Model $M2$: upper bound = 1,285,667 and gap = 0.5%
- Model $M3$: upper bound = 1,285,720 and gap = 0.2%

Figure 4 illustrates the performance profile of each model in terms of computational time. The results of the experiment indicate that model $M2$ demonstrates a clear advantage in performance compared to model $M3$. Moreover, $M2$ outperforms $M1$, although their performance metrics are closely aligned.

The performance profile in Fig. 5 requires a different analysis, as higher lower bound values indicate better model performance. From Fig. 5, it is evident that model $M3$ achieves the highest LP lower bounds, demonstrating a clear performance advantage over model $M1$. Additionally, $M3$ outperforms $M2$, although their performance metrics are closely aligned.

Conclusions

Lot sizing plays a fundamental role in production planning. Considering the planning horizon phased into periods, this problem consists in making decisions with regard to plant, period, item, and amount of items to produce to meet all demands without delay. In multiplant capacitated lot sizing problem, it is possible to schedule items on multiple machines/plants enabled by transferring items to plants where they are demanded. This is the subject of this study about which is presented a brief literature review, primarily focusing on the existing solution methods and approaches to its solution.

A few efficient solution methods were specially designed to tackle the multiplant capacitated lot sizing problem (MPCLSP). The hard nature of this problem, for which not even the uncapacitated variant has a polynomial algorithm to find optimal solutions, may be the reason behind the low interest in developing frameworks. Nevertheless, two Lagrangian heuristics recently proposed achieved good results mainly on large-scale instances and instances with high setup costs. For smaller instances and those with low setup costs, CPLEX significantly outperformed them.

Even though being NP-hard, few formulations were specially designed for the multiplant uncapacitated lot sizing problem (MPULSP). The relevance in studying the MPULSP, besides approaching production lines that do not have capacity constraints, is to enable a study of strategies that relax capacity constraints to browse the search space for feasible solutions for the MPCLSP. This chapter introduces a network flow-based formulation for the MPULSP and evaluates a recently proposed mathematical formulation for the MPCLSP by relaxing the capacity constraints to contrast their performance in solving instances according to solver CPLEX. Moreover, the firstly proposed formulation for the MPULSP was investigated in the computational experiments. For such, experiments with instances found in the literature were carried out by evaluating the time to solution, assessed with Dolan-Moré performance profiles.

Finally, the updated version of this chapter, based on [6], focuses on the multiplant capacitated lot sizing problem (MPCLSP) and its extensions. Unlike the standard problem with parallel resources, these extensions introduce a limited amount of flexibility, allowing each plant to produce only certain types of items. Additionally, the model considers a network of clients dispersed around different plants. Three mathematical formulations are presented and evaluated through computational results.

Abstract

OGA is a Spanish consulting company based in Seville that applies optimization to help companies improve their business processes. Specializing in creating business value through the application of critical process optimization techniques, OGA mainly employs metaheuristic techniques to deliver high-quality solutions to practical problems faced by companies. to routing, the company approaches logistic problems in the supply chain to improve the operations of their final customer. In this chapter, we show the complexities of real-world optimization problems in an example of the beverage industry and how OGA efficiently solves them by applying metaheuristic technologies in a financially sustainable manner.

Keywords

OGA · Metaheuristics · Logistic sector · Business processes · Real-world optimization problems

Introduction

OGA is a consulting company specialized in the development of algorithms, models, and integral solutions for the optimization of critical business processes. It operates in various logistics sectors of the supply chain, where it tackles complex operational planning, fleet optimization, optimal locations of logistics centers or nodes, and integration of transport or distribution routes.

Management and business optimization consulting services assess the strengths and weaknesses of a company's supply chain, crafting optimal strategies and implementation plans from management, business processes, and IT viewpoints tailored to clients within the manufacturing and distribution sectors.

One crucial aspect of the role as consultants involves bridging the gap between clients and the latest research advancements from universities and research institutes in both Operations Research and Artificial Intelligence. Through effective communication with academia and industry alike, OGA delivers tailored solutions to meet the clients' real-world business requirements. As is well known in the sector, one of the main differences between the research developed in academia and published in journals, and the development and research performed in consultant firms, is the collaboration with clients who are looking for suitable solutions, even when the problem is initially vague, which may involve assisting in problem definition itself.

One of the specific characteristics of implementing heuristic algorithms in the business environment is the need to make the process economically efficient. Consulting firms must balance meeting client requirements with implementing solutions in short development times. Ideally speaking, consulting firms seek generic developments that serve different users, perhaps with minor customizations, to adapt predeveloped software to create new products. However, what often happens is that the end user has many requirements that hinder, if not prevent, the reusability of the code. In this chapter, we describe the in-between solution applied in OGA to reach a trade-off between customization and efficiency. In particular, in some projects, the company develops applications in which part of the solution process is based on an in-house implementation of heuristics, and the other part is

run with a commercial library also based on heuristics, which in this case is Hexaly (formerly known as Local Solver).

As advertised on their website, Hexaly is a well-known optimization solver for Routing, Scheduling, and Packing, among other models (www.hexaly.com). Its user community is growing, and there are currently around 1,000 developers who leveraged the Hexaly platform to build around 400 optimization apps for 20,000 users. It provides preestablished templates that the programmer may adapt to create a customized model for the specific problem at hand.

In this chapter, we describe a commercial application of OGA to customers in supply chain logistics, based on this paradigm of combining their own heuristic algorithms with Hexaly templates. In particular, section "Case Study" describes a case study based on a routing model. In section "Routing," we describe the vehicle routing model, and in section "The Hexaly Template" its implementation in Hexaly. Section "A Practical Case in the Beverage Industry" is devoted to the practical problem solved by OGA for an international company based in Spain. The chapter finishes with some computational experiments, shown in section "Computational Experiments," to show in practical terms the quality of the solutions obtained with the built application, and the associated conclusions.

Case Study

Logistics-focused companies dedicate their efforts to various aspects, including the transportation of goods and ancillary services such as warehouse administration and inventory oversight. Although transportation is the main focus within this sector, effective stock control and effective product storage management are equally vital. Consequently, decision support systems play a key role in facilitating this management process.

Smart mobility refers to efficient transportation of people or goods. The growth of cities and the importance of mobility within the urban area have led to research on ways to minimize traffic, its impact on the environment, and increase the efficiency of travel. In this section, we describe an application developed by the OGA team in the context of the supply chain. Specifically, we consider a routing problem since it represents an important family of combinatorial optimization problems and therefore illustrates representative problems in consulting companies.

In the logistics consulting industry, clients have varying needs when it comes to the speed of obtaining solutions. Some clients operate with flexible timelines and are open to receiving solutions within a broader time frame. They may prioritize thorough analysis and strategic planning over immediate responses. However, clients face a significant challenge that requires fast turnaround times. For these clients, receiving solutions in seconds or in a few minutes is critical due to the urgency of their operational demands or market pressures.

This disparity in client needs presents a considerable challenge for the logistics industry and specifically for consulting firms like OGA. On the one hand, the ability to deliver solutions quickly requires robust systems, streamlined processes, and advanced technology to ensure that responses are not only fast but also accurate and effective. However, accommodating clients with more flexible timelines still requires a high level of service and precision, although the pressure to act immediately is less intense.

Routing

The Capacitated Vehicle Routing Problem (CVRP) can be mathematically formulated as an integer optimization problem with binary variables from the following input elements in terms of graphs:

- $G = (V, E)$: a complete undirected graph where V represents the set of nodes (including the depot and customer locations) and E represents the set of edges between nodes
- c_{ij}: the cost (distance, time, or monetary value) of traveling from node i to node j
- d_i: the demand of customer i
- Q: the capacity of each vehicle
- K: the number of available vehicles

The CVRP aims to minimize the total distance traveled. It also ensures that each customer's demand is met and that vehicle capacity is not exceeded. The mathematical formulation of the CVRP can be given as follows by introducing binary decision variables x_{ij} indicating whether a vehicle travels from node i to node j, i.e., $x_{ij} = 1$ if vehicle travels from i to j, and $x_{ij} = 0$ otherwise.

$$\text{minimize} \quad \sum_{i \in V} \sum_{j \in V, j \neq i} c_{ij} \cdot x_{ij}$$

subject to:

1. Each customer is visited exactly once:

$$\sum_{j \in V, j \neq i} x_{ij} = 1, \quad \forall i \in V \setminus \{0\}.$$

2. Each vehicle must leave and return to the depot:

$$\sum_{j \in V} x_{0j} = K$$

$$\sum_{j \in V} x_{j0} = K.$$

3. Capacity constraint at each customer node:

$$\sum_{j \in V, j \neq i} d_j \cdot x_{ji} \leq Q, \quad \forall i \in V \setminus \{0\}.$$

4. Flow conservation at each node (except the depot):

$$\sum_{j \in V, j \neq i} x_{ij} - \sum_{j \in V, j \neq i} x_{ji} = 0, \quad \forall i \in V \setminus \{0\}.$$

5. Binary restrictions on decision variables:

$$x_{ij} \in \{0, 1\}, \quad \forall i, j \in V, i \neq j.$$

The objective function minimizes the total distance traveled by all vehicles, subject to constraints that ensure that each customer is visited exactly once, vehicles leave and return to the depot, capacity constraints are satisfied, and flow conservation is maintained at each node.

CVRP is known to be difficult to solve (NP hard) [3]. Over the years, routing has evolved into a relevant research area, which might include real-life characteristics such as multiple criteria, soft constraints, or stochastic travel times, just to name a few. Additionally, when we move from the academic to the business context, optimization problems become even more complex to solve. In particular, the first issue we face is the instance size, which in many cases makes the model impractical. The second problem is usually the existence of numerous additional constraints, due to the specific characteristics of the client.

Generally speaking, we can identify five categories to classify routing problems: characteristics of the network, vehicles, facility, demand, and objective:

- *Network*: *Directed*, *undirected*, or *mixed*.
- *Vehicles* are typically identical, but we can also find a *heterogeneous fleet*.
- *Multiple or mobile depots* are characteristics related to *facilities*, in which we consider several depots or intermediate facilities.
- The *demand* can be deterministic or stochastic, reflecting the latter practical situations in waste collection or reverse logistics with uncertainty in the data.
- *Objective*: Single or *multiple objectives*, including: service and labor cost, overtime and penalty costs, duration and duration of routes, etc.

One of the most popular extensions of the VRP involves a diverse fleet comprising various types of trucks with differing capacities and costs, reflecting the situation of many transportation companies. This variant, called Heterogeneous or simply Mixed Fleet VRP, has received less attention compared to the standard VRP due to its increased complexity. Yet another significant variation is the VRP that incorporates Time Windows (VRPTW), where customers can be attended to only within designated time frames, necessitating the scheduling of vehicle trips.

Vehicles can also be *multicompartment*, having the required edges a demand for different commodities that must be kept segregated during the transportation action.

In recent years, increased focus has been directed toward more intricate variants of the VRP, often referred to as "rich" VRPs, addressing real-world distribution challenges. These variants commonly feature multiple depots, the need for multiple vehicle trips, diverse vehicle types, and additional operational complexities such as loading constraints.

In spite of the practical need of solving very large VRP instances due to the operations of large companies, algorithm development in the academic context has concentrated on tackling routing problems involving only a few hundred customers at most. The rationale behind this focus remains ambiguous. One possible explanation could be attributed to the prevalent size of the commonly employed benchmark instances. The standard benchmark set in VRP was introduced by Golden et al. [4], with instances featuring up to 483 customers, while more contemporary benchmarks, like the one established by Uchoa et al. [8], include instances with a maximum of 1000 customers.

Special mention deserves FILO, probably the best heuristic published so far for the CVRP. It is based on the Iterated Local Search (ILS) paradigm and incorporates various existing acceleration techniques along with novel strategies for localized and controlled optimization tailored to the current instance and solution. Using a Simulated Annealing neighbor acceptance criterion, FILO ensures continuous diversification, exploring different regions of the search space to avoid premature convergence. Accorsi and Vigo [1] have recently published a benchmark test in extensively studied instances to show that FILO is highly competitive with state-of-the-art algorithms in terms of computing time and solution quality. The paper also provides open-source guidelines, algorithm source code, and a library of reusable components to promote further research and reproducibility.

Figure 1 shows a partial representation of an OGA-solved instance for a client in the beverage business. In particular, it depicts part of the map of a city in Spain where the company has to provide service to 20,000 clients. This is a very large instance of a special case of the VRP, so we cannot directly apply existing solvers, and we have to design and implement a solving method to address its particularities through additional constraints.

The Hexaly Template

Hexaly optimizer provides solutions for the most common routing problems, namely the traveling salesman problem (TSP), the capacitated vehicle routing problem (CVRP), and the capacitated vehicle routing problem with time windows (CVRPTW). Templates for these models are available at www.hexaly.com with sample data and ready-to-use code in LSP, C++, Java, .NET, and Python. It reaches a 1.2% average gap after 60 seconds of running time in the CVRP instances tested [8].

The CVRP problem is modeled with a *list variable* per truck in the fleet, and the coverage of all customers is enforced by a partition constraint. The list operator

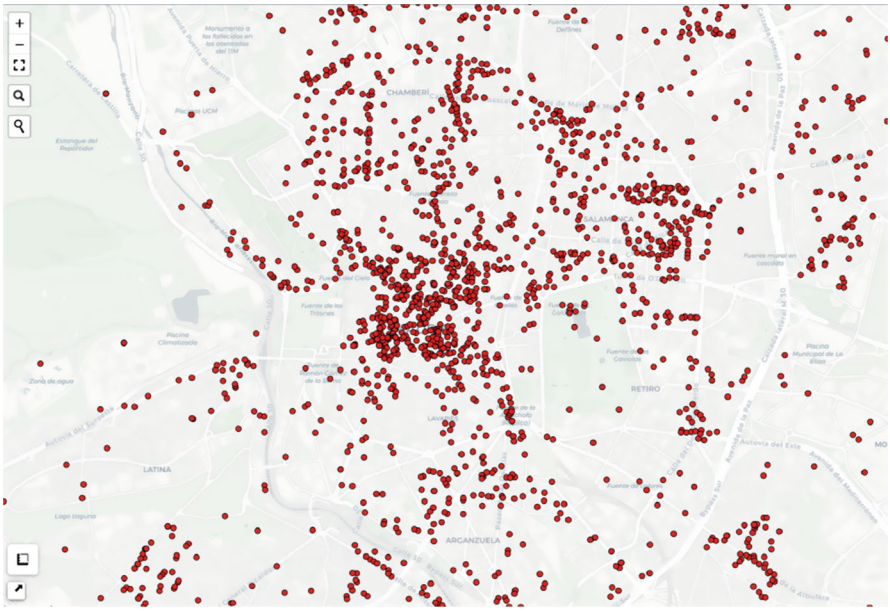

Fig. 1 Example of clients in a map

allows us to define a decision variable whose value is a collection of integers within $[0, n-1]$ where n is the operator's argument. The following template, provided by the company, illustrates how easy it is to create a model in Python to solve a standard CVRP. It shows that we only need to call the minimize function after including the constraints. Hexaly automatically performs the local search-based optimization and returns the best solution found. We refer the reader to the website of the company at www.hexaly.com for a detailed description of the following code.

```
function model() {
    // Sequence of customers visited by each truck
    customersSequences[k in 1..nbTrucks]
    <- list(nbCustomers);

    // All customers must be visited by the trucks
    constraint partition[k in 1..nbTrucks]
    (customersSequences[k]);

    for [k in 1..nbTrucks] {
        local sequence <- customersSequences[k];
        local c <- count(sequence);

        // Sum of demands along the route must not
        exceed the truck capacity
```

```
        constraint sum(sequence, j => demands[j])
        <= truckCapacity;

        // Distance traveled by the truck
        routeDistances[k] <- sum(1..c-1, i =>
        distanceMatrix[sequence[i - 1]][sequence[i]])
             + (c > 0 ? (distanceWarehouse
                [sequence[0]] + distanceWarehouse
                    [sequence[c - 1]]) : 0);
    }

    // Minimize the total distance traveled by all
    trucks
    minimize sum[k in 1..nbTrucks](routeDistances[k]);
}
```

As mentioned above, our solving methodology is based on a combination of in-house development and Hexaly post-optimization. We apply a sort of multistart method in which the randomized construction is performed with a specific algorithm, and the typical local search post-optimization is done with a customized Hexaly model from the basic code above in which we add all the customers' requirements.

A Practical Case in the Beverage Industry

One of the most difficult decision problems confronting a distribution manager in the soft-drink industry on a day-to-day basis concerns the routing, scheduling, and staffing of delivery vehicles. The Operations Research journal published in 1987 a practical paper devoted to this topic [3], in which the authors stated that given the large volume of soft-drink sales, the expenses associated with the distribution activities are enormous, and recommended, even in these early times, the use of computer software packages to optimize its cost. The paper describes the particularities of the routing problem in this context, such as determine driver territories or create compact routes.

In the context of logistics consulting services provided by companies like OGA, managing and maintaining distance and time matrices is a critical and often challenging aspect. These matrices serve as foundational tools for optimizing routes, managing supply chains, and making informed decisions. The generation of these matrices involves calculating the distances and travel times between various points in a network, which can be complex due to the need for accuracy and comprehensiveness.

For many consulting firms, the initial creation of these matrices can be a significant "pain point." It requires integrating data from various sources, including geographic information systems (GIS), traffic databases, and historical data to

ensure precision. This process often involves considerable effort and experience to develop an initial matrix that accurately reflects real-world conditions. Once established, maintaining these matrices becomes another challenge. Traffic patterns, road conditions, and other factors can change frequently, making it crucial to update the matrices regularly to retain their relevance and accuracy. Failure to do so can lead to outdated information that negatively affects decision-making and logistics efficiency.

In our particular problem, we apply a multistart scheme in which we call the Hexaly solver at certain stages, to improve specific aspects of the solution. The algorithm has the following six main steps:

1. **Preprocessing**. Determining the search strategy based on the overall load compared to the capacity of the truck. Computing the target values for the objectives to build a goal programming model based on the load balance, to obtain similar truck loads, compactness of the route shape, and route overlapping. Group orders and determining special routes with high priority.
2. **Construction**. Fleet allocation based on delivery zones and order according to priority. Calls to the Hexaly solver for each zone, providing a pool of orders and a pool of vehicles.
3. **Construction postprocessing**. Attempts to add orders left for the second tour to their nearest route. If it meets the constraints, it is added to the route and removed from the second tour.
4. **Improvement**. Cross-checking. The polygon representing each route is checked whether it intersects with other polygons to evaluate their overlapping. If so, they are sent together to the Hexaly solver for a post-optimization. We have empirically found that the company prefers nonoverlapping routes among other reasons because it reduces conflicts between drivers.
5. **Improvement postprocessing**. Attempts to add orders left for the second tour to their nearest route in the first tour after cross-checking. If it meets the constraints, it is added to the route and removed from the second tour.
6. **Solution completion**. Add the remaining elements to the second tour.

As shown in the algorithm above, Hexaly is called in both the construction and improvement to optimize different objective functions. We have empirically found that it is more efficient than developing code to optimize these criteria.

Figure 2 shows the complete flow diagram of our complete heuristic. It starts by determining whether the overall load is high or low compared to the truck capacity (Step 1), since two different strategies are applied to the trucks in each case. Similarly the complete preprocessing takes place in steps 1 to 4 of the flowchart (depicted in orange in the diagram). The following blocks in the flowchart correspond to the steps 2 to 6 in the algorithm, namely construction (2 blocks), construction postprocessing (1 block), improvement (crosscheck routes block), improvement postprocessing, and finally solution completion (second tour).

Note that the user interacts with the main front-end screen to set the different options of the software. Figure 3 shows it.

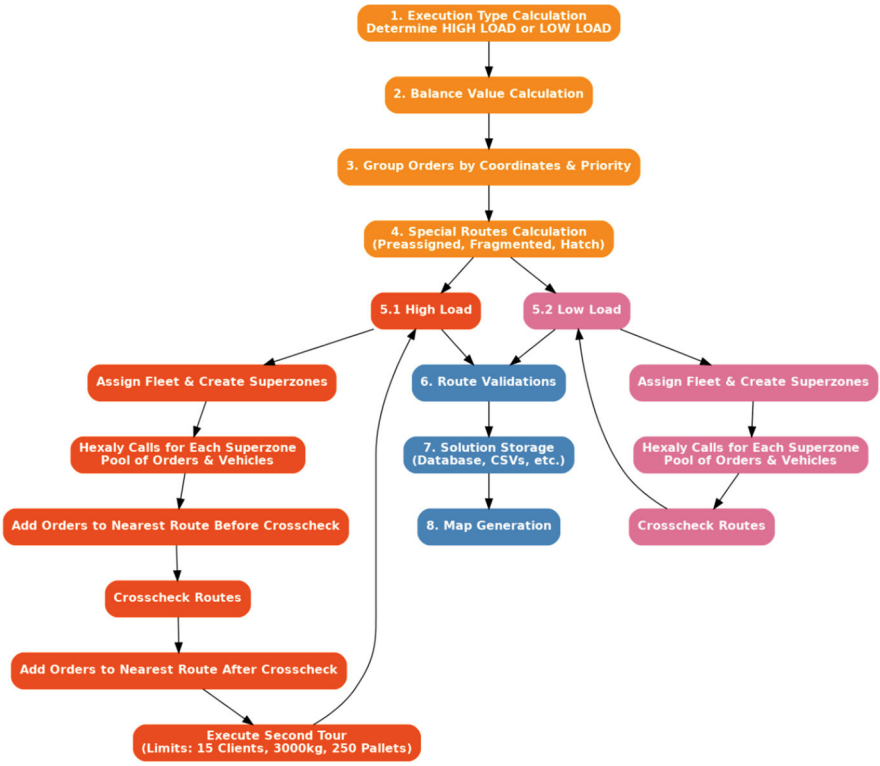

Fig. 2 Flowchart of the entire algorithm

Computational Experiments

In this section, we describe the solutions obtained by OGA in this problem. Note that due to confidentiality, we cannot disclose all the details of the instances or the solutions.

The customer has about 33,000 sales points, and they are visited from Monday to Friday in two shifts (an average of 6,600 points daily). Aggregated demand varies according to the day of the week and the time of year (between 300,000 kg and 1.5 million kg). The fleet used varies according to the day, but once known, they must all be used. They use approximately 105 to 140 trucks of 6200 kg and up to 15 vans of a capacity of 1500 kg. On low-load days, all trucks make only one trip, and the vans make two trips per shift. On high-load days, trucks can make up to two trips per shift (the minimization of second trips is added as an objective) and vans a maximum of three trips. Once the above data are known, the model is run until no further significant improvement is achieved and returns the high-quality solution obtained. This usually happens after about 2 to 3 minutes of execution. As a point of comparison, the customer previously required five people to plan routes manually for about 4 hours.

We now illustrate the performance of the algorithm with the example partially represented in Fig. 1. OGA has to solve this example periodically, and in each instance the number of clients usually ranges from 10,000 to 20,000 approximately. The challenge is that the fleet of vehicles remains the same in all the cases: 150 trucks.

A typical simplification in this type of problem is to group clients in delivery zones and restrict each truck to serve clients only within one zone. Figure 4 shows in different colors the delivery zones in our case study. It is clear that this simplification may lead to suboptimal solutions since in optimization terms we are considerably restricting the solution space. On the other hand, in technical terms, this leads to a simplified computation of the distances because within a delivery zone we may simply use the Euclidean distance as a proxy to the travel distance based on streets and traffic, which would be very inaccurate if a truck may serve clients in the entire map. Our constructive method is partially based on these zones, but it allows us to cross the boundary of the delivery zones in an effort to reach better solutions. Figure 5 shows five constructed routes in our example.

It must be noted that, to represent the solutions in a clear way, we avoid the inclusion of the first arc in the route from the depot as well as the last arc to the depot. Figure 6 shows in (a) what we represent (without these two arcs with the depot) and in (b) the complete routes that include them.

