Abstract

Iterated greedy is a search method that iterates through applications of construction heuristics using the repeated execution of two main phases, the partial destruction of a complete candidate solution and a subsequent reconstruction of a complete candidate solution. Iterated greedy is based on a simple principle, and methods based on this principle have been proposed and published several times in the literature under different names such as simulated annealing, iterative flattening, ruin-and-recreate, large neighborhood search, and others. Despite its simplicity, iterated greedy has led to rather high-performing algorithms. In combination with other heuristic optimization techniques such as a local search, it has given place to state-of-the-art algorithms for various problems. This chapter reviews the main principles of iterated greedy algorithms, relates the basic technique to the various proposals based on this principle, discusses its relationship with other optimization techniques, and gives an overview of problems to which iterated greedy has been successfully applied.

Introduction

Many effective algorithms for $\mathcal{NP}$-hard combinatorial optimization problems rely on the efficient, repeated execution of some simple, underlying mechanisms. A common example is perturbative search methods that iterate over neighborhood searches or iteratively apply underlying iterative improvement procedures. Examples of such methods include simulated annealing, tabu search, iterated local search, memetic algorithms, or dynamic local search [50,60]. In fact, simulated annealing, tabu search, or dynamic local search at each step explores the neighborhood of a current solution, while iterated local search and memetic algorithms can be seen as iterating across repeated applications of improvement algorithms. Less frequently, stochastic local search (SLS) methods make use of the iterative application of solution construction algorithms. Examples for these latter methods are ant colony optimization (ACO) [30, 31], greedy randomized adaptive search procedures (GRASP) [37, 38], or the pilot and rollout method [13, 34].

In this chapter, we review another SLS method that relies on the iterative application of solution construction procedures: iterated greedy. The method builds a sequence of solutions by iterating through phases of (partial) solution destruction and subsequent reconstruction of a complete candidate solution. A first complete solution in this sequence is generated by some constructive method. Then the following three steps are iteratively executed. First, components of a complete candidate solution s are removed, resulting in a partial solution s_p. Second, starting

from s_p, a complete candidate solution s' is rebuilt. Third, an acceptance criterion decides whether to continue this process from s or s'.

Iterated greedy has a clear underlying principle, and it is generally applicable to any problem for which constructive methods can be conceived. As such, iterated greedy is clearly a general-purpose method. Iterated greedy is a rather simple method that needs typically only short development times, especially if already a constructive heuristic is available. Iterated greedy provides also a rather simple way of improving over the single application of a constructive method, and for various problems, very high-quality solutions are generated. Additionally, basic versions of iterated greedy do only incur few main parameters, and their impact on the search process is rather intuitive to understand. All these reasons make iterated greedy a desirable technique for developers of heuristic algorithms.

Given the simple underlying principle, it is maybe also not surprising that the method that we here call iterated greedy has been (re-)discovered and applied a large number of times under different names by different authors (including ourselves). Algorithms that rely to a significant extent on the same underlying principle have been given names such as simulated annealing [62], evolutionary heuristic [77], iterative flattening [22], ruin-and-recreate [117], iterative construction heuristic [107], large neighborhood search [118], or, as here, iterated greedy [60, 114]. We will review these different developments and other related procedures in the section "IG Applications: Historical Development."

Despite the possible confusion that may arise for the reader due to the different names and the, in part, different views on the method, we want to stress that the really important aspect is the principle that underlies all these algorithms. In fact, in all these proposals, a repeated usage of constructive methods is made that starts from some intermediate, partial candidate solutions. This principle is a generic one of a potential large utility, and it should be understood as one of the basic principles that can be used to develop optimization algorithms. This basic principle may also be only one of the principles that is used in the development of a hybrid optimization algorithm that combines elements from different techniques. For example, several algorithms that make use of the iterated greedy principle include also a local search phase that may improve the solutions generated by the constructive mechanisms [114].

The structure of the chapter is as follows. In the section "Iterated Greedy," we review the basic principles of iterated greedy algorithms. Next, in the section "Some Simple Examples of Iterated Greedy Algorithms," we give some concrete examples of iterated greedy algorithms. In the section "Case Study: Iterated Greedy for Flow Shop Scheduling," we give some results of an experimental study that discusses the main trade-offs in the design of an iterated greedy algorithm for the permutation flow shop problem. We then present other algorithms that make use of the same principle as iterated greedy in the section "IG Applications: Historical Development." The relationship of iterated greedy to some other methods is discussed in the section "Relationship to Other Approaches." References to some noteworthy applications of iterated greedy are given in the section "Applications," and we conclude in section "Conclusions."

Iterated Greedy

Greedy Construction Heuristics

Constructive algorithms build candidate solutions to optimization or decision problems step by step, starting from an empty solution. At each step, they add a solution component to the current partial solution and repeat these steps until a complete candidate solution is obtained. Commonly, constructive algorithms use a heuristic function that estimates for each solution component the benefit of including it into a partial candidate solution. A baseline construction algorithm is formed by so-called greedy (constructive) algorithms that at each step add a solution component for which the value of the heuristic function is the best (see also Fig. 1). If more than one solution component has the same best heuristic value, a tiebreaking criterion is used to decide which solution component is actually added; in the simplest case, this tiebreaking is done uniformly at random, but it also may be done by a secondary heuristic function.

Greedy construction heuristics are frequently used when tackling combinatorial optimization problems due to a number of reasons. First, greedy construction heuristics are rather fast, and at the same time they generate solutions that are usually much better than those generated uniformly at random or by a randomized but heuristically biased construction. Second, these algorithms are often used to seed (perturbative) local search methods such as iterative improvement algorithms, more sophisticated SLS methods such as tabu search and simulated annealing, or population-based methods such as memetic algorithms. In the latter case, typically some members of the population are generated by greedy constructive methods, while others may be randomly generated. Seeding perturbative local search methods with solutions from greedy construction algorithms can incur advantages such as improved quality of local optima, faster identification of local optima, and a better trade-off between computation times and solution quality, that is, better anytime behavior [140]. Third, sometimes, one can prove guarantees on the quality of the solutions that are generated in the worst case, leading to so-called approximation algorithms. Often, the best provable guarantees that can be obtained even for more complex SLS algorithms are the guarantees that directly stem from those of the initial greedy construction. Fourth, for various polynomially solvable problems, greedy algorithms are also guaranteed to generate optimal solutions, the Kruskal algorithm for minimum spanning trees being a well-known example. However, for $\mathcal{NP}$-hard problems, this is not the case. Finally, they build the basis for a

Fig. 1 Algorithmic outline of a greedy heuristic

```
procedure Greedy Constructive Heuristic:
    s = ∅
    while s is not a complete solution do
        choose a best rated solution component c
        s = s + c
    end while
end
```

number of other methods such as GRASP [37, 38], ACO [30], or squeaky wheel optimization [64].