The compactness and overlap of the solution are probably the most difficult characteristics to achieve. This is related to the visual attractiveness of the routes [7], which, as mentioned above, is a standard criterion in practical routing problems. Figure 7 shows in (a) two routes with overlap areas that the company wants to avoid due to the agreement with the drivers. In (b), we show a good solution in terms of overlap. Furthermore, it should be noted that in beverage delivery in urban areas,

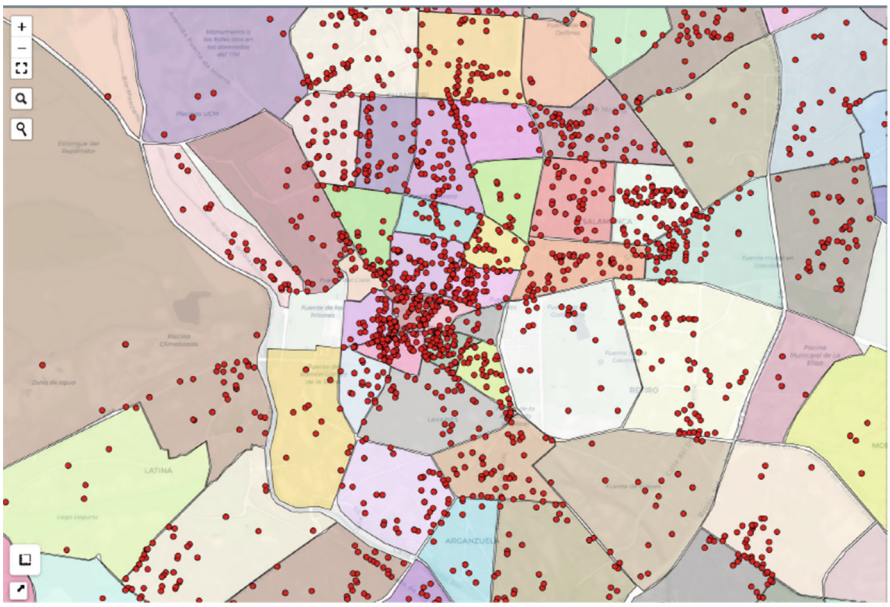

Fig. 4 Example of delivery zones

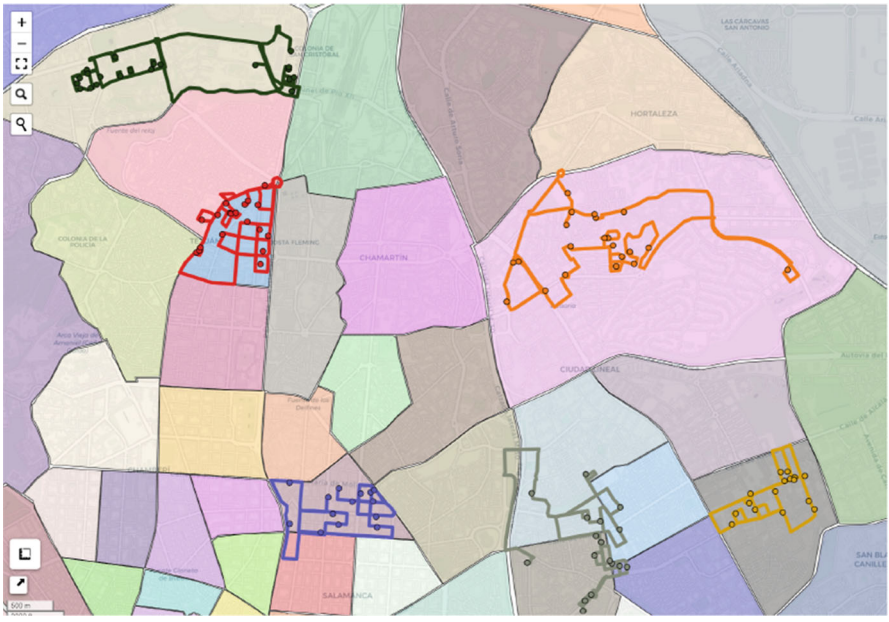

Fig. 5 Some routes partially based on delivery zones

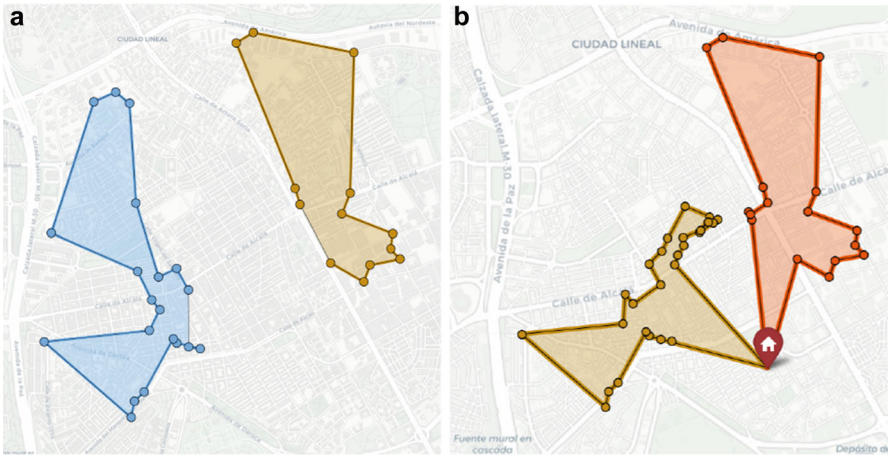

Fig. 6 Routes representation in a simplified way. (**a**) Depicted. (**b**) Complete

Fig. 7 Overlapping routes. (**a**) Overlapping. (**b**) Optimized

trucks park in a spot and from there provide service to several customers with a handcart. This is why a compact route is better than a straight-line route, since grouping customers around a parking spot simplifies the driver task.

Figure 7a clearly shows that routes 3 and 4 present and overlapping. They can be qualified as not friendly by the drivers since they both cover a similar territory. Alternatively, Fig. 7b organizes the customers in different nonoverlapping routes that are considered more friendly by the drivers, since they feel that no one interferes with their assigned territory.

Table 1 Low-demand comparison

COMPUTATIONAL RESULTS		Monday Nov-2023 Low Load	Thursday Nov 2023 Low Load	Friday Nov 2023 Low Load
Total NumTrucks		119	130	141
Total NumVans		0	15	15
Extra NumVans Trips		0	0	0
Delivered Orders		2165	3912	4851
Delivered Weight (kg)		339138.99	625764.3	840786.95
Balanced Objective Value in NumTrucks (BOV)		250	400	560
Vans < 800 kg	Total	0	0	0
	Min	–	–	–
	Mean	–	–	–
	Max	–	–	–
Truck Boxes $< 75\%$ BOV	Ref. Limit	188	300	420
	Total	8	15	20
	Min	156	277	109
	Mean	166	291	368
	Max	174	299	419
Truck Boxes $> 125\%$ BOV	Ref. Limit	314	500	700
	Total	6	0	0
	Min	323	–	–
	Mean	335	–	–
	Max	344	–	–

We complement the figures above with the following tables in which we report on the solutions obtained with our algorithm on different days of the week in 2023 (to compare the robustness of our method). In particular, Table 1 shows the computational results in three days in which the load of the trucks (the demand) is relatively low compared to their total capacity. Table 2 shows the results for two days with a high load on trucks (high demand). In particular, these two tables report the following statistics:

- **Total #Trucks**: Number of trucks included in the planning. Note that in this problem we have to use all the trucks.
- **Total #Vans**: Number of vans included in the planning.
- **Extra #Vans Trips**: Number of trips on the van above the maximum allowed that is required to provide the service.
- **Delivered Orders**: Number of orders to be delivered.
- **Delivered Weight (kg)**: Amount of weight of the total order.

Table 2 High-demand comparison

COMPUTATIONAL RESULTS		Tuesday Sept 2023 High Load	Wednesday Nov 2023 High Load
Total Trucks		138	141
Total Vans		17	17
Extra Vans Trips		4	0
Delivered Orders		4939	4375
Delivered Weight		1094715.78	999679.14
Mean Trucks Boxes		–	–
Vans < 800 kg	Total	1	4
	Min	658	44
	Mean	658	429.5
	Max	658	771.2
Trucks First Trip < 4000 kg	Total	0	4
	Min	–	60.6
	Mean	–	900.27
	Max	–	2326.57
Trucks First Trip < 5000 kg	Total	4	14
	Min	4711	60.6
	Mean	4823	3472.06
	Max	4983	4933.64
Trucks First Trip < 5500 kg	Total	18	37
	Min	4711	60.6
	Mean	5097	4560.71
	Max	5497	5482.02
Trucks Second Tips < 1500 kg	Total	4	5
	Min	127	290.4
	Mean	623	724.24
	Max	1477	1276.02

- **Balanced Objective Value** in #Trucks (BOV): Target value in the number of load boxes that we want to achieve in the solution corresponding to the low-demand days.
- **Vans < 800 kg**: Number of vans with a load lower than 800 kg. These vans are considered underused and, therefore, a good solution should have a low value of this statistic.
- **Truck Boxes $< 75\%$ BOV**: Number of trucks with a load in the number of boxes lower than 75% of the target value BOV.
- **Truck Boxes $> 125\%$ BOV**: Number of trucks with a load in the number of boxes higher than 125% of the target value BOV.
- **Trucks First Trip < 4000 kg**: Number of trucks that are below 4000 kg on the first trip on high-demand days.

- **Trucks First Trip $<$ 5000 kg**: Number of trucks that are below 5000 kg on the first trip on high-demand days.
- **Trucks First Trip $<$ 5500 kg**: Number of trucks that are below 5500 kg on the first trip on high-demand days.
- **Trucks Second Trip $<$ 1500 kg**: Number of trucks that are less than 1500 kg on the second trip on days of high demand.

Table 1 shows that the algorithm obtains high-quality results. This can be seen by analyzing the statistics reported in this figure. The first indicator is in *Extra Vans* = 0, which shows that no additional van was required. The second is in the wide row $Vans < 800$ kg and the symbols N/A represent that no van is underused. Furthermore, the number of trucks with boxes less than 75% of the target value is low. In particular, for Monday it is 8 out of 119 trucks, for Tuesday 15 out of 130, and for Friday 20 out of 141. Similarly, the number of trucks with overload, as measured by the number of boxes over 125% of the target value, is also low (6, 0, and 0 for the three days considered, respectively).

In Table 2 we can observe similar results in the case of high-demand days. In particular, here we look for maximum use of the vehicles in terms of their capacity because these days the demand is high and we cannot afford the underused of the vehicles. The statistics show that the number of underused vehicles is very low compared to the total number of vehicles. A close examination of the few cases in which some vehicles carry a low load discloses that it is due to isolated points that make it very difficult, if not impossible, to complete the load of the vehicle in an efficient route.

Comparison with Existing Solutions

We now illustrate the relative improvement achieved with the OGA solution compared to the current solution applied by the company.

To represent a larger area of the map, we avoid the inclusion of lines in the company solution (see Fig. 8) and only depict the customer's points. Points in the same color indicate that they belong to the same route. Since OGA's solution is clearer, we can include the lines in the associated map (see Fig. 9).

To analyze the issues of the current solution of the company, in Fig. 10 we circle some of the areas that we want to highlight. In the red circles of the figure, we identify a large number of overlappings among the polygons representing the routes. We can easily see that in Fig. 9 there are no overlaps. It is important to note that in both cases the routes are balanced, meaning that they have a similar load, which makes the optimization process (to avoid overlapping) challenging. Additionally, we can see in the optimized OGA solution the reduction in the number of zones that each route visits, thus increasing their compactness.

We conclude our experimentation with another example to compare the initial solution (the one implemented by the company using their own means) in Fig. 11,

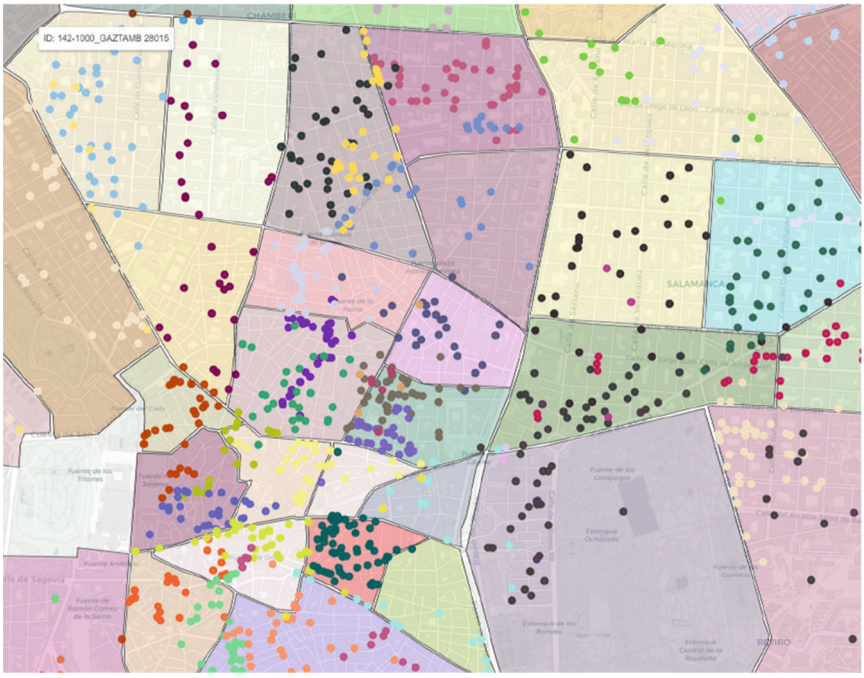

Fig. 8 Current solution applied by the company

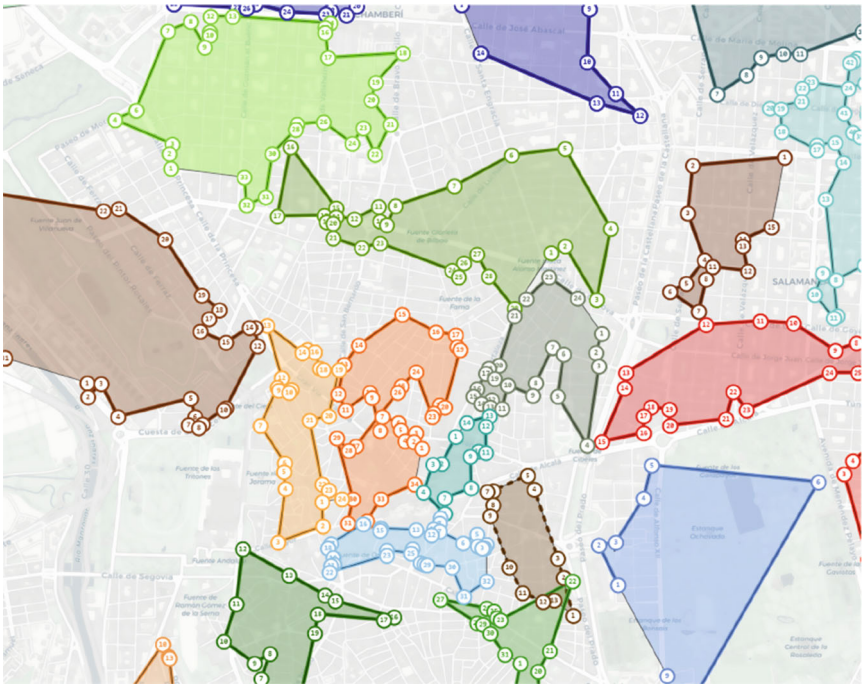

Fig. 9 Optimized solution obtained by OGA

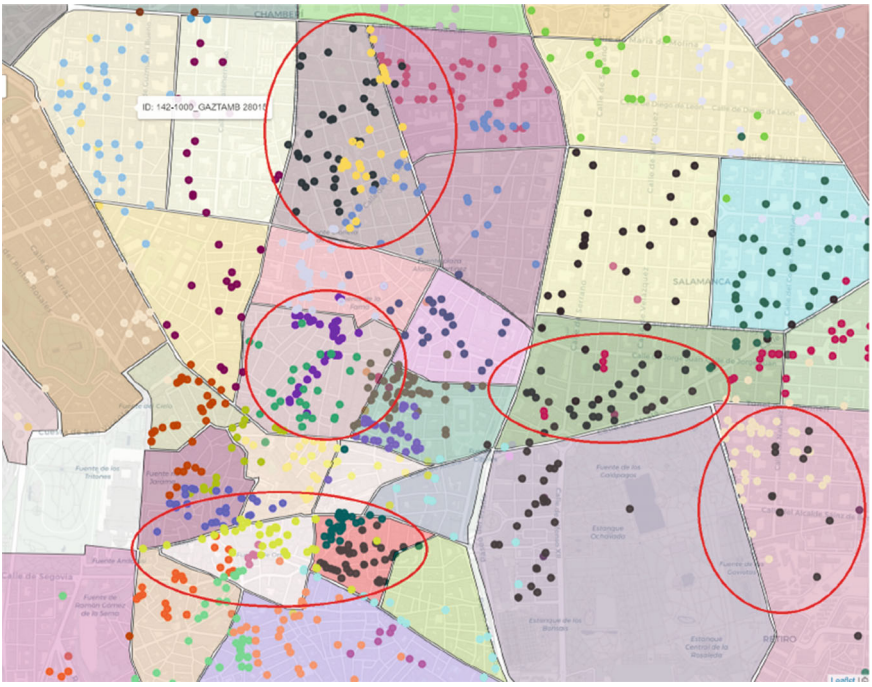

Fig. 10 Issues identified in current solution

Fig. 11 Solution created by the company

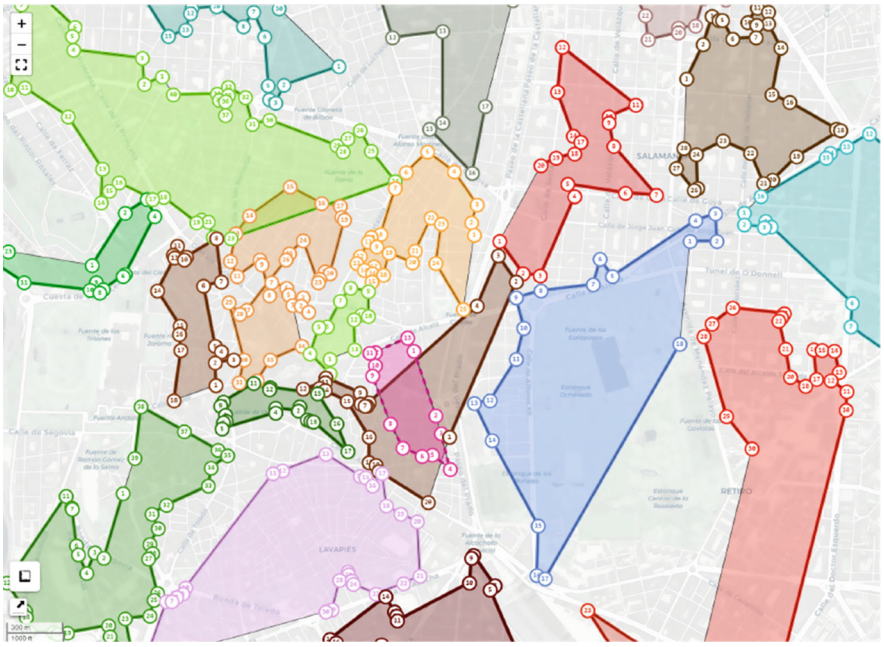

Fig. 12 Solution provided by OGA

Table 3 Numerical comparison between the company and OGA solutions

	Routes	Load	Pallets	Customers	Ldev.	Pdev.	LowLoad	LowPallets
Company	134	4113.8	438.5	17.8	33.6%	38.5%	36	50
OGA	133	3807.9	352.1	18.1	29.8%	36.8%	33	37

and the efficient solution in Fig. 12 provided by OGA with the application of the algorithm described in this chapter.

Figures 11 and 12 confirm the superiority of our proposal, based on metaheuristic technologies, compared with the initial solutions implemented by the company. We complement the visual analysis of the solutions with a quantitative comparison of the example shown in these figures. Table 3 compares the two solutions according to the following statistics:

- Routes. Number of routes in the solution
- Load. Average number of kilograms in the load of each truck
- Pallets. Average number of pallets in each truck
- Customers. Average number of customers served by each truck on each route
- Ldev. Average percentage deviation of the load of each truck with respect to the reference value of 4000 Kg set by the company
- Pdev. Average percentage deviation of the pallets of each truck with respect to the reference value of 400 pallets by truck set by the company

- LowLoad. Number of trucks (routes) with a load lower than the reference value of 4000 Kg set by the company
- LowPallets. Number of trucks (routes) with a number of pallets lower than the reference value of 400 pallets set by the company

The statistics reported in Table 3 clearly show the superiority of the OGA proposal over the previous solution implemented by the company. It must also be noted that it was obtained with the algorithm partially described in this chapter in a few minutes, while the solution developed by the company was manually created and required a few hours of the specialized engineers.

Conclusions

In this chapter, we have explored the application of metaheuristic techniques by OGA, a Spanish consulting company, to solve a complex real-world optimization problem in the beverage distribution business. Through our examination, several key conclusions have emerged:

- **Effective Application of Metaheuristics**. OGA has demonstrated that metaheuristic methodologies can be effectively employed to address intricate optimization problems in different domains, such as routing. The flexibility and robustness of these techniques enable OGA to tackle various logistical challenges, thus optimizing supply chain operations for their clients.
- **Broad Range of Techniques**. In line with other top consulting companies that apply metaheuristics, OGA utilizes a broad spectrum of methodologies, including Genetic Algorithms, GRASP, or tabu search among others. The selection of appropriate techniques based on the specific characteristics of each problem provides a powerful approach to solving real problems.
- **Financial Sustainability**. One of the standout aspects of OGA's approach is their ability to apply metaheuristic solutions in a financially sustainable manner. The combination of in-house development and a commercial solver such as Hexaly allows fast solutions to be created in a cost-effective way.
- **Handling Real-World Complexities**. The real-world problems addressed by OGA often come with multiple constraints and dynamic variables, making them highly complex. We illustrate with an example from the distribution business how a heuristic algorithm can provide high-quality solutions to these problems.
- **Contribution to Business Value**. By improving logistics and supply chain operations, OGA creates substantial business value for its clients. Optimization of these critical processes not only streamlines operations, but also enhances overall competitiveness and service delivery, leading to tangible improvements in business performance.

In conclusion, OGA's application of metaheuristic techniques showcases the profound impact these methodologies have on solving real-world optimization problems. Their success provides a valuable blueprint for other companies seeking to leverage similar technologies to enhance their business processes and achieve financial sustainability.

Abstract

Trees and forests have been a fascinating research topic in Operations Research (OR)/Management Science (MS) throughout the years because they are involved in numerous difficult problems, have interesting theoretical properties, and cover a large number of practical applications. A tree is a finite undirected connected simple graph with no cycles, while a set of independent trees is called a forest. A spanning tree is a tree covering all nodes of a graph. In this chapter, key components for solving difficult tree and forest problems, as well as insights to develop efficient heuristics relying on such structures, are surveyed. They are usually combined to obtain very efficient metaheuristics, hybrid methods, and matheuristics. Some emerging topics and trends in trees and forests are pointed out. This is followed by two case studies: A Lagrangian-based heuristic for the minimum degree-constrained spanning tree problem and an evolutionary algorithm for a generalization of the bounded-diameter minimum spanning tree problem. Both problems find applications in network design, telecommunication, and transportation fields, among others.

Introduction

Trees and forests have been a fascinating topic in Operations Research (OR)/Management Science (MS) throughout the years because they are the core of difficult problems, have interesting theoretical properties, and cover a large number of practical applications. Their interest remains intact due to the technical and scientific challenges and the rich diversity of applications using such structures. For instance, several applications have been recently addressed: people tracking is modeled as a minimum cost arborescence problem by [1]; cluster-based topologies with connecting requirements are defined as a minimum spanning tree (MST) to improve wireless sensor network lifetime in [2]; peer-to-peer distributed interactions are studied by [3] as a spanning tree, where end-to-end delays are minimized; reliable telecommunication networks have been investigated by [4], in which redundancy is added to spanning trees by introducing k-cliques ($k \geq 2$); and difficult MST problems have been investigated including uncertain data [5], new variants for optical multicast network design [6], or even multiobjective MST versions [7, 8].

Let $G = (V, E)$ be a finite, undirected, connected, and simple graph with a set V of vertices and a set E of edges, where $n = \mid V \mid$ and $m = \mid E \mid$. A tree $\mathcal{T} = \left(V', E'\right)$ is a connected subgraph of G with no cycles, such that $V' \subseteq V$ and $E' \subset E$. Whenever $V' = V$, the corresponding tree defines a spanning tree of G. An arborescence is a special directed tree with a root node r. Moreover, a forest is a set of disjoint trees

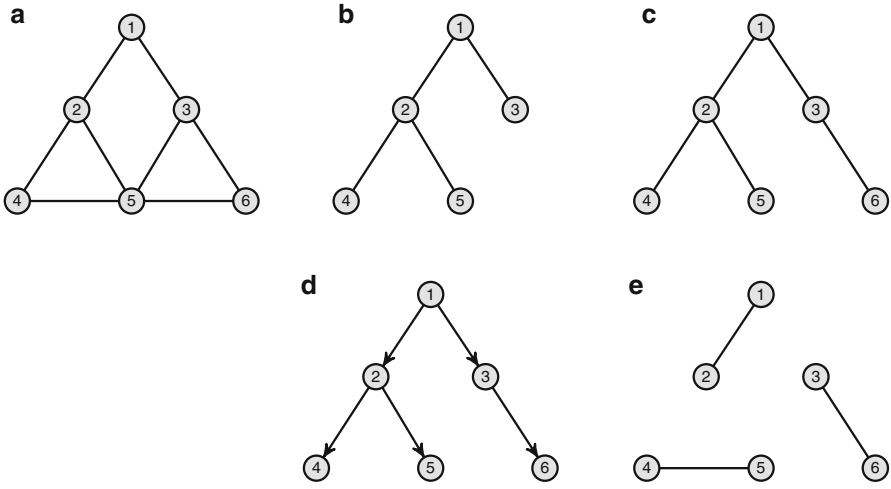

Fig. 1 Examples of tree, spanning tree, arborescence, and forest. (**a**) Graph G', (**b**) Tree, (**c**) Spanning tree, (**d**) Arborescence, and (**e**) Forest

$\mathcal{F} = \{\mathcal{T}_1, \mathcal{T}_2, \ldots, \mathcal{T}_l\}$. An example of graph G' is given in Fig. 1a, followed by examples of a tree, a spanning tree, an arborescence, and a forest of G', respectively, in Fig. 1b–e where $r = 1$. In this chapter, it is assumed familiarity with basic graph definitions such as connected graphs, connected components, subgraphs, paths, cycles, edges incident to nodes, node degree, etc.

The basic minimum spanning tree (MST) problem is defined in a weighted graph G, where a cost $c_{ij} \geq 0$ is associated with every edge $[i, j] \in E$. It aims at finding a spanning tree $\mathcal{T}$ of G such that its total cost is minimized. The number of possible MSTs for a graph is very high with up to n^{n-2} for complete graphs [9]. However, polynomial-time algorithms such as Prim's, Kruskal's, Boruvka's, and cycle elimination algorithm [10] are available to compute an MST. The general idea of Prim's algorithm is to extend an MST from an initial node $i \in V$. At each step it includes the cheapest-weight edge $[i, j] \in E$ such that one of its extremities belongs to the tree, while the other one does not. Thus, the connected component is extended until all nodes $i \in V$ belong to the solution. Kruskal's algorithm performs forest merging as follows. Initially, each vertex is a tree. Then, at each iteration, the cheapest edge connecting two forests is selected, and the two forests are merged, whenever it does not form a cycle. Boruvka's algorithm is quite similar to Kruskal's algorithm, except that, at each iteration, the cheapest edge connecting each forest to another one is selected. Then the merges are done accordingly. Both Kruskal's and Boruvka's algorithms can be developed with asymptotic complexity of $O(m \log n)$, as well as Prim's algorithm using binary heaps. Moreover, Prim's algorithm complexity can be improved to $O(m + n \log n)$ by using Fibonacci heaps; see [10] for details. The cycle elimination algorithm scans the graph using a depth-first search (DFS) strategy. The edge $[i, j]$ is added to the tree whenever a vertex

$j \in V$ not yet visited is found from the current node i of the DFS. However, if j has already been visited, it means a cycle has been found. In this case, the highest-weight edge from the found cycle is removed from the incumbent partial solution. DFS complexity is $O(m + n)$. Thus, considering a complete graph, the cycle elimination algorithm runs in $O(mn)$ since there are $O(m - n - 1)$ possible back edges and a cycle scan is done in $O(n)$. Several NP-hard problems rely on an MST with additional constraints on nodes, on edges, or even on the MST general structure. Thus, algorithms that compute an MST are usually adapted for such NP-hard extensions in order to define basic heuristics and obtain initial feasible solutions.

A large number of difficult problems rely on trees and forests. Studies [11–14] provide a collection of such problems, along with their complexity analysis. An example where constraints on the tree structure make the problem difficult is the Steiner Tree problem [15–18]. Given a subset $N \subset V$ of Steiner nodes (also referred as terminal nodes), the Steiner Tree problem consists in determining a particular minimum tree covering N. Also, setting constraints on the nodes or on the edges (paths) of an MST can transform the problem into an NP-hard problem. For instance, the degree-constrained minimum spanning tree (DCMST) problem [19–21] consists in finding an MST such that each vertex has a degree not larger than a maximum given value $k \in \mathbb{N}^*$. The bounded-diameter minimum spanning tree (BDMST) problem [7, 22, 23] is an example of a difficult problem where constraints are imposed on the MST diameter, i.e., the diameter of a tree is the number of edges in the longest path among any pair of vertices. Thus, the BDMST aims at finding an MST where the unique path between any pair of nodes does not exceed a given number of edges. Basic problems can also become difficult due to the nature of the data. For instance, the Minimum Arborescence problem [24] is defined in a digraph with real cost values associated with each arc. The objective is to find a minimum cost arborescence. Thus, for problems involving trees and forests, adding constraints or even changing few parameters or data can turn a P problem into an NP-complete problem.

Key components for solving difficult tree and forest problems, as well as insights to develop efficient heuristics relying on such structures, are surveyed here. They are usually combined to obtain very efficient metaheuristics, hybrid methods, and matheuristics. Section "Basic Features for Trees and Forests" is dedicated to a number of basic heuristics, local searches, etc. Then, two applications are described as examples, respectively, in sections "A Lagrangian Heuristic for DCMST" and "Evolutionary Heuristic for a Generalization of BDMST." Two different strategies to handle the difficult constraints are presented in these sections. The strategy used for DCMST consists of removing the difficult constraints and adding them into the objective function, following a Lagrangian relaxation. Another strategy is considered for the BDMST, where the difficult constraints are addressed as a new criterion and a bi-objective genetic algorithm is used.

Basic Features for Trees and Forests

Several heuristics, local searches, operators, different encodings, and perturbations are available in the literature to build trees and forests. They are very often combined to produce sophisticated methods. The most common heuristic structures are classified as shown in Fig. 2. The idea of this classification is not to cover all available heuristics for trees and forests, but to introduce the most used strategies having a strong potential to derive other heuristics for various difficult problems. There are two major classes of heuristics: constructive and improvement heuristics. The former includes edges or nodes at each iteration to obtain a feasible solution. The latter starts with an initial solution (e.g., a spanning tree), not necessarily feasible, and try to improve it in order to obtain better feasible solutions. Constructive and improvement heuristics are presented below, in such a way they can be adapted and applied to different difficult problems on trees and forests, where nodes, edges, or structural additional constraints are considered.

Constructive heuristics generate a feasible solution iteratively, using mainly two strategies: tree expansion and tree fusion. In the tree expansion strategy, one node is added at a time by means of an edge $e = [i, j] \in E$, where one extremity of e belongs to the solution under construction and the other extremity does not. Thus the partial incumbent solution is always a connected component. Tree expansion heuristics are usually implemented using Prim's algorithm. Examples of tree expansion heuristics are the One Time Tree (OTT) [25] and randomized greedy heuristic (RGH) [26] developed for the BDMST. Fusion heuristics start from initial disconnected forests and try to connect them by adding an edge $e = [i, j] \in E$ at a time. Thus a partial solution contains several connected components and Kruskal's algorithm can be adapted and applied [27], see section "A Greedy Heuristic for DCST." The way new edges/vertices are selected for inclusion in partial solutions (e.g., constructive heuristics) or for removal from a solution (e.g., improvement heuristics), after evaluating the objective function, has a strong impact on the final

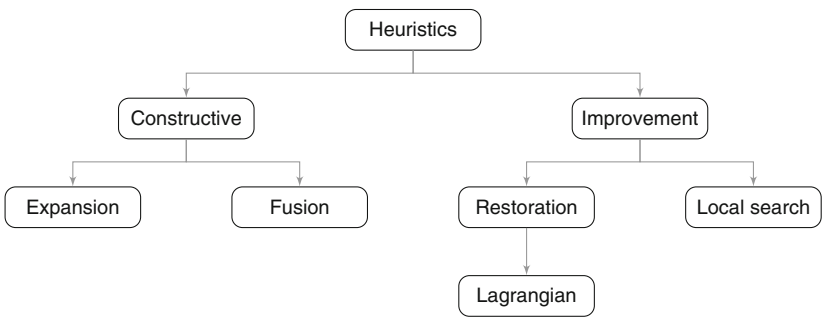

Fig. 2 A classification of heuristics for trees

solution quality. The most common ways to select edges/vertices are greedy, semi-greedy, and random. They can also be handled considering a single criterion or multi-criteria. Without loss of generality and considering a minimization function, a greedy criterion selects the edge/vertex insertion that leads to the smallest increase in the objective function. One way to handle a semi-greedy criterion is to build a list of good candidates to enter the solution, not necessarily the best ones, and make a random choice from this list. Another idea frequently found in the literature is to consider a normalized ratio between the cost and the impact on difficult constraints, e.g., a ratio between the edge cost and the additional increase in the diameter for the BDMST. Various criteria can also be addressed using a priority order instead of a ratio. For instance, one can use a second optimization criterion to select one edge, e.g., the impact on difficult constraints, whenever several edges with the smallest costs occur.

Improvement heuristics start from a solution, not necessarily feasible, and try to obtain a feasible solution by exchanging edges in the tree (resp. in a forest) with edges outside the solution. They can be roughly classified as restoration and local search heuristics. The restoration heuristics try to transform solutions in feasible ones by minimizing violations. A classical example of restoration heuristics is Lagrangian heuristics which have appeared with the pioneering works of [28, 29]. They have been broadly applied to a number of difficult problems relying on trees and forests [30–32]. The general idea is to relax difficult constraints and transfer them to the objective function, keeping a simple problem that is refined until a good solution to the overall problem is obtained. Consider a generic NP-hard optimization problem given by $Z = \{\min cx: Ax \geq b, Bx \geq d, x \in \{0, 1\}^t\}$, where A and B are matrix with rational coefficients and with dimensions $r \times t$ and $s \times t$, respectively; b, c, and d are rational vectors, and $x \in \{0, 1\}^t$ are integer variables. Let $\{\min cx: Bx \geq d, x \in \{0, 1\}^t\}$ be an easy problem that can be solved in polynomial time, and $Ax \geq b$ be the difficult constraints. Thus, Lagrangian multipliers $\lambda \in \mathbb{R}^r_+$ are associated with the difficult constraints and added into the objective function. The Lagrangian problem (LP) is given by $LP = \{\min cx + \lambda(b - Ax): Bx \geq d, x \in \{0, 1\}^t\}$ which is a lower bound on Z. The best lower bound is given by $LP(\lambda^*) = \max\{LP(\lambda), \lambda \geq 0\}$, called dual Lagrangian problem. The dual Lagrangian problem can be solved by using, for example, the subgradient methods of [33] or the volume algorithm of [34] or even by computing the Lagrange multipliers approximately using the multiplier adjustment method [35]. Theoretical results to determine the conditions stating when a Lagrangian relaxation can be better than a linear relaxation are provided by [36]. Obviously, the mathematical formulation and the decomposition will strongly impact the quality of solutions produced using Lagrangian relaxation. This kind of restoration heuristic has an interesting property: at each iteration dual and primal solutions can be built.

Local searches are very sophisticated improvement heuristics which contribute to producing very good local optima (eventually global optima). The most common local search moves, broadly applied to trees, are the *edge drop* move and the *edge insertion* move [23, 37]. Given an initial feasible solution for a difficult problem

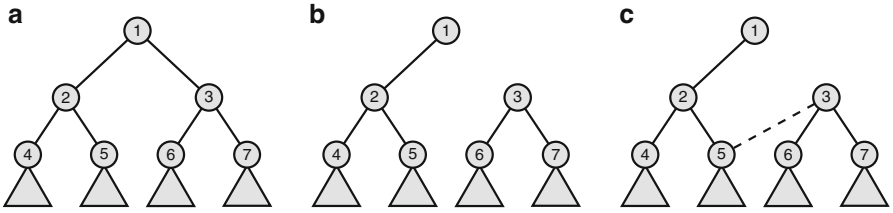

Fig. 3 Example of an *edge drop* move. (**a**) Tree, (**b**) Disconnecting 1 and 3, and (**c**) Reconnecting 3 and 5

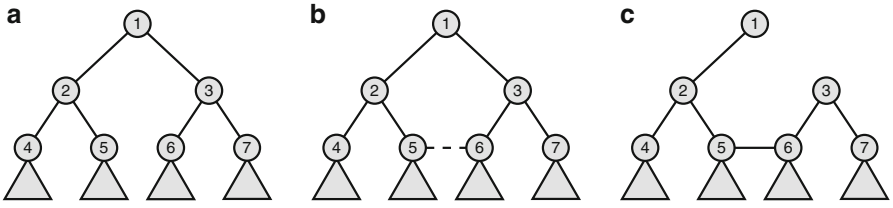

Fig. 4 Example of an *edge insertion* move. (**a**) Tree, (**b**) Connecting 5 and 6, and (**c**) Disconnecting 1 and 3

relying on a tree, the *edge drop* move consists of removing an edge from the tree. This produces two distinct connected components which are reconnected using an edge not in the tree. The greedy and semi-greedy criteria and multi-criteria can be used to choose the edge to enter the tree. Figure 3 illustrates an example, where Fig. 3a is a feasible initial solution. Then edge [1, 3] is removed as shown in Fig. 3b, generating two separate connected components. Consider [3, 5] as the edge which produces the best improvement possible. Thus it enters the solution following a greedy strategy as shown in Fig. 3c.

On the other hand, in the *edge insertion* move, an edge is first inserted in the tree. By definition of a tree, it necessarily results in a cycle. Then, an edge may be removed from the cycle. Figure 4 depicts an example for this move. A feasible solution is presented in Fig. 4a. In the sequel, edge [5, 6] is introduced and the cycle {5, 6, 3, 1, 2, 5} is formed as shown in Fig. 4b. Suppose that removing edge [1, 3] will produce the highest gain in the objective function. Thus this edge is dropped following a greedy strategy as depicted in Fig. 4c.

A number of variations on the *edge drop* and *edge insertion* moves are found in the literature. These moves are also referred as 1-opt since one edge in the incumbent solution is replaced by another one that does not belong to the solution. When applied to trees, two strategies are available to perform such a 1-opt move: either first dropping an edge or first inserting an edge. This may lead to different final solutions. The k-opt generalizes the 1-opt move by replacing k edges from an incumbent solution. This move is formalized in section "A Lagrangian Heuristic for DCMST."

Data Structures for Trees

Choosing the adequate data structure for representing and manipulating a solution is a critical task since it directly impacts the complexity of basic operations. They include both building and modifying a solution. Two mapping functions are associated with the data structures: How to store the information from a given tree (encoding) and how to obtain a tree out of the information (decoding). In this section, a basic direct representation is presented as well as several data to handle additional constraints on the trees. In section "Encodings for Trees," other representations are presented, along with the way to obtain the associated tree. Several insights are given regarding their use in evolutionary algorithms.

Let $G = (V, E)$ and $s \in V$ be, respectively, a graph defined as before and an arbitrary root vertex [10]. The following data structure can be used for directed and undirected trees, depending on the root node which can be artificial or not. The predecessor j of a vertex i in a tree is the first vertex in the path from i to s. By definition of a tree, j is unique and only depends on the choice of s. A successor j of a vertex i is a vertex whose predecessor is i. One of the simplest ways to store the information of a tree in a fixed-size data structure is to use the predecessors. This direct representation keeps the predecessors in a vertex-indexed vector *pred*. Thus $pred(i)$ is the predecessor of vertex i or, alternatively, the edge between i and $pred(i)$. The root has no predecessors; then $pred(s) = \emptyset$. Such a structure allows an $O(1)$ access to each predecessor and to each edge connecting the subtree rooted at i with the rest of the tree. It also allows a scan of all edges of a tree in $O(n)$.

Additional redundant data may be useful to perform tree manipulation and to allow efficient checking operations. One such data is the list of all the direct successors of a vertex. It can be explicitly defined as a list of vertices for each vertex, as well as be implicitly stored by adding two attributes to each vertex i: its first successor $succ(i)$ and $next(i)$, the next successor for $pred(i)$. For instance, if the direct successors of vertex a are $\{b, c, d\}$, the first successor of a is $b = succ(a)$. The successors of a are as follows: $c = next(b)$, $d = next(c)$ and $next(d) = \emptyset$. This encoding shares similarities with the forward star structure presented in [38] for graphs, and the implicit list can be made bidirectional by adding an attribute $pred(i)$ to each vertex which stores the previous successor in the list of $pred(i)$. This way, $O(1)$ operations such as successor insertion or deletion are ensured. The number of direct successors $nb_succ(i)$ can be kept as well.

Successor and predecessor structures allow managing several operations such as finding a cycle for *edge insertion* moves, finding the cheapest-weight costs for *edge drop* moves, and, with a few additional information, addressing difficult constraints like degree and diameter constraints. For instance, the $depth(i)$ of a vertex i is equal to the number of edges in the unique path from a given root vertex s to i. It can be used for checking hop and diameter constraints.

Scanning a cycle created by adding an edge $[i, j] \in E$ into a spanning tree can be done efficiently using the predecessor structure. First, each node in the path $i \rightarrow s$ is set as visited. The same is done in the path $j \rightarrow s$, stopping as soon as a given

vertex k has already been visited. Thus k belongs to both paths $i \rightarrow s$ and $j \rightarrow s$. Getting the edge with the highest cost can be done by keeping the edge with the highest cost found when scanning the path $i \rightarrow s$ (resp. $j \rightarrow s$) at each visited node. A modified DFS or breadth-first search (BFS) starting at i and stopping as soon as j is found could also be used. However, this would require more sophisticated tree data structures to obtain $O(n)$ complexity as for the predecessor vector. This way, the *edge insertion* move can be performed in $O(n)$.

Another useful data can be defined to quickly check if a vertex belongs to a subtree. Let $first(i)$ and $last(i)$ be two indexes associated with each vertex i. A DFS is applied on the tree, starting from s. Then $first(i)$ stores the DFS vertex counter the first time i is visited and $last(i)$ gets the DFS vertex counter when the DFS leaves the subtree of i. Thus, vertex j belongs to the subtree of vertex i if and only if $first(j) \in [first(i), last(i)]$. Besides, the number of vertices in the subtree of i, i included, is $size(i) = last(i) - first(i) + 1$. This information can be used to check for special cases in *edge insertion* moves, if one extremity belongs to the subtree of the other one. The same idea can be used to check if a tree is feasible in the capacitated MST [12, 37]. A demand D_i is associated with each vertex i and the sum of the demands in any subtree must not exceed a capacity Q. A demand counter is used instead of a vertex counter in the DFS.

The *edge drop* move requires reconnecting two trees disconnected after an edge $[i, j]$ has been removed. Without loss of generality, suppose i is the predecessor of j, i.e., $i = pred(j)$. First, all the vertices are set as unvisited. Then, all vertices in the subtree of j (included) are set as visited by performing a DFS or a BFS, using the list of successors presented before. Getting the lowest cost edge reconnecting the two trees can be done in $O(m)$ by finding the smallest edge in E with one extremity visited and the other one unvisited. This last operation is the most expensive and the *edge drop* move is in $O(m)$.

As mentioned before, the depth of a vertex from the root in a tree can be used to check hop and diameter constraints. For the root vertex, $depth(s) = 0$. A simple DFS or BFS starting from s is sufficient to compute the depth of each vertex in $O(n)$. They may require an artificial vertex 0 playing the role of center, $depth(0) = 0$. The artificial vertex connects the central vertex whenever D is even and one of the extremities for a central edge if D is odd. Let $L = D/2$ and $L = (D - 1)/2$ be the maximum depth allowed for a node, respectively, when D is even resp. odd. Thus, whenever an artificial vertex is used, a diameter limit D on the tree corresponds to a depth limit $L + 1$ for each vertex from vertex 0. Checking the degree is simpler; one may just add the number of successors and predecessors for each vertex.

Encodings for Trees

The tree representation given in the section "Data Structures for Trees" can be used for most constructive heuristics and for moves in local searches and metaheuristics. However, evolutionary algorithms (EAs) usually require additional properties on

the representation, and several other tree encodings have been proposed. In EAs, operations are mostly done on encodings (the chromosomes) rather than on the solutions. These usually consist of crossovers and mutations in order to make the set of encodings (the population) evolve. Selection is done to obtain the best elements. It requires the evaluation of each element through the construction of the associated solution, named decoding.

Several properties on the encoding/decoding, i.e., the mapping between encodings and solutions, are needed to fully benefit from the design of EAs: (i) the time and space complexities for those operations should be as low as possible, (ii) any encoding should correspond to a feasible solution, (iii) the decoding should be unbiased, (iv) there should be at least one encoding leading to each optimal solution, (v) any offspring obtained from crossover and mutation should be valid, and (vi) the offsprings should share as much similarities as possible with their parents.

According to those criteria, the predecessor structure presented before offers a $O(n)$ complexity for encoding/decoding. However, a random vector of predecessors is very unlikely to be feasible. Classical crossovers and mutations also generate infeasible offsprings and a repair operator is required. On the other hand, there always exists one encoding for each optimal solution and the feasible offsprings inherit a lot of similarities from their parents.

Another classical representation is the Boolean edge-indexed vector. The status of each edge (used/unused) is stored in the solution. Thus it follows the binary encoding paradigm suggested in the early versions of genetic algorithms (GAs). However, a random vector is highly unlikely to be feasible and crossovers and mutations seldom produce feasible offsprings. Thus the repair operator is mandatory, unless defining dedicated crossovers and mutations.

Prüfer sequences have also been used to encode trees. They were introduced in [39] to prove the Cayley's theorem [9] and there is a bijection between the set of spanning trees and the set of Prüfer sequences. They are basically repetition vectors of size $n - 2$ in which each vertex i appears $degree(i) - 1$ times. Encoding and decoding can be done in $O(n \log n)$. There is no need for repair operator since every sequence corresponds to a feasible spanning tree. However, while appealing, this representation suffers from several drawbacks [40], especially with respect to property (vi) since a small change in the sequence might lead to a completely different solution.

Random keys [41] have also been used and are quite popular. A random key is a weight in [0, 1]. For trees, one random key is associated with each edge, leading to a real-valued vector of size m. The decoding first consists of sorting the edges according to their random key and then applying a Kruskal-based constructive heuristic. Thus, it is done in $O(m \log m)$. It always leads to a feasible spanning tree and does not require a repair operator.

All the encodings suffer from shortcomings with respect to the properties (i)–(vi) mentioned before [42]. Moreover, they may not be able to handle sparse graph or additional constraints on the tree structure. Aside from random keys, a good alternative seems to be edge-set encoding [42]: The edges of the tree are directly stored in a variable-length vector. Thus, this is an explicit variable-size encoding

whose encoding/decoding can be done in $O(n)$. It is less biased toward special trees than random keys. It has been shown to be quite effective for solving NP-hard extensions of MST, provided dedicated crossovers and mutations are used.

A Lagrangian Heuristic for DCMST

The use of Lagrangian relaxation in heuristic procedures has been proved to be quite a powerful tool for solving certain problems, especially DCMST. A Lagrangian heuristic (LH) involves a small number of ingredients that can be implemented efficiently: (i) determining Lagrange multipliers and evaluating Lagrange subproblems, (ii) obtaining feasible solutions from the Lagrange multipliers, and (iii) improving feasible solutions by a local search. The main advantages of an LH are that it is simple to implement, solutions of good quality can be obtained in a reasonable computational time, and lower bounds (LB) and upper bounds (UB) are available at each iteration. In addition, an LH can be used to obtain starting incumbent solutions in more complex exact algorithms.

Let $G = (V, E)$ be a graph defined as before. Costs $c_e \in \mathbb{R}^+$ are associated with each edge $e \in E$, and a maximum degree $d_v \in \mathbb{N}^*$ is associated with each node $v \in V$. The DCMST problem consists in finding a minimal cost spanning tree $\mathcal{T}$ of G such that the degree constraints are ensured for each node.

Figure 5a illustrates an example of a graph G, in which edge costs are reported in the middle of each edge and the maximum node degree constraints for spanning trees of G are given in brackets near each node. An MST of G, with cost equal to 5, is given in Fig. 5b. One may note that this MST violates the degree constraint in node 1. A feasible solution for the degree-constrained spanning tree (DCST) for G is provided in Fig. 5c, with cost equal to 9.

Problem Formulation

In order to present a mathematical model for DCMST problem, let $E(S) \subseteq E$ be the set of edges with both extremities in $S \subseteq V$. Let $\delta(v) \subseteq E$ be the set of edges adjacent

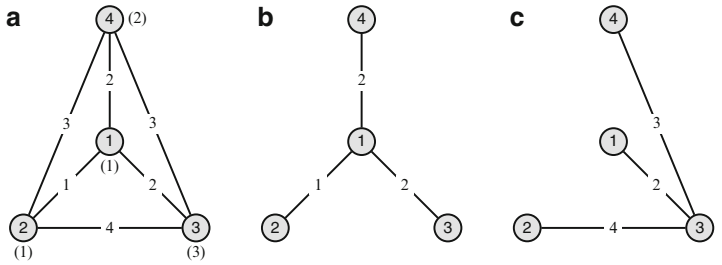

Fig. 5 Example of a tree with degree constraints. (**a**) A graph G, (**b**) MST of G, and (**c**) A DCST of G

to $v \in V$. Binary variables x_e, for all $e \in E$, represent the characteristic vector for a spanning tree of G, where $x_e = 1$ if an edge e belongs to the solution, and $x_e = 0$ otherwise. The mathematical formulation is given from (1) to (4).

$$(P) \quad \min_{x \in \{0,1\}^m} \quad \sum_{e \in E} c_e x_e \tag{1}$$

$$s.t. \quad \sum_{e \in E} x_e = n - 1, \tag{2}$$

$$\sum_{e \in E(S)} x_e \leq |S| - 1, S \subset V, \tag{3}$$

$$\sum_{e \in \delta(v)} x_e \leq d_v, \forall \ v \in V. \tag{4}$$

An MST is defined from (1) to (3) and constraints (4) control the degree of each vertex. These last constraints are the difficult ones. Thus they are relaxed in the LH presented next. Note that when $d_v = 2$, for all $v \in V$, the problem is reduced to finding a Hamiltonian path of minimum cost in G. Thus the DCMST is NP-hard [12].

The role of Lagrange penalties or multipliers is to take into account violations on some relaxed constraints. Given a tree $\mathcal{T}$ and for every node $v \in V$, the amount of node violation is the difference $\sum_{e \in \delta(v)} x_e - d_v$ between its maximum degree d_v and its degree in $\mathcal{T}$. In a DCST only non-positive node violations are allowed. Positive node violation is penalized by associating a non-negative penalty λ_i with each violated node i. In this case, every edge incident to i has its cost increased by λ_i. When both end nodes i and j of an edge $[i, j] \in E$ have positive penalties λ_i and λ_j, respectively, the resulting Lagrange cost becomes $c_{ij} + \lambda_i + \lambda_j$.

Consider the MST in Fig. 5b. It violates the degree constraint of node 1 (three edges are adjacent to this node and the maximum allowed is one). Figure 6 illustrates an example of MSTs computed with edge costs modified by Lagrange multipliers, where spanning trees of minimum cost are defined by solid lines in each graph. If a penalty $\lambda_1 = 10$ is set and $\lambda_i = 0$ for $i \in V \backslash \{1\}$ and an MST is computed for the graph with modified edge costs, the spanning tree in Fig. 6a is obtained. The degree constraint of node 2 is violated. Alternatively, if $\lambda_1 = 10$, $\lambda_2 = 2$, and $\lambda_i = 0$ for $i \in V \backslash \{1, 2\}$, an MST on the modified graph is in Fig. 6b. It is also feasible for the original graph G in Fig. 5a.

Thus, the idea is to determine the "best" set of Lagrange multipliers leading to an MST on the graph with modified edge costs whose Lagrangian solution value is equal to the value of an optimal DCMST. To do so, the Lagrangian problem (P_λ) is defined by associating Lagrange multipliers $\lambda \in \mathbb{R}^n_+$ with constraints (4) and bringing them to the objective function (1).

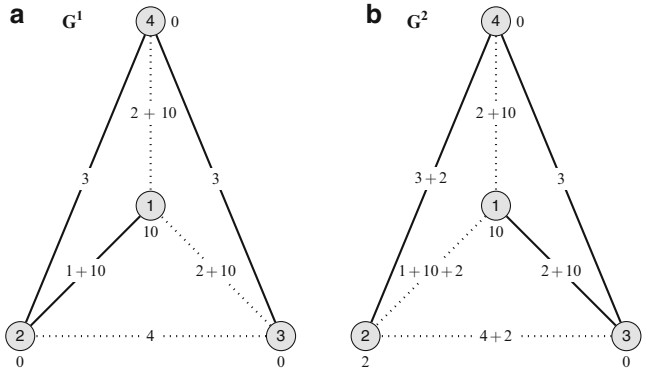

Fig. 6 Example of graphs with edge cost modified by Lagrange multipliers. (**a**) MST with $\lambda_1 = 10$. (**b**) MST with $\lambda_1 = 10$, $\lambda_2 = 2$

$$(P_\lambda) \quad \min_{x\in\{0,1\}^m} \sum_{[i,j]\in E} \left(c_{ij} + \lambda_i + \lambda_j\right) x_{ij} - \sum_{i\in V} \lambda_i d_i \qquad (5)$$
$$s.t. \qquad (2) - (3).$$

For any $\lambda \geq 0$, the solution value of (P_λ) is a lower bound on the optimal solution of (P). Consequently, the solution of the problem (D) is the best lower bound one can get for the solution of (P). Problem (D) is the Lagrangian dual problem of (P).

$$(D) \quad \max_{\lambda\geq 0} \quad \min_{x\in\{0,1\}^m} \sum_{[i,j]\in E} \left(c_{ij} + \lambda_i + \lambda_j\right) x_{ij} - \sum_{i\in V} \lambda_i d_i \qquad (6)$$
$$s.t. \qquad (2) - (3).$$

The MST on the graph G^2 in Fig. 6b has a cost $(3 + 5 + 12) - (10 \times 1 + 2 \times 1) = 8$. This is a lower bound on the optimal DCMST value of the graph in Fig. 5a. It is optimal since that solution is feasible for G and its original cost in G is 8.

A Subgradient Procedure for DCMST Problem

The classical subgradient (SG) method of Held et al. [43] is used to compute Lagrange multipliers λ iteratively for problem (P_λ). At each iteration k of the method, the idea is to find a direction s^k and a step size t_k to move from λ^k to a new set of multipliers λ^{k+1}:

$$\lambda^{k+1} = \max\left\{0, \lambda^k + t_k s^k\right\} \qquad (7)$$

s^k is the subgradient of $\left(P_{\lambda^k}\right)$ with respect to the Lagrangian solution x^k. Its coordinates are given by

$$s_i^k = \sum_{e \in \delta(i)} x_e^k - d_i, \quad \forall i \in V \tag{8}$$

Determining the step size t_k requires an incumbent UB on the optimal solution value of (P), the Lagrangian value LB^k referred to x^k, and the norm of the direction s^k. It is defined as

$$t_k = \frac{\alpha \left(UB - LB^k\right)}{\left\|s^k\right\|^2} \tag{9}$$

where α is a scaling factor. Initially $\alpha = 2$ and it is reduced (usually $\alpha \leftarrow \alpha/2$) after some iterations with no improvement on the best LB. Thus, convergence of the SG algorithm is ensured. The number of iterations can be limited to a maximum value determined according to the characteristic of the problem instances being solved. If the Lagrangian solution is feasible for (P) and its Lagrangian value is equal to UB, it is optimal and the algorithm stops. Further details on the SG algorithm for DCMST problem can be found in [30].

As an example, the SG algorithm is applied to the graph G in Fig. 5a. Initially $\lambda^0 = 0$ and the resulting graph $G(\lambda^0)$ has the same edge costs as in G. The Lagrangian solution $\mathcal{T}^0$ for $G(\lambda^0)$ is the MST of G (Fig. 5b), and its Lagrangian cost is $\mathrm{LB}^0 = 5$. The degree of nodes 1, 2, 3, and 4 in $\mathcal{T}^0$ are 3, 1, 1, and 1, respectively. The initial subgradient direction is $(s^0)^t = (2, 0, -2, -1)$. Figure 8 presents graphs $G(\lambda^k)$ of each SG iteration k. The Lagrange edge costs are displayed near each edge and Lagrange multipliers near each node. Moreover, Lagrangian solutions $\mathcal{T}^k$ of $G(\lambda^k)$ are defined by solid lines. Lagrange multipliers are computed according to Fig. 5 as follows: suppose the incumbent $\mathrm{UB} = 9$ is given by the DCST in Fig. 5c, as computed by heuristic in section "A Greedy Heuristic for DCST." The new set of Lagrange multipliers is $(\lambda^1)^t = (16/9, 0, 0, 0)$. The corresponding graph $G(\lambda^1)$ leads to the Lagrangian solution $\mathcal{T}^1$ in Fig. 7, in solid lines. The new direction s^1 is carried forward in Fig. 8, column $\mathcal{T}^1$. The SG algorithm iterates until iteration 4, where the Lagrangian solution $\mathcal{T}^4$ is a feasible DCST for G. The original cost of $\mathcal{T}^4$ in G is 8 and its Lagrangian cost is $\mathrm{LB}^4 = 596/75$. As all edges of G have integer costs, the optimal solution value must be integer. Therefore, the optimal solution value UB^* is such that $\lceil 596/75 \rceil \leq \mathrm{UB}^* \leq 8$. Thus $\mathcal{T}^4$ is optimal and the algorithm stops.

A Greedy Heuristic for DCST

Kruskal's algorithm can be adapted [30] to compute DCSTs on a graph $G = (V, E)$. It consists of (i) ordering the edges in E by non-decreasing edge costs; (ii) creating a forest with $|V|$ trivial trees $C_i = \{i\}$, for all $i \in V$; and (iii) connecting all disjoint trees (forests) by including one edge at a time, using the ordered list until a spanning tree is obtained. A vertex is saturated if its degree matches the maximum degree

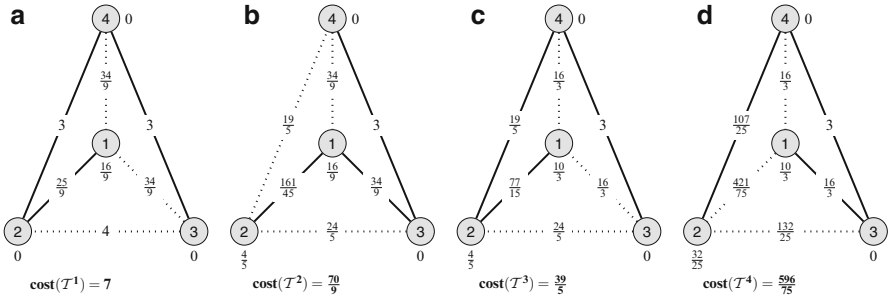

Fig. 7 Example of iterations for the SG method. (**a**) $\mathbf{G}(\boldsymbol{\lambda}^1)$, (**b**) $\mathbf{G}(\boldsymbol{\lambda}^2)$, (**c**) $\mathbf{G}(\boldsymbol{\lambda}^3)$, and (**d**) $\mathbf{G}(\boldsymbol{\lambda}^4)$

$$\mathcal{T}^1 \quad \lambda^1 = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 0 \end{pmatrix} + \frac{2(9-5)}{9} \begin{pmatrix} 2 \\ 0 \\ -2 \\ -1 \end{pmatrix} \overset{\lambda \geq 0}{=} \begin{pmatrix} \frac{16}{9} \\ 0 \\ 0 \\ 0 \end{pmatrix} \quad s^1 = \begin{pmatrix} 0 \\ 1 \\ -2 \\ 0 \end{pmatrix}$$

$$\mathcal{T}^2 \quad \lambda^2 = \begin{pmatrix} \frac{16}{9} \\ 0 \\ 0 \\ 0 \end{pmatrix} + \frac{2(9-7)}{5} \begin{pmatrix} 0 \\ 1 \\ -2 \\ 0 \end{pmatrix} \overset{\lambda \geq 0}{=} \begin{pmatrix} \frac{16}{9} \\ \frac{4}{5} \\ 0 \\ 0 \end{pmatrix} \quad s^2 = \begin{pmatrix} 1 \\ 0 \\ -1 \\ -1 \end{pmatrix}$$

$$\mathcal{T}^3 \quad \lambda^3 = \begin{pmatrix} \frac{16}{9} \\ \frac{4}{5} \\ 0 \\ 0 \end{pmatrix} + \frac{2(9-\frac{70}{9})}{3} \begin{pmatrix} 1 \\ 0 \\ -1 \\ -1 \end{pmatrix} \overset{\lambda \geq 0}{=} \begin{pmatrix} \frac{10}{3} \\ \frac{4}{5} \\ 0 \\ 0 \end{pmatrix} \quad s^3 = \begin{pmatrix} 0 \\ 1 \\ -2 \\ 0 \end{pmatrix}$$

$$\mathcal{T}^4 \quad \lambda^4 = \begin{pmatrix} \frac{10}{3} \\ \frac{4}{5} \\ 0 \\ 0 \end{pmatrix} + \frac{2(9-\frac{39}{5})}{5} \begin{pmatrix} 0 \\ 1 \\ -2 \\ 0 \end{pmatrix} \overset{\lambda \geq 0}{=} \begin{pmatrix} \frac{10}{3} \\ \frac{32}{25} \\ 0 \\ 0 \end{pmatrix} \quad s^4 = \begin{pmatrix} 0 \\ 0 \\ -1 \\ 0 \end{pmatrix}$$

Fig. 8 Updating Lagrange multipliers during the SG iterations shown in Fig. 7

allowed. A tree is saturated if all its vertices are saturated. Then, an edge $[u, v] \in E$ is inserted in the solution if both u and v are not saturated and if they do not belong to the same tree. Moreover, merging the two trees using $[u, v]$ must not lead to a saturated tree, except if the resulting tree spans V.

Consider the graph G in Fig. 5a and assume that the ordered list of edges is {[1, 2], [1, 4], [1, 3], [2, 4], [3, 4], [2, 3]}. Initially, each vertex is a trivial tree. The first edge to be considered is [1, 2]. It is discarded as its inclusion would result in a saturated tree. In the sequel, edge [1, 4] can be added since it does not saturate vertices 1 and 4 nor create a cycle. Node 1 is saturated; thus, the third edge [1, 3] is rejected. The fourth edge [2, 4] is also not accepted because it would result in

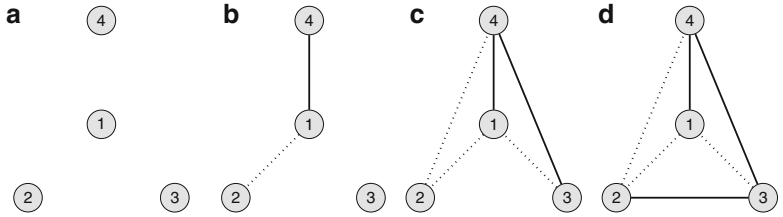

Fig. 9 Example of Kruskal-based heuristic for DCST. (**a**) Initial, (**b**) First edge, (**c**) Second edge, and (**d**) Third edge

a saturated tree. The fifth edge [3, 4] is included, *idem* for the sixth edge [2, 3]. Then the algorithm stops with a feasible DCST. Note that this heuristic stops with a feasible solution for complete graphs only. Figure 9 presents this example with the ordered list of edges defined above. Solid lines correspond to edges included, while dotted lines correspond to discarded edges.

This heuristic can also be applied to graphs with modified Lagrange edge costs during the SG and compute its cost on the graph G. Nevertheless, doing this every SG iteration is time consuming. Finally, this heuristic can be used only when a Lagrangian solution improves the best incumbent LB on the optimal solution of (P).

Improving DCSTs with a Local Search

Given a graph $G = (V, E)$ and a spanning tree $\mathcal{T}$ of G, let $E(\mathcal{T})$ be the set of edges in $\mathcal{T}$. Moreover, consider a given subset $\{e_1, e_2, \cdots, e_k\} \subset E(\mathcal{T})$ of the edges belonging to $\mathcal{T}$. If there is a subset of edges $\left\{\hat{e}_1, \hat{e}_2, \cdots, \hat{e}_k\right\} \subset E \backslash E(\mathcal{T})$ such that $E(\mathcal{T}) \setminus \{e_1, e_2, \cdots, e_k\} \cup \left\{\hat{e}_1, \hat{e}_2, \cdots, \hat{e}_k\right\}$ induces a spanning tree $\hat{\mathcal{T}}$ of G, then $\hat{\mathcal{T}}$ is said to belong to a k-neighborhood of $\mathcal{T}$, denoted by $\hat{\mathcal{T}} \in N_k(\mathcal{T})$, and that $\mathcal{T} \in N_k\left(\hat{\mathcal{T}}\right)$.

Consider $k+1$ connected components $C_1, C_2, \cdots, C_{k+1}$ obtained after removing k edges $\{e_1, e_2, \cdots, e_k\} \subset E(\mathcal{T})$ from a given spanning tree $\mathcal{T}$. If $\{\overline{e}_1, \overline{e}_2, \cdots, \overline{e}_k\} \subset E \backslash E(\mathcal{T})$ is a minimum cost subset of k edges to reconnect the $k+1$ components $C_1, C_2, \cdots, C_{k+1}$ forming a new spanning tree, then $\mathcal{T} \cup \{\overline{e}_1, \overline{e}_2, \cdots, \overline{e}_k\} \setminus \{e_1, e_2, \cdots, e_k\}$ is called a *k -opt edge exchange*. Such a move corresponds to applying k times an *edge drop* or an *edge insertion* move, as seen in section "Basic Features for Trees and Forests."

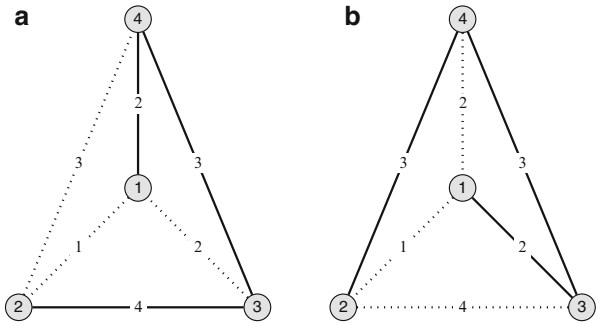

Fig. 10 Example of a *2-opt edge exchange* move. (**a**) Tree $\mathcal{T}$, (**b**) Tree $\mathcal{T}^1$

Figure 10 illustrates an example of a *2-opt edge exchange*. Tree $\mathcal{T}^1$ in Fig. 10b is obtained from $\mathcal{T}$ in Fig. 10a by removing the edges [1, 4], [2, 3] and adding the edges [1, 3], [2, 4] while keeping the feasibility of the resulting tree.

Determining the best *k-opt edge exchange* move among all $\binom{|E(\mathcal{T})|}{k}$ combinations of k edges of $E(\mathcal{T})$ is very time consuming. A reasonable trade-off between solution quality and processing time is to limit k to 3. A greedy local search then iteratively performs *k-opt edge exchange* moves, until reaching a local optimum.

A Lagrangian Heuristic for DCMST

Using the components presented before, Algorithm 1 is a Lagrangian heuristic for DCMST problem. Given a graph $G = (V, E)$, a feasible starting DCST $\mathcal{T}^*$ is computed by the heuristic in section "A Greedy Heuristic for DCST." A limit *MaxIter* is set to the number of SG iterations. Basically, the subgradient method (section "A Subgradient Procedure for DCMST Problem") is used to update Lagrange multipliers until the stopping criterion (number of iterations or optimal solution) is met. At each iteration k, the classical Kruskal's algorithm [27] computes a Lagrangian solution $\mathcal{T}^k$ on the graph $G(\lambda^k)$: $\mathcal{T}^k \backslash \text{MST}\left(G\left(\lambda^k\right)\right)$. The Lagrangian solution cost of $\mathcal{T}^k$ (LagrCost $\left(\mathcal{T}^k\right)$) gives a lower bound LB^k on the optimal solution value. If it improves LB, the new value LB^k is updated. Eventually, $\mathcal{T}^k$ is a DCST. In this case, a local search procedure (section "Improving DCSTs with a Local Search") is called to improve $\mathcal{T}^k$ if the cost Cost $\left(\mathcal{T}^k\right)$ of $\mathcal{T}^k$ in G improves UB: $\mathcal{T}^* \backslash \text{LocalSearch}\left(\mathcal{T}^k\right)$.

Algorithm 1 Lagrangian heuristic [30]

Data: a graph $G = (V, E)$, a DCST $\mathcal{T}^*$, a maximum number of iterations $MaxIter$;
Result: a DCST of G;
initialization: $k \leftarrow 0$; $\lambda^0 \leftarrow \mathbf{0}$; $T^0 \leftarrow MST(G(\lambda^0))$; LB$\leftarrow LagrCost(\mathcal{T}^0)$; UB$\leftarrow Cost(\mathcal{T}^*)$; **while** *(LB<UB* **and** $k < MaxIter$*)* **do**
  compute λ^{k+1} by using Equation (7);
  set $\mathcal{T}^k \leftarrow MST(G(\lambda^k))$ and LB$^k \leftarrow LagrCost(\mathcal{T}^k)$;
  if *(*LB$^k >$ *LB)* **then**
    LB$\leftarrow$LB^k;
  end
  if *(*$\mathcal{T}^k$ *is a DCST* **and** $Cost(\mathcal{T}^k) <$*UB)* **then**
    $\mathcal{T}^* \leftarrow LocalSearch(\mathcal{T}^k)$;
    UB$\leftarrow Cost(\mathcal{T}^*)$;
  end
  $k \leftarrow k + 1$;
end
return $\mathcal{T}^*$;

As mentioned before, halving α after some SG iterations without any improvement on LB guarantees the convergence of the subgradient procedure. Also, one can work with a reduced instance $G' = (V, E')$ of the problem, by considering only a subset $E' \subset E$ of ordered edges required to obtain a feasible DCST for the problem, by using the modified Kruskal's algorithm from section "A Greedy Heuristic for DCST." Moreover, more sophisticated local searches and even metaheuristics can be used instead of the local search presented in section "Improving DCSTs with a Local Search." For instance, variable neighborhood search (VNS), dynamic variable neighborhood descent (VND), and absorption function [44] have been used in [19]. As the k-opt local search procedure is based on a greedy criterion, the Lagrangian heuristic may not escape local optima. To overcome this issue, the authors in [19] suggest to integrate a VNS and a dynamic VND, as well as absorption functions of [44].

The LH presented here has been applied to a number of benchmark instances from the literature: Euclidean And-inst, Hamiltonian Ham-inst, Shrd [45], M-graph and R-graph instances, and the new Dr-inst and De-inst instances [21]. In addition, the solutions obtained by LH have been used as cutoff to speed up exact methods [19, 21] for DCMST problems.

Results obtained by LH have provided new average gaps of up to 0.188% and 6.230% for And-inst and Ham-inst instances, respectively. Moreover, it has solved to optimality the SHRD, M-graph, and R-graph sets. After introducing the VNS, optimality was reached for 23 out of 25 And-inst instances, 4 out of 15 Ham-inst

instances, and 8 out of 18 De-inst instances. Furthermore, optimal solutions were obtained for all Dr-inst instances. Thus, LH has been shown to be a powerful approach for DCMST problems.

Evolutionary Heuristic for a Generalization of BDMST

In this section, another way to handle difficult constraints is described for a generalization of the BDMST. The difficult constraints of the problem are defined on the paths of the tree rather than on the nodes as for DCMST. BDMST is defined in a connected and undirected graph $G = (V, E)$, where costs $c_{ij} \geq 0$ are associated with each edge $[i, j] \in E$. Consider $\mathcal{T}$ as a spanning tree of G. By MST definition, there is a unique path $\mathcal{P}_{ij}$ in $\mathcal{T}$ between any pair of nodes $i, j \in V$. Thus, given ρ_{ij} the number of edges in the path $\mathcal{P}_{ij}$, the diameter D of $\mathcal{T}$ is defined as $D = \max\{\rho_{ij} : \forall\, i, j \in V, i \neq j\}$. The BDMST consists in finding an MST such that its diameter does not exceed a given $k \in \mathbb{N}^*$, i.e., $D \leq k$. This problem belongs to the NP-hard class whenever $3 < k < n - 1$ [12].

An example is shown in Fig. 11 for $k = 2$, considering the graph given in Fig. 11a. The MST is presented in Fig. 11b. It violates the diameter since $D = 3$. The optimal BDMST solution is provided in Fig. 11c, where the longest path has two edges ($D = 2$).

Several works are found in the literature for BDMST such as mathematical formulations [46–48], exact methods [22, 49, 50], and heuristics [23, 26, 51]. Yet, optimality has not been proved for an important benchmark of instances proposed by [26], containing complete graphs whose size varies from 50 to 1000 vertices. Thus, an original strategy is to investigate the search space of this problem by using bi-objective approaches to compute the Pareto front. The idea is to drop the difficult constraints, i.e., diameter, and to consider them as a new criterion. Then a bi-objective optimization problem is solved. Thus the total tree cost and the diameter are minimized simultaneously. The problem remains difficult since the goal is to determine a Pareto front. However, the multiobjective strategy is interesting since every spanning tree is feasible and efficient algorithms are available to compute

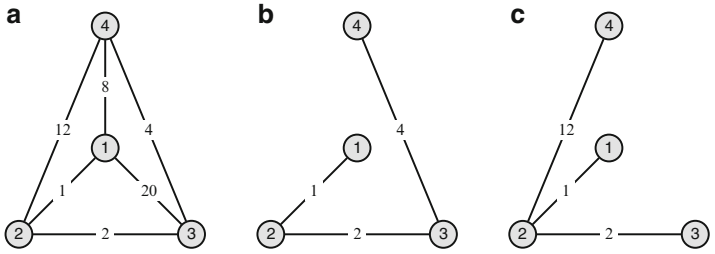

Fig. 11 Example of a tree with diameter constraints. (**a**) A graph G, (**b**) MST of G, and (**c**) A BDMST of G

them. Moreover, in recent years, several advances have been done in solving multiobjective (bi-objective) problems using heuristics and metaheuristics. In addition, bi-objective heuristics do not depend on a good mathematical formulation. Another key point is that it is possible to bound the values for each criteria for problems relying on trees such as BDMST.

Bi-objective optimization for MSTs has already been investigated considering two cost objective functions. For example, a branch-and-bound was proposed in [8] and a two-phase enumeration was introduced in [52, 53]. Bi-objective metaheuristics are also used for two cost objective functions as in [54, 55]. A multiobjective evolutionary algorithm (MOEA) for the network design problem is presented in [55] to minimize the infrastructure cost and the maintenance cost, while a multiobjective greedy randomized adaptive search procedure (GRASP) is applied in [54] to find MST with two costs. Using this idea to handle difficult constraints seems to be more recent, in particular for the BDMST. Works [7, 56, 57] are dedicated to multiobjective strategies for the BDMST, referred as the bi-objective minimum diameter-cost spanning tree (bi-MDCST) problem. One of the most efficient multiobjective heuristics developed for bi-MDCST is the non-dominated sorting genetic algorithm (NSGA-II), presented in the sequel.

Problem Definition

Without loss of generality, applying bi-objective heuristics for a problem $\mathcal{P}$ like the bi-MDCST implies the minimization of two objective functions $\{\min f_1(x), \min f_2(x) \ | x \in \mathcal{X}\}$. $\mathcal{X}$ is the feasible solution space of $\mathcal{P}$ and $f(x)$ is the vector of objective functions. For the bi-MDCST, $\{f_1(x), f_2(x)\}$ denote the cost and the diameter, respectively. Then a set of compromise solutions with respect to the two objective functions has to be obtained instead of a single solution as for the classical BDMST.

The concept of dominance is used to define the set of compromise solutions, usually called Pareto front. Considering two bi-MDCST solutions x and y, x *dominates* y if and only if the following conditions hold:

$$\begin{cases} f_k(x) < f_k(y) \ \exists k \in \{1, 2\} \\ f_k(x) \leq f_k(y) \ \forall k \in \{1, 2\} \end{cases} \text{and} \tag{10}$$

A Pareto solution x^* is optimal whenever it is not dominated by any solution in $\mathcal{X}$. The Pareto-optimal front is composed of the Pareto-optimal solutions (non-dominated). The bi-MDCST seeks a set of Pareto-optimal spanning trees $\mathcal{T}$ of G where f_1 and f_2 are simultaneously minimized. Figure 12 presents three solutions for bi-MDCST, considering the graph of Fig. 11a. The cost and the diameter for $\mathcal{T}_1$, $\mathcal{T}_2$, and $\mathcal{T}_3$ are, respectively, $\{29, 2\}$, $\{14, 3\}$, and $\{24, 2\}$. Solution $\mathcal{T}_1$ is dominated by $\mathcal{T}_3$ due to the cost. However, solutions $\mathcal{T}_2$ and $\mathcal{T}_3$ are not dominated by each other since $\mathcal{T}_2$ has a smaller cost than $\mathcal{T}_3$, while $\mathcal{T}_3$ has a smaller diameter than $\mathcal{T}_2$. One may

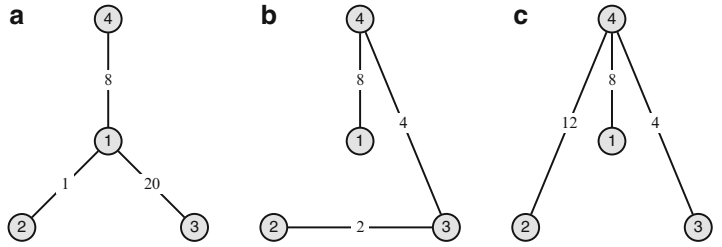

Fig. 12 Example of solutions for bi-MDCST. (**a**) Solution $\mathcal{T}_1$, (**b**) Solution $\mathcal{T}_2$, and (**c**) Solution $\mathcal{T}_3$

note that solutions $\mathcal{T}_2$ and $\mathcal{T}_3$ are not Pareto-optimal because they are, respectively, dominated by the MST depicted in Fig. 11b of value {7,3} and the solution shown in Fig. 11c of values {15,2}.

For bi-MDCST, an obvious LB on the cost can be obtained by computing an MST on the graph. The diameter of this solution also provides an UB on the diameter. In addition, for complete graphs, the star is also a trivial LB on the diameter. The minimal cost of a star in the graph can provide an UB for the cost. Spanning trees of diameters $D \in \{2, 3\}$ can be computed in polynomial time as shown in [7]. Those LB on the diameter may not necessarily exist on general graphs. However, checking if a graph contains at least one such spanning tree can be done in polynomial time.

An NSGA-II for Bi-MDCST

The NSGA-II has been proposed by [58] and is one of the metaheuristics available to compute Pareto fronts for multiobjective optimization problems. This method has been applied to a number of multiobjective optimization problems for the past ten years. Moreover, it uses simple and efficient operators to manage the Pareto front convergence. Such operators are added to a classical genetic algorithm (GA), which is very popular in the scientific literature. The two special multiobjective operators are the *ranking* and the *crowding distance*. These two operators are computed for each solution and are responsible to manage the Pareto front convergence. Both the *ranking* and the *crowding distance* are associated with each solution. Given a target solution $\mathcal{T}$, the *ranking* contains the number of solutions that dominate $\mathcal{T}$. Thus, the lower the ranking, the better the solution. Fronts are then defined by solutions of same ranking. Given a front of M solutions, the *crowding distance* w is computed following Eq. (11), where $sc(j)$ and $pr(j)$ are, respectively, the value which precedes j in w and the value which follows j in w. For any (nondegenerate) front with more than one solution, ${z_m}^{\max} \neq {z_m}^{\min}$. The bi-MDCST involves two objectives $m = 1, 2$; thus, ${z_m}^{\max}$ and ${z_m}^{\min}$ are the maximum and the minimum objective function values, which need to be properly normalized. The crowding distance is a kind of Manhattan distance between two solutions from the same front. Then, the higher the crowding distance is, the more distant the two solutions are. As a consequence, solutions with larger crowding distance are preferred since they belong to less covered areas.

$$w_j = \sum_{m=1}^{M} \left(\frac{z_m^{sc(j)} - z_m^{pr(j)}}{z_m^{\max} - z_m^{\min}} \right) \tag{11}$$

The algorithm performs the following steps: (1) generate the initial population (set of solutions), (2) compute and order the population using the ranking and crowding distance, (3) select the first half elements of the population, and (4) generate the remaining elements using genetic operators and go to step (2). These steps are repeated until stopping criteria are met and are detailed below. In addition, a local search can be applied to each new solution in the population, i.e., before moving to step 2. In the vocabulary of GA, the use of a local search within a GA is referred as a memetic algorithm (MA). The idea of generating all $2n$ solutions and ordering them before cutting n solutions avoids cutting good solutions.

Given a graph $G = (V, E)$, a solution for bi-MDSCT (also referred as chromosome in the GA vocabulary) can be encoded using a vector of size n containing the direct predecessor of a vertex in the tree. A population can be generated using any heuristics (greedy, randomized, etc.) or even randomly generated spanning trees (step 1). The work [48] suggests an initial population of size $2n$ which contains (i) two specific solutions, an MST of G and a spanning tree of diameter $D = 2$ or $D = 3$, if it applies; (ii) half of the population obtained randomly; and (iii) the remaining solutions computed using a randomized version of Prim's algorithm (i.e., the vertex entering the solution is randomly selected from a list of good candidates).

As mentioned above, the *ranking* and the *crowding distance* are computed for each solution in the initial population (step 2). Then, these operators will be responsible for the selection of solutions, following a multiobjective evolutionary approach rather than directly considering their cost and diameter. The comparison between two solutions $\mathcal{T}_1$ and $\mathcal{T}_2$ with respect to their *ranking* r_1 and r_2 and their *crowding distance* w_1 and w_2 is as follows:

$$(r_1 < r_2) \text{ or } ((r_1 = r_2) \text{ and } (w_1 > w_2)) \tag{12}$$

$\mathcal{T}_1$ is said to be better than $\mathcal{T}_2$ whenever the condition (12) holds. In the following (step 2), the population is ordered. Now, the algorithm proceeds to the selection (step 3) by keeping the n best solutions for the next iteration. The n new solutions to enter the population can be generated by the crossover proposed by [59] (step 3). One advantage of this crossover is that feasibility of new solution is ensured, even for sparse graphs. The way to select the parents in the crossover can follow a classical elitist strategy, i.e., one parent from the elite set and the other one randomly selected from the remaining population. The crossover proposed by [59] works as follows: given two solutions (parents) $\mathcal{T}_1$ and $\mathcal{T}_2$, a support graph G' containing all edges from $\mathcal{T}_1$ and $\mathcal{T}_2$ is built. Then, an MST is computed on G' to obtain the new solution. Figure 13 illustrates this crossover, considering the graph G shown

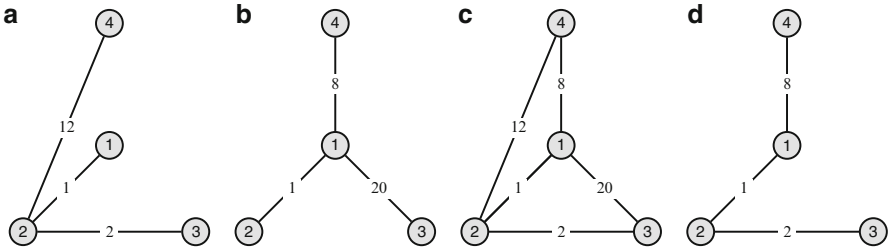

Fig. 13 Example of the crossover operator. (**a**) Solution $\mathcal{T}_1$, (**b**) Solution $\mathcal{T}_2$, (**c**) Graph G', and (**d**) MST of G'

in Fig. 11a. The two parents $\mathcal{T}_1$ and $\mathcal{T}_2$ are, respectively, given in Fig. 13a and b. The resulting support graph G' is presented in Fig. 13c and the new individual is provided in Fig. 13d, for which $Cost = 11$ and $D = 3$.

The local search iteratively performs a 2-opt move until no improvement can be done on the current solution. The 2-opt move uses the *edge drop* move previously presented. A specific feature of the 2-opt move for bi-MDCST suggested by [7] is that a move is accepted if and only if the diameter does not change and the cost is reduced. This means the local search will reach a local optima having the same diameter as the current solution.

The main insights obtained in [7, 56] by applying the NSGA-II for bi-MDSCT are summarized below. Three main sets of instances available in the literature for the BDMST were used in the experiments. They were proposed by [23, 26, 46], respectively. In addition, two test sets were proposed by [7] containing 9 and 11 instances, named Hamiltonian cycle and Hamiltonian path, respectively. Results produced by NSGA-II were compared with available optimal values for the BDMST from [22, 48]. The NSGA-II for bi-MDCST manages to find some optimal diameter values of the BDMST and it is very close in the other cases. The computational time does not exceed the computational time spent by dedicated and sophisticated methods for the BDMST. The Pareto-optimal fronts for the test sets used in [7, 23].

Some interesting characteristics have been observed: (i) a significant difference in tree cost occurs in the Pareto-optimal front between solutions with $D = 2$ and $D = 3$; (ii) since the instances from [23] have edges with similar cost, there are several MSTs with different diameters; (iii) some diameters are not interesting because the best corresponding solutions are dominated; and (iv) for the majority of instances from the sets mentioned above, up to 15 target diameters exist. The multiobjective approach has shown to be effective. It works consistently well and can provide useful information about the search space and the Pareto front for bi-MDCST problems.

Conclusion

Trees and forests are very rich topics, both in terms of theoretical and practical issues. Integrating good ingredients in sophisticated heuristics is the first step to produce good, competitive heuristics and even find new better results for NP-hard problems relying on these structures. In this context, some basic components for trees and forests are summarized in this chapter and two ways of addressing difficult constraints (degree and diameter) are presented, with the hope it will inspire new and fruitful research on these topics.

In terms of constructive heuristics, two basic ways have been addressed in the literature: tree expansion and tree fusion. Concerning the improvement heuristics, two main classes appear: restoration and local search. Some of these strategies use tree properties such as the local searches based on k-opt moves. In fact, by definition of a tree, removing an edge from a tree results in two connected components and inserting an edge in a tree obviously creates a cycle. Thus even an 1-opt can be considered two ways, either by first removing an edge or by first adding an edge. Even if they basically are 1-opt moves, these may impact the way the search space is explored.

Some key points are also provided in order to represent a tree in terms of data structures. Encoding and decoding a tree can be done directly by means of predecessor vectors indexed on the vertex or edge sets. It can also be done indirectly by using random keys. Additional data structures are also required to handle difficult constraints such as degrees and diameter. The choice of data structures will mainly impact the algorithm complexity. As a consequence, careful choices can save running time.

Two different strategies to address difficult constraints have been presented. The first, more classical, relies on a Lagrangian relaxation in which the constraints are relaxed and integrated into the objective function using the Lagrangian penalties. The second way consists of dropping the constraints, considering them as a new criterion. The resulting bi-objective problem is then solved by multiobjective approaches. The former presents the advantages of being simple to implement; it obtains solutions of good quality in a reasonable computational time, and lower and upper bounds are available at each iteration. A drawback is that it strongly depends on the mathematical formulation and the chosen decomposition. The latter is far less investigated in the literature, in particular for addressing difficult constraints. It has the following advantages: it provides additional information about the search space, and the computational time to obtain the Pareto front is very close to the time spent applying sophisticated dedicated methods. Moreover, limits in the search space can be computed and dominance rules can speed up the inspection of the solutions. A drawback is that the problem remains difficult since it may involve solving several NP-hard problems. However, facing NP-hard problems from a multiobjective perspective remains an interesting direction for further research.

Abstract

This chapter presents a heuristic for a multi-objective ranking problem using a dataset of international interest as an example of its application, namely, the ranking of the world's top educational institutions. The problem of ranking academic institutions is a subject of keen interest for administrators, consumers, and research policy makers. From a mathematical perspective, the proposed heuristic addresses the need for more transparent models and associated methods related to the problem of identifying sound relative rankings of objects with multiple attributes. The low complexity of the method allows software implementations that scale well for thousands of objects as well as permitting reasonable visualization. It is shown that a simple and multi-objective-aware ranking system can easily be implemented, which naturally leads to intuitive research policies resulting from varying scenarios presented within. The only assumption that this method relies on is the ability to sort the candidate objects according to each given attribute. Thus the attributes could be numerical or ordinal in nature. This helps to avoid the selection of an ad hoc single score based on an arbitrary assignment of attributes' weights as other heuristics do. To illustrate the use of this proposed methodology, results are presented and obtained using the dataset on the ranking of world universities (of the years 2007–2012), by academic performance, published annually by ARWU.

Introduction

Ranking multi-attributed objects is ubiquitous in the twenty-first century. This is not an overstatement. Every time people use a web search engine and query it using a particular keyword or phrase, a ranked list of webpages appears on our screen. This ranking is automatic, in most cases deterministic, and is well defined in mathematical terms. Not only the speed but the quality of the ranking may decide the fate of the company that has created that search engine. Every time people read a newspaper, or watch television, the news stories provided have been edited, and

the core subject has been ranked and selected. Today, our governments want to decide on spending based on the objective rankings of institutions, their quality, performance, and delivery of service.

Specifically, the ranking of educational institutions has received increasing interest from scholars, policy developers, and strategic decision-makers worldwide. Our society, regardless of nationality, enjoys (and in some cases needs) to rank tennis players, sport teams, health systems, supercomputers, economical performance, scientists' achievements, most and least "liveable" countries and cities, restaurants, waiting lists for surgery and transplantation [1], targets in structure-based virtual screening of three-dimensional protein libraries [2], genes in microarray experiments [3, 4] or in association studies [5], athletic training education programs [6], pedestrian crash zones [7], stressfulness of joints and joint motions in ergonomics applications [8], movie stars, dental esthetics [9]), and even US presidents.

The academic ranking of world universities follows the general trend of globalization of the economy. Researchers agree that ranking global universities is attracting increasing attention as it is a topic of high interest to many different stakeholders; see, for instance, [10–13], among others. If you look at universities as service providers and if their potential students are free to choose among a variety of them, it is natural to pay attention to rankings to help them select the best tailored to their interests. This has become of even greater importance in recent years due to the increased mobility of students, researchers, and staff [14]. Furthermore, strategic decision-making within institutions, and policy development at a larger scale, relies on the provision of useful information regarding an institution's quality, excellence, and global ranking position.

Needless to say, ranking global universities is a quest of great impact and social significance [15]; however, the methodologies proposed are naive at best. It could be said that the problem is inherently *ill posed*. First, outcomes of ranking activities should be user centric. A student who has to choose where to go for graduate school studies may be more interested in the quality of their specific disciplines that constitute the core set of knowledge she is looking for and may dismiss an institution that has Nobel Prize winners lecturing using chalk and a blackboard (see [16] for a discussion on how to define quality). Managers and strategic decision-makers need to have access to information about how their institution benchmarks against their "competitors" in order to successfully and optimally allocate their resources and funds. Furthermore, it is important to remember that different stakeholders have different expectations about quality [11] and different expectations of an educational institution in general. In essence, it is important to highlight that ranking systems should be developed allowing the various users of these systems to easily add or remove an attribute of the objects in order to suit their specific needs and interests.

The request of [17] *"...there is still a dearth of peer-reviewed scientific publications on international ranking methods. Raw data and several key details about the methodology still remain unavailable to public scrutiny."* [17] easily resonates with this study. In addition to this, it recognized that the trustworthiness of many ranking systems is sensitive to the conceptual framework (its indicators) as well as the modeling choices such as weighting of indicators [14]. In order to fill this methodological gap, the issue of academic rankings of universities is addressed as an

illustrative test case. This chapter thus aims to differ from Ioannidis et al. who have well articulated their case for the importance of a common international consensus on the validity of the measured attributes for each institution. The methodology presented here moves away from the traditional comparison of one-dimensional lists between ranked objects.

In this chapter other metrics that can be computed are included as well as a very simple heuristic that, using raw data, allows users to select/deselect attributes to better target their interests. This approach can "tailor" a ranking system according to the user's individual preferences. Therefore, this system naturally provides a user-centric experience, while it is still based on quantitative nonsubjective information. This said, while this chapter is focussed on the largest online dataset of universities' performance, its final aim is to exemplify on its use to address the multi-objective ranking problem from a general methodological standpoint. In this method, the issue of sensitivity due to arbitrarily assigning of weights to indicators is addressed and the problems that arise in doing so, rather than using raw data.

The chapter is organized as follows. Section "Materials and Methods" illustrates where the data was obtained from, a brief description of the data, and an outline of the methodology used. Section "Results" has several subsections in order to display the results. Results for the computation of the dominance graph for the period 2007–2009 are displayed in section "University Ranking Results 2007–2009" followed by results describing transitive dominance as well as the implementation of symbolic regression modeling (section "Transitive Dominance Example Results"), mobility of universities in ranking (section "Sensitivity Analysis of Mobility over the Period 2010–2012"), and case examples of various universities, and, finally, a brief discussion on the attribute *Alumni* is included in section "The Case of the Alumni Attribute". Section "Discussion" provides a discussion of the results and includes the limitations thereof and recommendations for possible future areas of research.

Materials and Methods

To illustrate the proposed analysis methods for ranking, and to ensure reproducibility and interpretability of the results, the online publicly available information provided by the Academic Ranking of World Universities (ARWU) is used in this study. This is an annual publication and the data that is used for their ranking is provided by the Institute for Higher Education, Shanghai Jiao Tong University, since 2003.

The ARWU from the Shanghai Jiao Tong University is based on the performance of universities according to six categories (attributes). These attributes are displayed in Table 1 with their respective weighting given by the Shanghai Jiao Tong University and their explanations. The six attributes are *Alumni*, *Award*, *HiCi*, *N&S*, *SCI* (or PUB), and *Size* (or PCP). It is important to note that for institutions specializing in humanities and the social sciences, such as the London School of Economics, in the ARWU ranking systems, the attribute of N&S is not considered, and weighting is distributed to other indicators [11]. This borderline between

Table 1 Explanation of the institute for higher education, Shanghai Jiao Tong University ranking system. Note that the attribute "Size" is also referred to as "Per Capita Performance" (PCP) and the attribute "SCI" is also referred to as "PUB" in various articles and resources

Attribute	Weighting	Explanation
Alumni	10%	Number of alumni of the institution winning Nobel Prizes and Fields Medals
Award	20%	Number of staff of the institution winning Nobel Prize and Field Medals categories
HiCi	20%	Number of highly cited researchers in 21 broad subjects
N&S	20%	Number of articles published in Nature or Science
SCI	20%	Articles in Science Citation Index Expanded, Social Science Citation Index, and Arts and Humanities Citation Index
Size	10%	Academic performance with respect to the size of the institution

institutions, however, is somewhat arbitrary. Therefore, it has to be recognized that for some institutions only four attributes (with arbitrary weighting) remain for consideration and that is a natural aspect of its organization on a reduced number of fields. In each category a university will receive a value between 0 and 100. The university with the best performance in a particular category receives the top value of a 100, and the rest of the universities will receive a proportional value against this measure. Further details and explanation of these attributes and the scoring procedure can be found on the Shangai Jiao Tong University ARWU website (http://www.shanghairanking.com) or in Liu et al. [11].

The raw data of this ranking process for the years 2007–2012 is used. From the top 500 universities in each year, only those that are present in all years since 2007 are included. This means that in total, the scores of 444 universities are used in the method. With this information, three datasets for analysis are created; one for the years 2007–2009, another for 2010–2012, and a combined dataset including the attributes over the whole six-year period. The first two are an array U of 444 rows and 18 columns, and each value in the array represents the score that the institution has in each of the six categories in the three years. The combined array has, of course, 36 columns.

The purpose of this chapter is not to argue the accurateness of this information, but rather utilize this data for an application of the method proposed. The reader should recognize that the use of this dataset has been challenged in terms of its reproducibility by Razvan [18] and also recognize the work by Docampo [19] who also alert of some problems in the ARWU's processes. However, as highlighted by many authors, after recognition of these issues and also noting the criticisms revolving about the ARWU ranking, this contribution addresses two of them. In particular, in section "Results", the *Alumni* attribute and the attribute related to *Size* (PCP) deserve two separate experiments to understand their contribution. On this point, it can be argued that, to ensure transparency, an international standard on the universities reporting on performance on specific attributes should be made available and that it is best, for reproducibility, to work with raw data. This said, this information is taken bona fide, as correct and complete.

From this set of attributes, other types of ranking systems could create other attributes or "meta-features" by combining or multiplying multiple attributes of the dataset. Typically, aggregates should be avoided whenever possible, and normalizations (e.g., dividing total number of publications by the total number of full-time employees) can easily be derived should this be required or desired by the user. Having said this, these standards may not make the dataset used in this study fully satisfactory (aggregates exist, normalization by full-time employees equivalents are not made, other problems have been identified in Ioannidis et al. [17]), but this dataset is one of the world's best, regarding its coverage, and serves to illustrate our proposed methodology.

Construction of a Dominance Graph and Transitive Reduction

The method proposed in this chapter uses concepts inspired by transitive dominance to build a directed acyclic graph (DAG) ($G(V, A)$). A university x dominates university y, if and only if, for each attribute i the values of the universities for this attribute satisfy $x_i \geq y_i$, $\forall\, i : [1..m] \wedge \exists\, j \in [1..m] \,/\, x_j > y_j$. This means that the performance of university x is at least better or equal in all attributes than university y, with at least one attribute at having a higher value. This definition creates a DAG $G(V, A)$ where each vertex represents a university, and if there is an arc $a_{xy} \in A$, it means that university x dominates university y. Within this chapter it will be shown that this DAG naturally induces a hierarchy of universities, with universities at Level 1 being those that are *not* dominated by any other university in the set. Here it is implied that the notation $x_i \geq y_i$ is general in meaning and is valid for both numerical and ordinal attributes. It is assumed that the attributes' measures are selected in such a way that a higher value on them implies a higher standing. This is a strength of this method as it can deal with datasets of mixed attribute types.

The resulting graph of this procedure would be hard to visualize in two dimensions as there are 444 nodes and it is very dense. Therefore, in order to simplify the DAG, without losing the hierarchy created, a method similar to, but less restrictive than, *transitive reduction* [20] is used. As Bang-Jensen and Gutin [20] describe, a transitive reduction of a directed graph (digraph) D is a spanning subdigraph H of D with no *transitively irrelevant* arcs, and it is called *minimum equivalent subdigraph*. In transitive reduction, "reachability" between nodes is not affected as only superfluous arcs are removed [21]. The minimum equivalent subdigraph of an acyclic digraph can be found in polynomial time and is unique.

However, in this instance, another algorithm that reduces the number of arcs further is used so that it is less restrictive in maintaining the reachability condition. A simplified visualization of this procedure is presented in Fig. 1 and is mathematically outlined here:

1. Identify the set of all universities which are nondominated; this set will be called the set of "Level 1" universities;

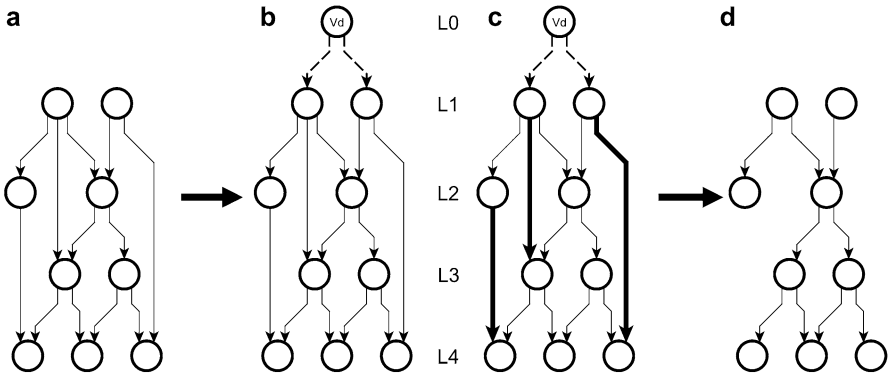

Fig. 1 Construction of the dominance graph. Each vertex represents a university, and there is an arc from each pair of universities (x, y) whenever x dominates y, according to the dominance definition given in the text. This method starts by first identifying the set of universities that are not dominated by any other university in the set. To illustrate on the algorithm, a set of figures are produced. Figure **(a)** shows the initial status. By assigning the nondominated set of universities to a top level, it would be possible to identify levels for all the other universities in the set. Figures **(b)**–**(d)** illustrate on the procedure to compute this and the resulting reduced graph as some arcs are removed. In **(b)** a dummy vertex v_d is added, which corresponds to a hypothetical "dream university" which is nondominated, which would be at "Level 0." From the dummy vertex to each of the nondominated universities, an arc is added (as shown in **(b)**). Then a level of a university is recursively defined as the maximum number of arcs that need to be transversed from v_d to it. Figure **(c)** shows arcs that connect universities for which the difference levels are more than one. These arcs are shown in boldface. Since visualizing such a dense directed graph would be unclear, these are removed as it would not affect the level of any given university. As a result, a reduced DAG is produced as shown in **(d)**, and through visualization it is shown how its results now uncover the underlying layer structure of **(a)**

2. Add a dummy vertex v_d, which would correspond to a hypothetical nondominated university by all universities in the set (the Level 0 or "dream university"), and draw an arc from v_d to each of the universities in Level 1 (Fig. 1b);
3. The level of a university (represented by a vertex v_i) is then equal to the number of arcs that need to be traversed in the longest directed path from the "dream university" (vertex v_d) to v_i;
4. For each arc $a_{xy} \in A$ if $|Level(x) - Level(y)| > 1$, then $A = A - \{a_{xy}\}$ (see, for instance, the bold arcs in Fig. 1c are deleted from the DAG Fig. 1d).

The resulting graph from this process has the same hierarchical properties as the original one. Based on this final reduced graph, university x *"closely dominates"* university y if $a_{xy} \in A$ after the reduction.

This heuristic ranking methodology in terms of levels comes from a clear algorithmic procedure and is nonparametric, and it does not require an ad hoc definition of weights to be applied to each attribute. It is based on established grounds in multi-objective optimization and clearly reflects all pairwise comparable

dominance relationships in the data. Furthermore, this method accepts numerical as well as categorical attributes allowing the inclusion of more variables in ranking activities.

Following the above process, in order to investigate "global" dominance relationships, the number of institutions that each university is transitively dominated by in the reduced graph will be calculated. This will provide an overall picture of where each institution is placed in comparison to all institutions included in the set. As an extra decision-making tool, it will provide institution leaders with the necessary information to compare and benchmark against other similar institutions. Examples of this are provided in section "Results".

Symbolic Regression Analysis to Predict Levels Using All Variables

In order to go one step further and investigate which variables are important in terms of "predicting" which level (rank) a university is going to be a part of, symbolic regression analysis is used in this chapter. By doing this, it clarifies whether the results found are consistent when using variables of each year for six consecutive iterations of the symbolic regression analysis. Symbolic regression is a data-driven method to find a structure in data. Unlike linear regression methods, symbolic regression not only finds the best values for a set of coefficients, it also finds the structure of the model that best fits the target variable [22] (including but not necessarily limited to linear models). In order to do this, a powerful software named *Eureqa* [23] is used which is based on evolutionary computation techniques to search for the best model. Eureqa runs an evolutionary search procedure to find the solution that fits the data best with the lowest possible level of complexity as is consistent with other symbolic regression methods [24].

In Eureqa, the "best models" are those that are observed in a Pareto optimality curve which imply a trade-off between their complexity and their fit. Complexity meaning the number of functions and "building blocks" used by *Eureqa* to fit a model to the target variable. The user selects a fitness function (for instance, absolute error or mean squared error) that guides Eureqa in selecting the best models. Users also have the option to select their preferred "building blocks" (for instance, arithmetic operations like multiplication, subtraction, and addition or the introduction of a constant). In a previous publication, the authors of Ref. [25] have shown the usefulness of symbolic regression and *Eureqa* in finding "functional constructs" from online consumer behavior data. Furthermore, the data-driven nature of symbolic regression is suitable to the context of this study as the aim is to make inferences on the data based on the information present in the data alone without a priori parameters or attribute weights.

In this study in particular, the aim is to find those variables that are of importance when "predicting" which level an institution is in as well as finding out whether the assignment to levels of all universities can be consistently predicted with variables from each of the years. To do this, the "level" is set as the target variable in *Eureqa*,

while it tries to fit a model to predict between Levels 1–11. The level ranking dataset used for this procedure is the ranking obtain from running the dominance graph on the whole dataset, i.e., years 2007–2012. Following this, six searches are conducted in *Eureqa* in which every search uses only one year of data. The reason is to find out whether the models are consistent in predicting one outcome of the dominance graph using variables from several years. The variables in the dataset that are most frequently used in the models are highlighted, and these are identified as the key variables in predicting "level membership." Furthermore, the best simple linear function found by *Eureqa* is used for further analysis which is consistent with a previous publication using this software [25]. In this manner it is possible to inspect the variables that are found to predict the target variable, in this case, ranking level in detail.

In this study, the following "building blocks" were selected for the *Eureqa* analysis, the use of a "constant," "integer constant," "input variable," "addition," "subtraction," and "multiplication." For all of the six years, the six searches are run two times, once with the error metric as *R-squared goodness of fit* and once with *squared error Akaike information criterion* [AIC]. The *squared error* with AIC is selected as AIC provides a means for model selection. AIC deals with the *goodness of fit* of the model and the complexity of the model which is in line with the other selection criteria that are used based on the Pareto optimality curve.

Results

The results based on the construction of the directed dominance graphs are presented here. The total dataset for the years of 2007–2012 was analyzed and split into two datasets representing the periods 2007–2009 and 2010–2012. In Figs. 2 and 3 the hierarchical layout of the graph created for the three-year periods of 2007–2009 and 2010–2012, respectively, can be seen.

Resulting from the ranking procedure, as outlined in the methodology, the graph of 2007–2009 has 12 levels with a different number of universities in each level in the first period. In the second period, the graph has 13 levels, with Level 13 only containing one university (University of Jyvaskyla, Finland). Furthermore, colors are used to highlight the correlation with the Shanghai Jiao Tong University study. Red corresponds to those institutions that have been considered at the top 10 according to the Shanghai Jiao Tong University study (in the last year included) with the remaining top 50 in orange, and the remaining top 100 are colored in green. Also included in this section are the results of the calculation of transitive dominance of institutions, the symbolic regression analysis testing, the volatility of ranking over a longer period of time, and the removal of the attribute Alumni as well as the attribute PCP (*Size*) in the ranking method and the effects of the removal of each of these attributes on the outcome. In the representation of results, various institutions are highlighted as examples in order to communicate the findings of this study.

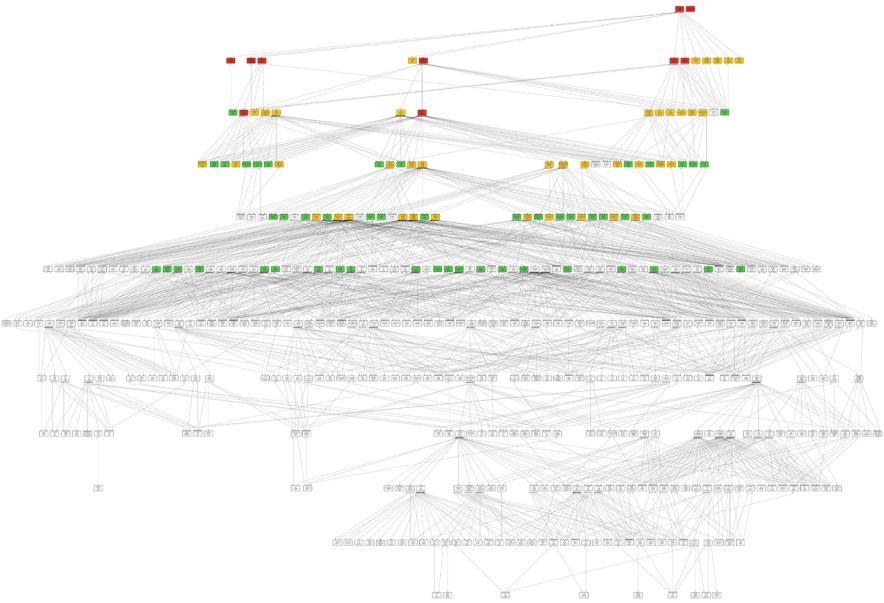

Fig. 2 The rankingof 444 world universities according to our proposed methodology using the same raw data provided by the Institute of Higher Education, Shanghai Jiao Tong University, for the years 2007, 2008, and 2009. Universities are arranged in *levels*, and a university is in a level if there exists another university that *closely dominates* it and is in the immediately higher level (the mathematical definition of this concept is outlined in the Methods Section). This graph provides important information for decision-making. In order to improve the overall ranking level, the university strategic decision-makers should pay attention to the best effective way of reaching the next level by improving in those attributes that would allow it to rank in the next level in the hierarchy. In addition, the university should also closely monitor the set of universities in the inferior level as they are the in direct competition for a position at the same level in the hierarchy. For instance, Yale University and Cornell University are two Level 3 universities that are both closely dominated by University of California at Berkeley. At the same time, these two institutions have a large number of institutions that they closely dominate at Level 4 (NB: A high-resolution version of this image can be found in the Supplementary material)

University Ranking Results 2007–2009

When looking at Level 1 in Fig. 2, some information that is clearly revealed by the method becomes apparent. The "Level 1" universities correspond to those which are not dominated by any other university in terms of the attributes considered in the method. In this graph, these are Harvard University and the California Institute of Technology (Caltech). While Harvard closely dominates several others, Caltech does not closely dominate any other institution of Level 2. Level 2 institutions are Stanford, Columbia University, the University of Tokyo, the University of California at Los Angeles, the University of Michigan at Ann Arbor, the University of Pennsylvania, the University of Washington, the University of California at

Berkeley, the University of Toronto, the University of Cambridge, Massachusetts Institute of Technology, and Princeton University.

The reason for Caltech's position in Level 1 can be explained not by Caltech's total productivity but rather its productivity regarding its size. Here it is noted that instead of normalizing raw data on the institution's performance by the number of full-time academics (or their equivalent full-time aggregated data), the Institute of Higher Education, Shanghai Jiao Tong University proposed the addition of an attribute called *"Academic performance with respect to the size of an institution"* or "Performance Per Capita" (PCP). It is important to remark that Caltech is a special case in terms of size. As pointed out by Baty in early 2014 [26], Caltech may be called not just "small," but *"tiny"* with its 300 professorial faculty, about 600 research scholars, and, at the last count, only 1204 graduate students and just 977 undergraduates. This translates to an almost 3:1 student to faculty ratio. As a result of the introduction of the "Performance Per Capita" (PCP) attribute, which relates to the size of the institution in the ranking method, Caltech (with its "tiny" size) is "singled out" at the top due to its maximum value of this attribute without any close domination of Level 2 institutions. This reflects the consensus that the lack of normalization of the other attributes would bias ranking systems to benefit larger institutions. For instance, Rockefeller University is another small-sized institution that is very productive and is at Level 3, closely dominated by the Massachusetts Institute of Technology at Level 2.

Other Level 3 institutions include the Ecole Normale Superioure of Paris, the University of Chicago, Cornell University, Yale University, the University of Oxford, the University of California of San Diego, Kyoto University, Duke University, John Hopkins University, the University of Minnesota at Twin Cities, the University of Wisconsin at Madison, the University of Sao Paulo, and the University of Pittsburg. The University of Sao Paulo (Brazil) consolidates its position as a world Level 3 institution due to its relatively large SCI performance score.

At Level 4, the international mix of institutions is more clear. Level 4 includes the Hebrew University of Jerusalem (Israel), two German universities (the Technical University Munich and the University of Munich), three UK institutions (the Imperial College of Science, Technology, and Medicine, London School of Hygiene and Tropical Medicine, and the University College London), three from France (Pierre and Marie Curie University Paris, the University of Paris-Sud, and the University of Montpellier), the University of Oslo (Norway), the University of Basel (Switzerland), Moscow State University (Russia), the University of British Columbia (Canada), Osaka University (Japan), and a large group of USA-based universities, Carnegie Mellon University, the University of Colorado at Boulder, the University of California San Francisco, Pennsylvania State University—University Park, the University of Illinois at Urbana-Champaign, the University of Texas Southwestern Medical Center at Dallas, Northwestern University, the University of California Davis, The Ohio State University Columbus, Case Western Reserve University, the University of Florida, Washington University in St. Louis, and the University of Rochester.

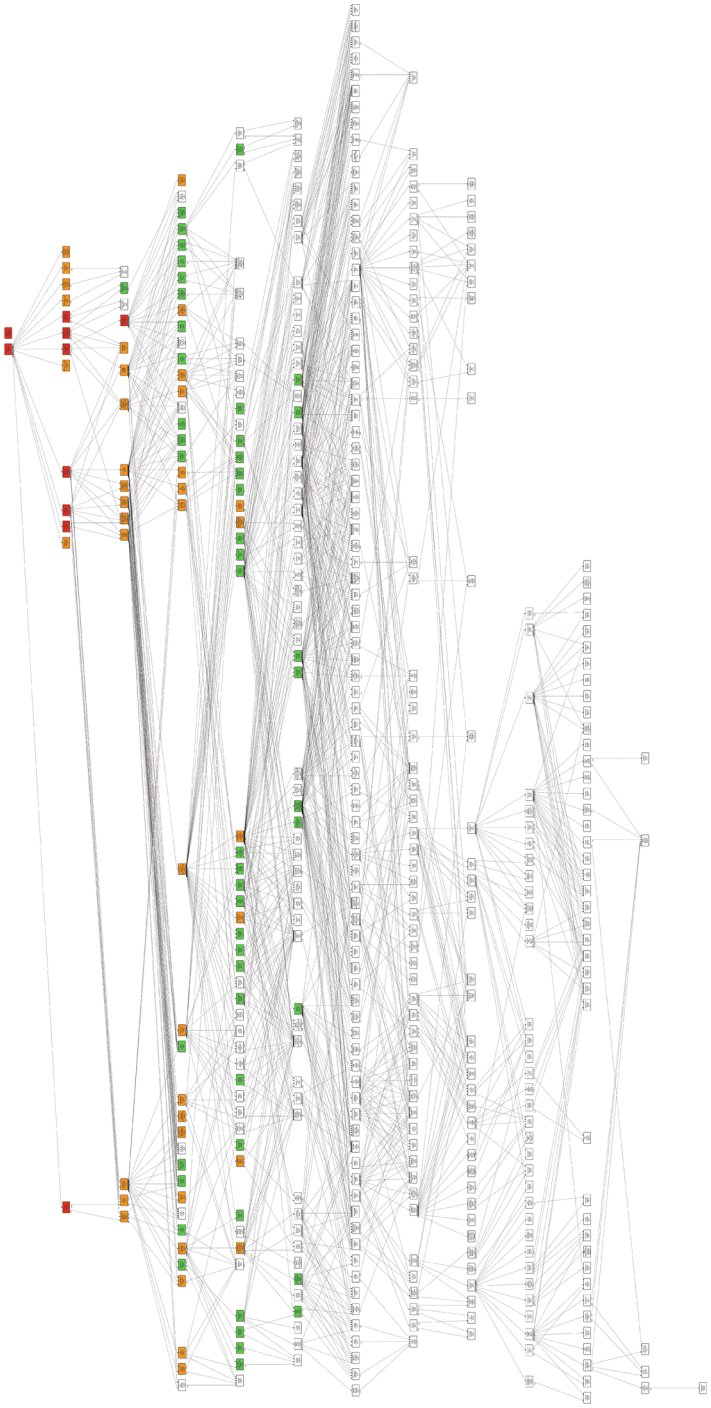

Fig. 3 The rankingof 444 world universities according to our proposed methodology using the same raw data provided by the Institute of Higher Education, Shanghai Jiao Tong University, for the years 2010, 2011, and 2012. The California Institute of Technology and Harvard University continue to be the single institutions at Level 1. At Level 2, there is almost the same group of American institutions (and The Universities of Tokyo and Cambridge).

Lastly, the Ecole Polytechnique Federale de Lausanne (EPFL) Institute in Switzerland is also situated on Level 4. This institution is highlighted because Ioannidis et al. in [17] have pointed out how the EPFL of Lausanne was a missing institution in the top lists of Shanghai Jiao Tong University ranking system in previous years, yet the methodology in this chapter has the EPFL institution in a relatively high position. The EPFL is located at Level 4 as shown in Fig. 2. Furthermore, as is to be expected, as you move down the levels further, the number of institutions in each level increases, and the variety of origins becomes more apparent which can be examined in Fig. 2. A full presentation of institutions at all remaining levels can be found in Fig. 2.

Transitive Dominance Example Results

As stated, the number of institutions that each university is transitively dominated by and which ones it dominates has been computed, for instance, looking at the three UK-based institutions at Level 4, the Imperial College of Science, Technology, and Medicine, London School of Hygiene and Tropical Medicine, and the University College London. The Imperial College is transitively dominated by only seven universities in the world, while it transitively dominates 337 institutions. This is an impressive number for a Level 4 university, very close to the 346 institutions dominated by Caltech at Level 1. The University College London (UCL) numbers are equally impressive with only five institutions that transitively dominate it and with 377 transitively dominated by UCL. In contrast, the London School of Hygiene and Tropical Medicine is transitively dominated by only 12 institutions (consistent with the overall trend of expected dominance for an institution at this high level), but it does not dominate any other institution.

The same numbers of the three French institutions at Level 4 are Pierre and Marie Curie University Paris (9 and 209), the University of Paris-Sud (9 and 117), and the

Fig. 3 (continued) However, the University of Pennsylvania now is at Level 3, and John Hopkins University and the University of Oxford now climb a level and now are at Level 2. If a single city of interest is to be highlighted, the universities in Hong Kong show a clear upward trend with the City University of Hong Kong climbing (climbing from Level 10 to Level 7), the Chinese University of Hong Kong and the University of Hong Kong (both raised from Level 8 to Level 6), and the Hong Kong Polytechnic University (from Level 10 to Level 8). Other Asian institutions raised three levels (Sun Yat-sen University and Hanyang University, from a Level 11 to Level 8). In Europe the remarkable uphill move of the Italy's Scuola Normale Superiore di Pisa that raised from Level 6 to Level 3 can be noted, as well as Sweden's Stockholm School of Economics (from Level 7 to Level 4) and Austria's Medical University of Innsbruck that from the bottom Level 12 is now at Level 7. However, over the three-year subsequent period, only 10% of the institutions raised two or more levels (and only 4.05% decreased it by a similar gap) indicating that as a metric is less volatile than other metrics to evaluate institutional performance (NB: A high-resolution version of this image can be found in the Supplementary material)

University of Montpellier 2 (13 and 45). This analysis provides some clarity on the peculiarities of some small-sized but intensively research-oriented institutions.

Sensitivity Analysis of Mobility Over the Period 2010–2012

Research policy makers can intuitively evaluate the chances that a university can climb the level structure by way of improving in different attributes. A university can climb up one level only if it improves on those categories in which it is being closely dominated by other institutions (given that those institutions do not move themselves). The inbound degree and the "weight" of each arc implicitly convey how likely it is for a university to improve its level. It is intuitive that the lower the inbound degree and the lower the weights, the easier it is for a university to climb levels up in the overall ranking.

There is a clear linear correlation trend between changes in levels and changes in the transitive dominance of a given university. In order to inspect this, a comparison is made between the change in level position of the 2010–2012 dominance graph and the 2007–2009 dominance graph. Firstly, several universities are highlighted as examples of level changes, followed by universities' changes in level over these two periods when the attribute PCP is removed from the dominance graph computation. This will show those changes that occur based on only the other attributes that remain.

Figure 4 shows five universities that provide different examples of changes in levels. Firstly, in Fig. 4a, the Netherland's Radboud University Nijmegen is shown. In the Figure it is noticeable that the attribute "Alumni" is nonexistent in the years 2007–2010 and appears for the years 2011–2012. For the case of the Radboud University Nijmegen, this steep increase is due to the fact that in 2010, two researchers affiliated to the University obtained the Nobel Prize in Physics for their research in the properties of graphene [27]. Examining these types of changes further, results show that the Radboud University Nijmegen shows an impressive improvement (from 58 institutions dominating it to only 12). Next in Fig. 4b, the USA-based Thomas Jefferson University attributes are shown which explain its level improvement to Level 6 from a previous Level 10 position and has only 41 universities dominating it from a previous 162 total. The Figure shows that between the period 2007–2009 and 2010–2012, the Thomas Jefferson University increased significantly in the attribute related to size (PCP). The Medical University of Innsbruck that was at the lowest level in 2007–2009 (Level 12) jumped to Level 7 in 2010–2012 also experienced the largest change in transitive dominance (from 222 to 88) and is shown in Fig. 4c. This is a change of approximately 60% in the number of institutions that dominate it. In this figure it shows that the Medical University of Innsbruck has a steep increase in the value for the attribute related to size. As stated, this attribute measures "Per Capita Performance" (PCP) in terms of research. Therefore, it could be that either the University reduced in size at this point in time or that it has significantly increased their research output with the same institutional size or even that some part of its research output was not previously included.

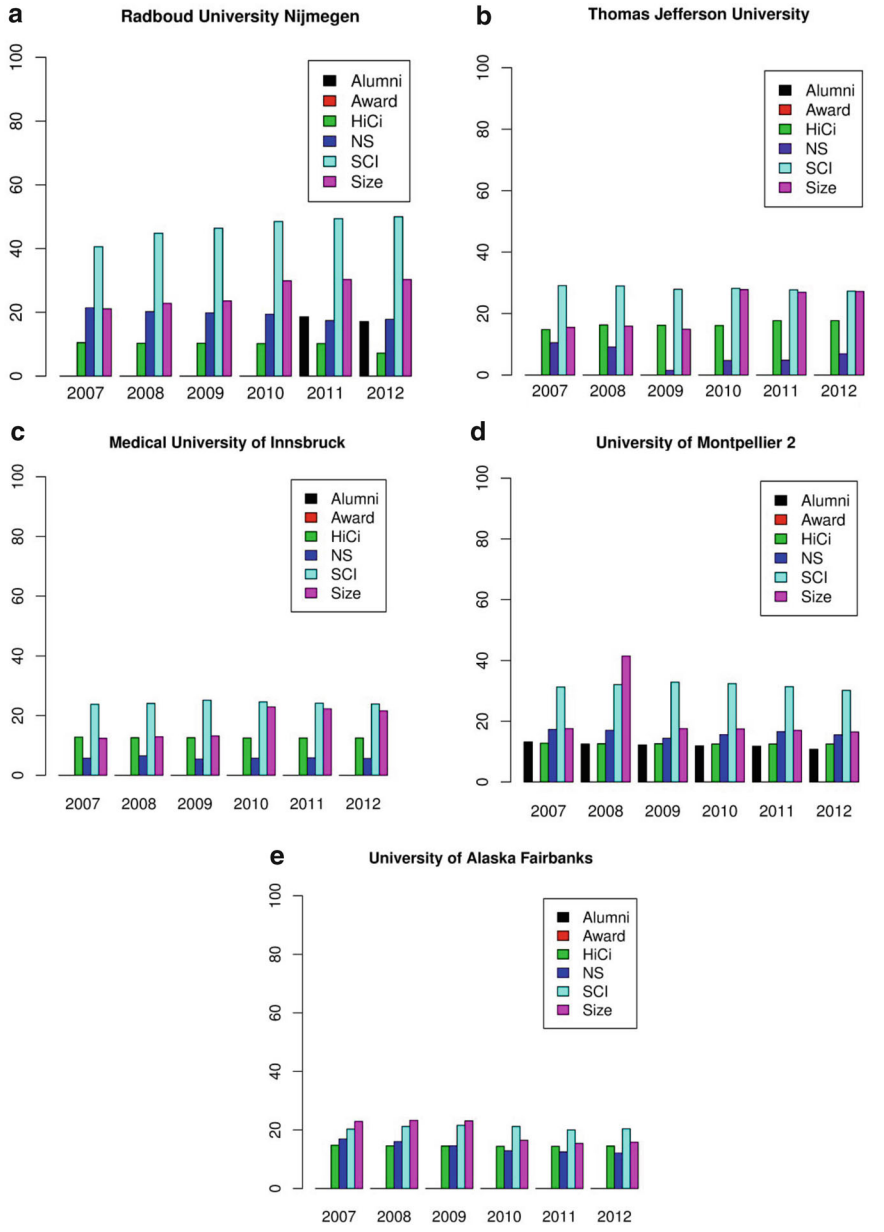

Fig. 4 Attribute values of universities that have changed levels over time—Figure **(a)** shows Radboud University which has climbed levels due to their increase in Alumni score. In figure **(b)**, Thomas Jefferson University provides an example of a university that has improved its level position due to an increase in Performance Per Capita (PCP), likely due to the institution

Furthermore, Fig. 4d shows the French University of Montpellier 2 and its peculiar values for the attribute "Size" (PCP). When comparing the two periods of time, the University of Montpellier 2 experiences a large drop in their level position from Level 4 to Level 8. In the figure it is evident that the University of Montpellier 2 had a steep decline in their score for the attribute "Size" (PCP). It may be argued that this could be due to an abnormality in one of the values of "PCP" (for the year 2008) which is conspicuously high. As a consequence, this may have affected the position of this university in the level for years 2010–2012. Finally, Fig. 4e shows the University of Alaska Fairbanks. This university is also an example of a university falling in its level position. The University of Alaska at Fairbanks is now at Level 10 from a previous position at Level 7. In the figure it can be seen that this drop is explained by the decrease in the attribute of N&S as well as a large decline in PCP.

Considering that many universities' drop in level can be attributed to their change in PCP, the results of the two periods without the PCP variable are compared. This will show those universities that still change in level position without considering their Performance Per Capita and may shed light on which other attributes are important to level position changes. Figure 5 shows four universities which provide examples of this. In Fig. 5a, the UK-based University of Bath is shown. The University of Bath declined in its position over the years due to a decrease in the value for N&S attribute. The USA-based Northeastern University and the Australian University of Tasmania are shown in Fig. 5b, c, respectively, and show the reason for their level improvement. For both of these universities, their level improvement can be attributed to their increase in value for the N&S attribute in the new three-year period. This means that it is likely that each of these institutions shifted resources, and academics allocated their time differently in order to publish more in the journals Nature and Science in the second period (2010–2012) than in the first period (2007–2009). Lastly, Fig. 5d shows the City University of Hong Kong which experienced a drop in their position due to the decline in citations in N&S. Interestingly, although their value for "HiCi" improves in the newest three-year period, the drop in N&S is enough to shift this university's level position.

A complete list of the results of universities' mobility over the two time periods, for those universities that fell or increased more than two levels, is shown in Table 2.

Fig. 4 (continued) changing in size. The Medical University of Innsbruck also provides an interesting example in figure **(c)** as it has the largest climb in level (from Level 12 to Level 7). It is possible to see for this university that all the categories are kept mostly the same, with the exception of category PCP, related to size. Figure **(d)** shows the university with the largest change in its level, University of Montpellier 2, which dropped from Level 4 to Level 8 when comparing the two periods that are investigated in this study. The profile of the university shows an unusual value for the PCP category in year 2008. This is probably due to an error in the data collected or published. Finally, in figure **(e)**, the University of Alaska Fairbanks drops from Level 7 to 10 which is explained by the drop in the category N&S, as well as the drop in PCP (Size)

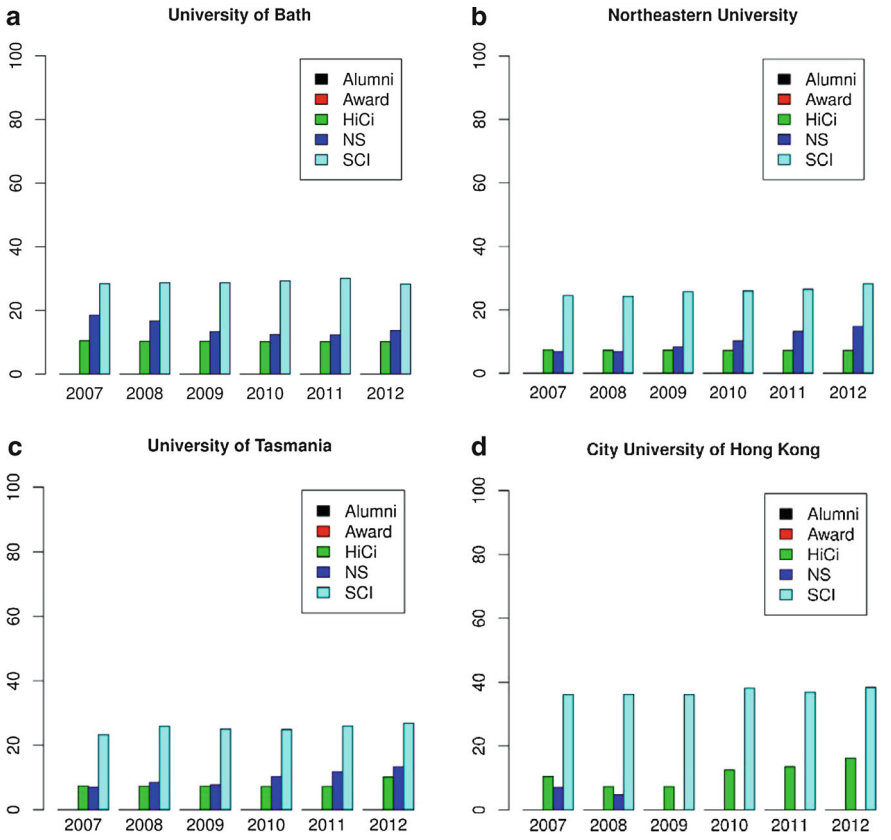

Fig. 5 Examples of universities that still moved levels in between the two periods of time when Performance Per Capita (PCP) was moved—This figure shows four universities that dropped or improved in their level position in the dominance graphs of 2007–2009 and 2010–2012 without PCP included. Figure **(a)** shows the University of Bath, which drops two levels between 2007–2009 and 2010–2012 due to their decrease in the value for the attribute N&S. Figure **(b)** shows Northeastern University which is the university that shows the largest improvement in level position in this comparison. As can be seen in this figure, their improvement can be attributed to their high values for N&S and SCI. Next, in figure **(c)**, the University of Tasmania shows that their rise from Level 16 to 13 is mainly due to their increase in the category N&S. Finally, figure **(d)**, the City University of Hong Kong jumps from Level 13 to 10 although they have a value of zero for the attribute N&S after 2009. The figure shows their level improvement is solely due to the increase in Highly Cited work HiCi

Dominance Graph Computation of 2007–2012 with Symbolic Regression Analysis

After the periods 2007–2009 and 2010–2012 were examined separately, the results of the dominance graph for the whole period are examined. The resulting dominance graph is displayed in Fig. 6.

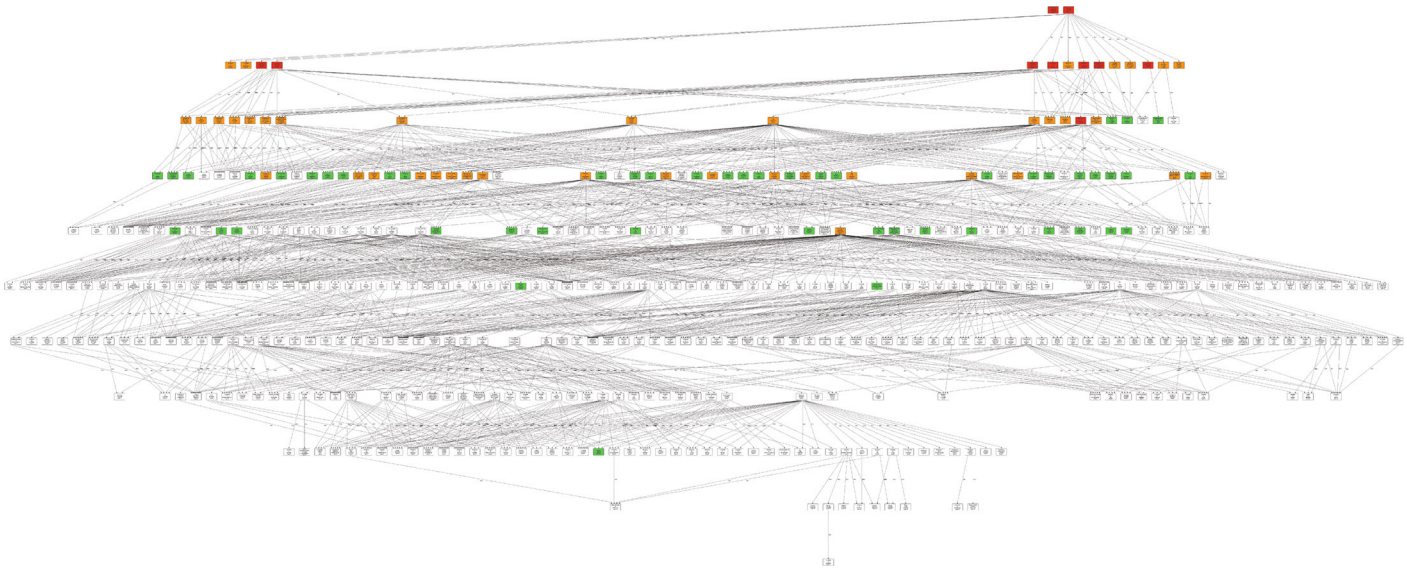

Fig. 6 Results of the dominance graph for the whole period 2007–2012. This graph contains a total of 11 levels, and consistent to the other results, Harvard University is still in Level 1 and directly dominates multiple universities in Level 2. The California Institute of Technology is again the only other institution on Level 1 but does not directly dominate and institutions in Level 2. Again, the coloring is consistent to the other dominance graph figures to highlight the ARWU ranking (NB: A high resolution quality of this image is available in Supplementary material)

Table 2 Universities that change more than two levels in the Pareto dominance graph in the two periods of years considered

University	Level		Change
	2007–2009	2010–2012	
Medical University of Innsbruck	12	7	− 5
Sao Paulo State University	11	7	− 4
Thomas Jefferson University	10	6	− 4
City University of Hong Kong	10	7	− 3
Hanyang University	11	8	− 3
Northeastern University	12	9	− 3
Scuola Normale Superiore di Pisa	6	3	− 3
Stockholm School of Economics	7	4	− 3
Sun Yat-sen University	11	8	− 3
University of Alaska Fairbanks	7	10	3
University of Montpellier 2	4	8	4

Examining the results of universities' position in the dominance graph over a total of 6 years allows the further investigation of the implications for institutions. This is because this graph compiles all the scores for all attributes for each year. With more information available in one ranking outcome like this, more inferences can be made for institutions, strategic planning activities, and research policy making. As stated in section "Materials and Methods", symbolic regression analysis is used on the 2007–2012 ranking results to find those variables that are important in predicting a universities' rank as well as test for consistencies using data from each year to predict the ranking of the 2007–2012 outcome. Using *Eureqa*, the aim is to find a linear function using the existing variables in the dataset to predict the level each university is a "member" of. Two separate error metrics are used to optimize the R^2 goodness of fit (GoF) and the squared error [AIC]. In each experiment the objective was to fit a model to predict the levels of the dominance graph shown in Fig. 6 using, in turn, the variables from each of the years 2007–2012. Results for the experiments optimizing R^2 GoF are shown in Table 3. Results optimizing the squared error [AIC] are shown in Table 4. As can be seen in these tables, all models contain the same variables, Alumni, PUB (research output), and PCP (related to size), for one exception which includes N&S (publications in Nature and Science) instead of PUB. However, it is noted that both PUB and N&S relate to a universities' research output and could therefore be seen as interchangeable as different institutions have higher research outputs in varying disciplines.

Furthermore, all models have highly similar coefficients. All constants at the start of each model range between 9.59 and 10.91 followed by highly similar coefficient attached to the Alumni attribute (ranged between 0.02 and 0.04). Following this, all models, except for that one using 2011 data and the Square Error [AIC], contain the attribute PUB with a coefficient ranging between 0.05 and 0.06. For the exception, N&S is included with a coefficient of also 0.05. This shows that for almost all models, PUB has a greater weighting in predicting universities' levels than the

Table 3 Results of the symbolic regression analysis predicting "level membership" or position. In this table the best linear models found using the R-squared goodness-of-fit measure are presented including the respective error metric. The experiment was run six times to include variables from each of the years separately to find consistencies in the variables used by *Eureqa*. As can be seen, all models are very similar; include the same three variables, Alumni, PUB (related to number of publications), and PCP (related to size); and even have almost identical coefficients

Year of variables used	Best linear model for level prediction	R^2 GoF
2007	Level = 10.40 – 0.02(Alumni) − 0.05(PUB) − 0.10(PCP)	0.71
2008	Level = 10.39 – 0.03(Alumni) − 0.05(PUB) − 0.09(PCP)	0.69
2009	Level = 10.41 – 0.02(Alumni) − 0.06(PUB) − 0.09(PCP)	0.71
2010	Level = 10.91 – 0.02(Alumni) − 0.06(PUB) − 0.10(PCP)	0.71
2011	Level = 10.90 – 0.02(Alumni) − 0.06(PUB) − 0.10(PCP)	0.71
2012	Level = 10.87 – 0.02(Alumni) − 0.06(PUB) − 0.10(PCP)	0.71

Table 4 Results of the symbolic regression analysis predicting "level membership." In this table the best linear models found using the squared error [AIC] measure are presented including the respective error metric. As in Table 3, the experiment was run six times to include variables from each of the years separately to find consistencies in the variables used by *Eureqa*

Year of variables used	Best linear model for level prediction	Mean squared error
2007	Level = 10.56 – 0.02(Alumni) − 0.05(PUB) − 0.10(PCP)	1.04
2008	Level = 10.40 – 0.03(Alumni) − 0.05(PUB) − 0.09(PCP)	1.11
2009	Level = 10.75 – 0.02(Alumni) − 0.06(PUB) − 0.10(PCP)	1.03
2010	Level = 10.87 – 0.03(Alumni) − 0.06(PUB) − 0.10(PCP)	1.04
2011	Level = 9.59 – 0.04(Alumni) − 0.05(N&S) − 0.06(PUB)	1.21
2012	Level = 10.76 – 0.03(Alumni) − 0.06(PUB) − 0.10(PCP)	1.05

Alumni attribute does. Finally, for all models other than the 2011 model in Table 4, PCP is the last included attribute with the heaviest weighted coefficient between 0.09 and 0.10. Again, the exception is the model using squared error [AIC] using 2011 data which includes PUB as its last variable with a coefficient of 0.06 (which is similar to the coefficient attached to PUB for all other models). Besides this one exception, these models show a high level of consistency across which variables are used to predict "level membership" for universities. These results indicate that PCP (size) has a big impact on predicting which level a university is part of in the dominance graph of the ARWU dataset. Furthermore, it can be observed that PUB has a stronger impact on determining which level a university is on than Alumni and that these three attributes combined predict the levels of the 2007–2012 dominance graph to reasonable error values (as shown in Tables 3 and 4). Finally, these symbolic regression results could assist a university in determining strategies for improvement in the ARWU ranking as they provide the strongest impacting attributes on which level a university is on.

To further illustrate the usefulness of the proposed ranking method in this chapter in detail, various examples are outlined from the 2007–2012 dominance graph. The universities selected to provide case examples are the University of Copenhagen, the

University of Amsterdam, and the Australian National University (ANU) as these institutions provide varying interesting cases.

Case Example of the University of Copenhagen

In the total period of 2007–2012, the University of Copenhagen was positioned on Level 4 of the dominance graph. As shown in Fig. 7, the University of Copenhagen is only closely dominated by one university, Yale, while it closely dominates 30 other institutions in Level 5. The fact that only Yale directly dominates the University of Copenhagen in our ranking result is a satisfactory achievement for the University of Copenhagen as this means the "inbound degree" of arcs for Copenhagen is low. However, it must be outlined that as the weight of the arc between Yale and Copenhagen equals to 36, it means that Yale dominates Copenhagen in every attribute for every year ($6 \times 6 = 36$). This shows that the weight of each arc is important in the dominance graph and provides information to the institutions wishing to directly benchmark with other institutions having very similar, though superior, profiles.

Case Example of the University of Amsterdam

In the total period of 2007–2012, the University of Amsterdam (UvA) was positioned on Level 5 of the dominance graph. It is one of the 30 universities that is closely dominated by the University of Copenhagen. Those universities that dominate the UvA and those that the UvA closely dominates are shown in Fig. 8 and create a cone-like shape that the UvA can analyze further for benchmarking purposes. As can be seen in the figure, the UvA is only closely dominated by Northwestern University, the University of Copenhagen, and the University of Illinois at Urbana-Champaign. The University of Amsterdam closely dominates nine universities at Level 6. Five of these universities are from Asia, Fudan University in China, Nanyang Technological University in Singapore, the University of Hong Kong, and the City University of Hong Kong. One such university is from Brazil, State University of Campinas; two universities from Europe, University of Erlangen-Nuremberg in Germany and the Swedish University of Agricultural Sciences; and, finally, one university from Israel, Yeshiva University.

Analyzing the relationship of UvA and the universities it is closely dominated by provides higher education decision-makers and research policy makers with further information about where to exert their resources more heavily. For instance, in the example of the UvA, it is shown how "close" UvA is to those universities that dominate it and possible areas of concentration for UvA to gradually improve its rank according to this system. For this, the scores of attributes only for the year 2012 are used as this is the most recent year in this dataset and therefore provide the most up-to-date answers. The attribute with the smallest difference in score for UvA and one of the universities is dominated by is "PCP" (Performance Per Capita). The UvA has a score in 2012 of 25.8, while the Northwestern University has a score of 26.4 making it only a 0.6 difference in score. This means that if the UvA improves in this item by just a mere 0.6 of a point score, it can change the domination status of one of the three institutions at a higher level that closely dominate it.

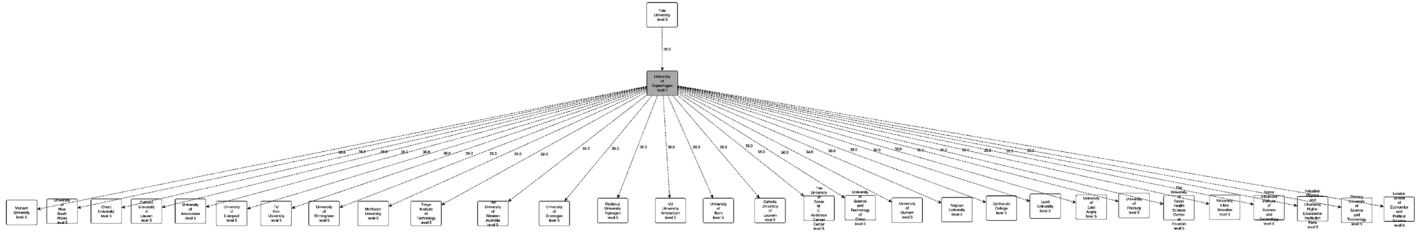

Fig. 7 The position of the University of Copenhagen at Level 4 in the dominance graph of the period 2007–2012. The University of Copenhagen provides an interesting example as it is only directly dominated by one university in Level -, Yale, and it dominates a total of 30 universities directly

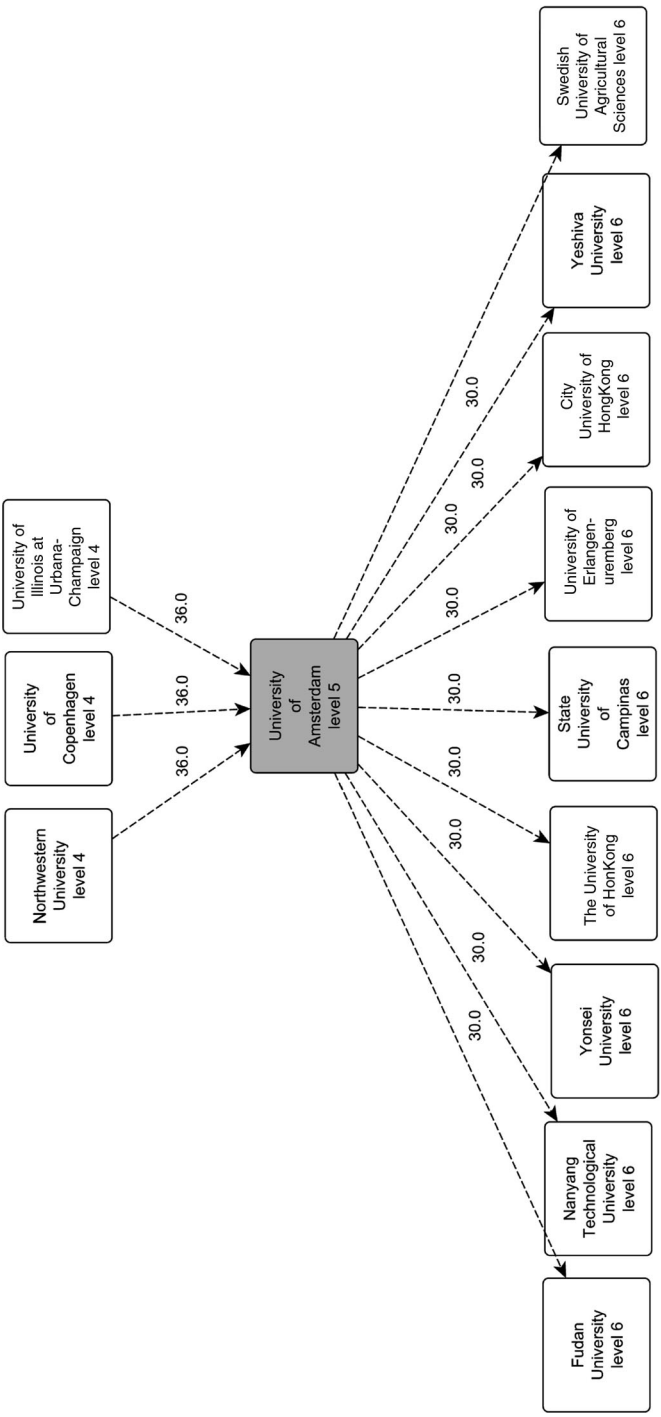

Fig. 8 The position of the University of Amsterdam at Level 5 in the dominance graph of the period 2007–2012. It shows that the University of Amsterdam is directly dominated by three universities at Level 4, Northwestern University, the University of Copenhagen, and the University of Illinois at Urbana-Champaign. In turn, the University of Amsterdam dominates nine other universities directly in Level 6 as shown in the figure

Furthermore, the University of Illinois at Urbana-Champaign has a score of 27.8 for PCP meaning that UvA is only 2% points lower. The University of Copenhagen has a score of 32.3 for PCP making it 6.5 points higher than UvA. The second closest attribute score for UvA and its dominating universities is in "PUB." UvA's score in this attribute in 2012 is 52.8 while the University of Illinois at Urbana-Champaign has a score of 56.1 meaning there is only a 3.3 point difference. Northwestern University has a score of 58.1 (5.3 point difference with UvA) and the University of Copenhagen has a score of 58.6 (5.8 point difference with UvA). These results tell us that the UvA is closest to its dominating institutions in these attributes. This can inform management at UvA to focus attention and resources on increasing publications in certain journals and in doing so improve their Performance Per Capita (PCP) instead of investing heavily in other attributes in which the differences are pronounced.

Case Example of the Australian National University

In the analysis using the total period of 2007–2012, the Australian National University (ANU) was positioned on Level 4 of the dominance graph which is the same level as the University of Copenhagen (see Fig. 9). ANU is closely dominated by six universities at Level 3, while it, in turn, closely dominates five universities at Level 5. The universities that dominate ANU are all from the USA or the UK, University of California San Diego; Yale University; University College London; the Imperial College of Science, Technology, and Medicine; Cornell University; and the University of Chicago. The universities that ANU closely dominates are a more international mix, the University of Bern in Switzerland, Oregon State University from the USA, the University of Durham and the University of East Anglia in the UK, and Korea Advanced Institute of Science and Technology.

ANU is taken as an example of how to investigate the relationship with those universities a given institution closely dominates. In the case of ANU, there are five. In this scenario it is important to investigate which universities would be close in certain attributes or in some cases almost equal. Once the university of interest is no longer better in all attributes, it will no longer closely dominate those universities. Again, only the scores from 2012 will be investigated to provide a scenario as up to date as possible. In the case of ANU, three of the closest scores are in the attribute "Alumni" which relates to the alumni of the institution that obtain a Nobel Prize. In most cases, this is extremely difficult to alter, and a discussion on this attribute is provided in the following section. The next attributes in which universities closely "compete" with ANU are the attributes N&S and PCP.

The closest university in terms of the attribute N&S is the University of Bern followed by Oregon State University. These universities have scores less than 4 points below that of ANU making them competitors for ANU in this system. In terms of PCP, the Korea Advanced Institute of Science and Technology and the University of Bern again come close to ANU. The reason these attributes are outlined rather than Alumni is because these attributes are more in the control of the university than the number of Nobel Prize winners they "produce." For instance, ANU could encourage and enable its researchers to publish articles in Nature

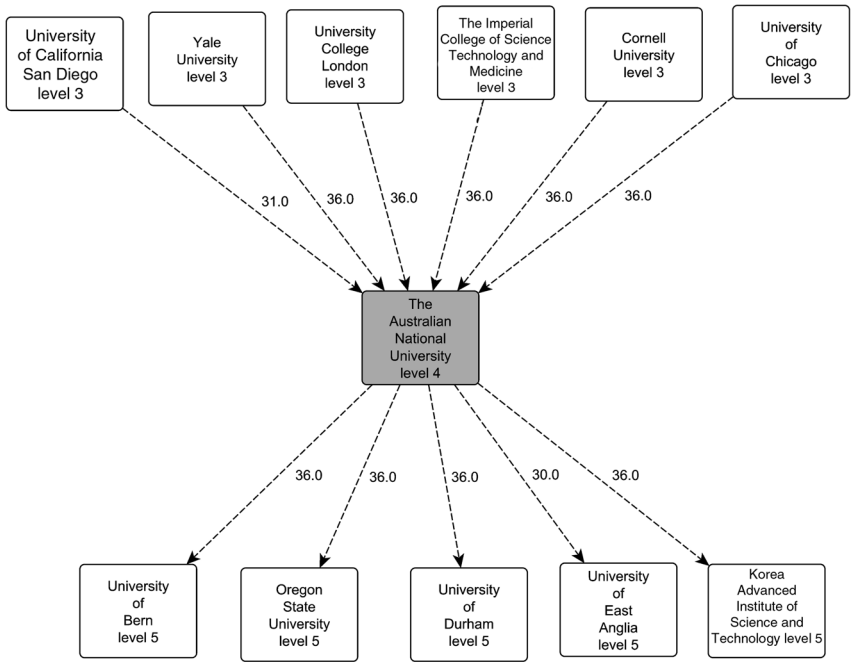

Fig. 9 The position of the National University of Australia at Level 4 in the dominance graph of the period 2007–2012. It is closely dominated by six universities at Level 3, while it, in turn, closely dominates five universities at Level 5

and Science rather than other journals in the field. Furthermore, when improving research output in terms of quality and volume without growing in size, it would be likely that Performance Per Capita would increase. These results show us the attributes that ANU needs to focus on in order to keep their competitive advantage and higher position in the dominance graph due to the universities they closely dominate.

The Case of the Alumni Attribute

In the ARWU ranking, the attribute measuring "Alumni," "the total number of the alumni of an institution winning Nobel Prizes and Fields Medals," has been extensively scrutinized and criticized for not measuring actual research or teaching excellence [28, 29]. As Ioannidis et al. [17] state, there is no doubt that research excellence *could* indirectly be measured by the Nobel and Field Medal faculty members working at a given institution. However, there is no justification to assume the existence of any clear correlation with the quality of teaching and research as a whole of the institution. Perhaps, it is only a measure of maturity, sheer size, number of graduates, financial support, and capital investment on a particular discipline

(only certain disciplines can give Nobel Awards or Field Medals). In addition, it is unclear why an event with such a low probability of occurrence (very few individuals receive Nobel Prizes or Field Medals) has such a large impact on the activities measured over populations of individuals. Furthermore, Ioannidis et al. have well argued that, in many cases, the affiliation of the Nobel and Field Medals differs at the time they actually conducted the award-winning work and the time that they were awarded the prize [17].

To prove that an attribute in the ranking process may be a spurious one, another type of sensitivity analysis is conducted as part of this chapter's proposed heuristic method. The attribute *Alumni* is eliminated and its effects on the ranking of the universities and their levels over the whole period 2007–2012 are subsequently investigated. It was previously observed that institutions such as the Netherland's Radboud University Nijmegen may have obtained dramatic changes in overall level position due to the attribution of Alumni alone (as can be seen in Fig. 4a shown by the black bar) which provides yet another reason for the comparison of these two outcomes.

According to the definition, the category Alumni represents *"the total number of the alumni of an institution winning Nobel Prizes and Fields Medals. Alumni are defined as those who obtain bachelor, Master's or doctoral degrees from the institution"*. In order to analyze the effect of this category in the ranking analysis, the dominance graph without the Alumni category is recalculated. Thus, each of the 444 universities performance is only observed in the remaining five scores in six consecutive years.

The resulting dominance graph on this dataset has 11 levels which is the same number of levels as the result of 2007–2012 period with all attributes included. This means that any changes in levels by a university is significant and provides useful information. However, here only those universities that increased or dropped by two or more levels are presented for the sake of brevity.

From the 444 universities, 196 universities (44.14%) do not change in level when the attribute Alumni is taken out of the dominance graph algorithm. There are 226 universities (50.9%) that change in only one level and only 21 universities (4.73%) that fall two or three levels. Furthermore, there is only one university (City University of New York City College) that falls four levels, indicating the robustness of this scheme. This points out the irrelevance of the Alumni attribute for the presented heuristic ranking method. This may please those opposed to Alumni being included as a proxy for measuring quality.

However, it is interesting to highlight how the performance of individual institutions may be affected by this choice. Looking at the City University of New York City College, without its impressive legacy of Nobel Prize winners, falls from Level 5 to Level 9. It was clearly in a higher level due to its high performance in the Alumni attribute (with a score of more than 37 in the three years), but the score in the rest of the categories is no higher than 18.

The three universities that fall more than three levels are Eotvos Lorand University in Hungary which fell from Level 7 to Level 10, University of Chile which fell from Level 8 to Level 11, and Saint Petersburg State University from Russia which

fell from Level 6 to Level 9. It is clear that these institutions, without their successful score in the Alumni attribute, fall down to lower levels as their scores reflect much lower results in the other categories. It is also interesting to note that the Radboud University Nijmegen in the Netherlands, which, as pointed out, increased in levels over the two separated periods (2007–2009 and 2010–2012), actually falls from Level 5 to Level 6 over the whole period (2007–2012) when the attribute Alumni is not considered. This strengthens the argument that their climb in levels over the six-year period is merely due to their Alumni winning the Nobel prize in Physics rather than a total improvement in "academic excellence" supporting those who argue the superfluous nature of the Alumni attribute in measuring "academic excellence." The results of all universities which dropped or gained two or more levels with the removal of the Alumni attribute are shown in Table 5.

The Case of the Performance Per Capita Attribute (Size)

In the ARWU ranking, the only way in which the "size" of an institution is taken into account is through the only per capita measure: Performance Per Capita (PCP). In the ARWU ranking, PCP is defined by as "*The weighted scores of the above five indicators divided by the number of full-time equivalent academic staff. If the*

Table 5 Universities that change more than two levels in the Pareto dominance graph in the period 2007–2012 when the attribute Alumni is not considered. There are another 226 universities that drop one level

University	Levels dropped
City University of New York City College	− 4
Eotvos Lorand University	− 3
University of Chile	− 3
Saint Petersburg State University	− 3
Case Western Reserve University	− 2
University of Nebraska Lincoln	− 2
University of Tuebingen	− 2
Queen Mary U. of London	− 2
Technical University of Berlin	− 2
The University of Connecticut Storrs	− 2

University of Warsaw	− 2
Istanbul University	− 2
Technical University of Braunschweig	− 2

number of academic staff for institutions of a country cannot be obtained, the weighted scores of the above five indicators is used." [30]. Since this attribute is the only variable in ARWU's ranking method which takes an institution's size into account, it is an interesting image to see the effect of its removal on our methodology.

The sample of 444 universities over the total period of 2007–2012 has been used for the dominance graph algorithm in order to compare its outcome to the result of the 2007–2012 results for all attributes. There are more changes to the outcome when PCP is removed than when Alumni was removed. Firstly, the resulting dominance graph has 12 levels which means that some universities may change in levels due to a total reorganization of the graph. This means that all universities which changed more than two levels are significant; however, this presents a total of 124 universities; therefore, again for the sake of brevity, only those universities which changed in more than three levels are reported here. In these results, only 138 universities (31.08%) did not change a level, 182 universities (40.99%) changed in only one level, 84 universities (18.92%) changed 2 levels, and exactly 40 universities (9%) changed three or more levels.

In the case of deleting the PCP attribute from the method, the most extreme result is the Scuola Normale Superiore di Pisa in Italy, which drops an impressive 8 levels from Level 3 to Level 11. This incredible drop is likely due to its extremely small size in terms of staff and students. The Scuola Normale Superiore (SNS) has only approximately 150 undergraduate students, 120 postgraduates, and only 190 doctoral students as it only takes approximately 60 new students annually through its highly selective entry exam. However, it is important to note that the SNS in Italy is an entirely special case. In order to attend this institution, students sit a rigorous entry exam and must obtain certain levels of grades to remain enrolled in SNS. Furthermore, what makes SNS a special case is that its undergraduate students follow courses at the public university, the University of Pisa (Level 6 in the results without PCP), while living on the SNS campuses. This means that its research academics are able to devote their time to research and that they only have high-caliber students. This explains their impressive result in terms of Performance Per Capita and the incredible drop when PCP is removed from the method.

Furthermore, a small Swiss Institution the Swiss Federal Institute of Technology (EPFL) located in Lausanne has previously been highlighted. Another small Swiss institution the Swiss Federal Institute of Technology Zurich (ETHZ) is highlighted for a different reason. ETHZ was located on Level 3 in the result when all attributes were included in the method; however, with PCP removed, ETHZ fell to Level 4. The removal of the PCP attribute also had a negative effect for EPFL which fell from Level 4 to Level 7. This shows that for many small institutions, the attribute which takes Size into account is important for their position on the ranking levels.

The last small institution that is discussed here provides a particularly interesting case, Princeton University. Between the result for 2007–2012 with all attributes included and the result with PCP removed, Princeton remains on Level 2. In both results, Princeton University is only closely dominated by Harvard. The only change is in the universities Princeton closely dominates as it dominates the Scuola Normale

Superiore di Pisa just discussed and Ecole Superieure Paris in the result of all attributes but does not closely dominate any institution when PCP is removed from the method. This is because both these institutions drop in levels when PCP is removed leaving no Level 3 institution closely dominated by Princeton. From this result for Princeton University, it can stated that even though it is a small institution when compared to the likes of Harvard, it "holds its ground" even when the only per capita measure is removed unlike the other small institutions that have been discussed.

Discussion

This section elaborates on the findings of the proposed heuristic ranking method and reflects on the contribution of this chapter from a mathematical standpoint as well as a research policy making standpoint which is the application in this chapter to highlight the usefulness of this method. Furthermore, a brief overview of other existing multi-objective ranking methods is provided as a means for comparing the method presented in this chapter. This brief review is then used to highlight several benefits of this chapter's methodology as well as define any future research possibilities to improve the method. Firstly, the two main contributions of this chapter are described in further detail which are a mathematical contribution in terms of a transparent, user-centric heuristic ranking method through the use of a dominance graph and the provision of implications for decision-makers, managers, and research policy makers at educational institutions and governmental offices.

A Transparent and User-Centric Ranking Method

As stated, many authors argue that current ranking systems which include arbitrarily assigned weights and measurement approaches are generally naive, biased, flawed, or a combination of all.

This chapter has attempted to provide a different approach to the ranking of objects with multiple attributes through the use of the global universities ranking example. Needless to say, the methodology is applicable to other types of problems and would allow users of this method to naturally deal with attributes that are numerical and/or ordinal in nature. For example, scores or attributes that have ordinal values in categories could be taken into consideration for this method allowing a much wider adoption of this method for different ranking needs that include a variety of attributes or objects. The aim of discussing particular case examples was to provide an illustration of the user-centric approach of this method which allows alternative ranking outcomes to be investigated according to the user's interests and needs. It is for these reasons that the simple method used in this chapter is easily transferable to other situations.

One of the main benefits of the heuristic ranking method proposed here is that each user with differing interests can be satisfied by selecting which of the

attributes must be included in the ranking. As it has been pointed out, the position of several universities changed with the deletion of an attribute. This means that this system allows users to look at the world ranking of universities based on attributes that matter to them and exclude those that do not. Naturally, this would also apply to other ranking and ordering exercises in different situations where users may have varying interests. Such instances could include the ranking of medical institutions for possible medical treatments, companies or organizations for prospective employment, or even the analysis of countries or cities with attributes relating to "livability."

Furthermore, the approach to ranking of global universities in this study provides a more transparent method as it uses raw data rather than accumulated, normalized, or weighted data. As it is the weighting of the data in the ARWU ranking of world universities that concerns a large number of authors [25], it is argued that the proposed heuristic hierarchical method presented in this chapter satisfies a missing need for transparently ranking universities based on raw data available publicly. As it has been explained, although current university ranking methods seem to be flawed and subject to data inaccuracy, scholars and educational institution leaders agree that these activities are "here to stay" [52]. Hence, utilizing a methodology which is transparent and user centric may be more appropriate for the world "need" of global university rankings and other ranking activities.

Implications for Research Policy Makers

As stated before, well-known annual rankings of global universities, such as the ARWU, are often criticized due to their level of volatility [52]. The advantage of the methodology proposed in this chapter is that it organizes global universities in levels based on a dominance graph rather than a "string list." This means that the real nature of slow and steady university growth and improvement is reflected in this method rather than highly volatile changes. As such, this methodological approach correlates well with the subjective assumption that large institutions, like universities, when compared with other institutions of similar size and prestige, do not experience high levels of volatility in terms of their status over periods spanning just a few years. This level-based scheme induced by a dominance graph shows low volatility over consecutive periods of three years and therefore reflects the *real-life* nature of large educational institution growth.

The ability of an educational institution to compare and benchmark itself within the "ladders" of the hierarchy of the presented layers is what actually brings university leaders a clear path for improvement as outlined in the case of the University of Amsterdam in section "Case Example of the University of Amsterdam". Or conversely, a clear image of close competitors in levels below that institution can be examined, as highlighted with the example of the Australian National University in section "Case Example of the Australian National University". In these examples it was easily and clearly identified that these universities' nearest objectives (subset of

the top layer that dominate that university) and those attributes they should consider to "protect their standing" (the ones a university closely dominates in the layer immediately below). This knowledge is of considerable value to universities and its research policy makers as it aides strategic decisions regarding the distribution of resources and funding. Although many different approaches to find the optimal allocation of resources by universities exist, for example, such as in [31], since global ranking systems are here to stay, ways of improving on these systems will become more valuable.

Furthermore, it has been found that changes in resource allocation have an impact on the type of activities academics concentrate on [31]. This means that those universities in sections "Case Example of the University of Amsterdam" and "Case Example of the Australian National University", who needed to improve in areas such as publications in Nature and Science, can base their decisions for allocations of resources on numbers that will actually help them in the global standing of universities.

Overview of Existing Multi-objective Ranking Methods

The problem of multicriteria ranking has been active in the decision-makers research community for several years. In most cases, authors aim to produce a total order of the alternatives, or as it has previously been referred to in this chapter, a "string list" of object number one to the bottom ranked object. It is possible to classify the methods presented in two approaches: the first one, and most common, is the use of different ways of aggregating the criteria (features) such that different ways of combining allow to obtained better rankings. Examples of the above can be found in [32–41]. It is arguable whether a specific way of combining or weighting criteria is better than other. The second approach to solving this problem is by modeling it as a multiobjective optimization problem and to solve it by using, for example, evolutionary algorithms. Examples of the above can be found in [42–46]. This approach has not been fully exploited, and recent advances in evolutionary algorithms and other techniques to solve multi-objective optimization can be applied. It is also well known that the use of specific knowledge of the problem in the solution leads to good performing methods. In the literature, several applications of domain-specific multicriteria ranking methods can also be found, which incorporate characteristics of the problem at hand in order to combine the different criteria to make the decision. Examples of the above can be found in [47–56].

Independently of the approach used, all methods aim to produce more reliable rankings and benefit decision-makers. The approach presented in this chapter differs from the ones presented above in that it neither aggregates criteria or produces a total ranking of the alternatives. The method uses multiple criteria (features) in the way they are delivered and only compares values of alternatives into each criteria. This simple method allows the user to scale to several alternatives or objects to be ranked

and produces groups or layers of alternatives that are distinguishable from the others, but that between them there is no single alternative that is better than other, according to the criteria considered. In other words, the results of the dominance graph heuristic approach "ranking" provides the user with more information for comparison as the different layers can be compared, as well as the outcomes within the layers.

Conclusion

This chapter has contributed a simple method for hierarchically ranking a set of objects according to multiple characteristics and with multiple objectives in mind. Several extensions and improvements can be made to this method in future efforts. Firstly, in this study only one dataset is used to present the methodology, those produced by the annual Shanghai ranking, to illustrate on the use of our methodology and its implications for research policy. However, even in the case of ranking global universities, other datasets and information sources are available. For instance, the Times Higher Education [57] ranks universities annually, utilizing a different approach. Future research could investigate the combination of information by the use of attributes that come from the different ranking organizations.

Secondly, as stated multiple times, the use of a dominance graph in order to investigate ranking problems is transferrable to different situations. For instance, other researchers could apply this method and test it on other datasets, potentially including a combination of numerical and categorical (ordinal only) data, without the need of an ad hoc weighting scheme, which is very useful under different circumstances. Any research problem in which the objective is to rank or order based on dominance using multiple variables could implement this method as part of the process.

In order to highlight the flexibility of the method presented in this chapter, some extremely different examples are explained. A different use of this method could be for the increased interest in dealing with protected area zoning for conservation as a multi-objective optimization problem [58]. For many years, when multiple geographic areas are examined, the objective is to create a priority ranking of these natural areas based on a variety of variables such as climax condition, educational suitability, species significance, community representation, and human impact [59]. Furthermore, as Smith and Theberge [60] explain, when evaluating natural areas using measurements for a series of criteria, it involves deciding which criteria are important and most significant based on their measurements. The use of a dominance graph would allow alteration and the inclusion or exclusion of certain criteria for each natural area individually and would thus be useful to many different instances across various natural circumstances. For instance, another circumstance for such analysis is the prioritization of farmland preservation for multiple objectives [61] in which the purpose is to preserve it from urbanization.

Another area of obvious application is that of sports [62–65] and other ranking games in academia, even if they can turn futile when using the wrong assumptions

[66]. We are also aware that, after the publication of this paper, a number of other alternative techniques will soon follow that may explore the directed acyclic graph construction hereby presented. We also envision that some researchers may try to exploit the transitive relations of dominance to build up different ranking scores even for objects at the same level. Given that this method is utilized in a global ranking of educational institutions could possibly be transferable to an area so different such as natural area conservation zoning or sports-related ranking activities, it becomes easy to imagine the wide use of dominance graphs in many other ranking activities.

In conclusion, this study adds to the literature a diverse and dynamic heuristic method for ranking multi-variable problems that is transparent and not biased by arbitrary weightings unilaterally and perpetually selected by the ranking organization. We have outlined the utility of this method in the case of ranking global universities using open, publicly available data and, in doing so, provided a novel methodology to approach the ranking of universities globally. This system allows for clearer benchmarking of universities which are at a similar standing. Overall it helps to provide assistance to research policy and decision-makers while at the same time enables a global standing of the universities in the world's landscape of diversified academic offers.
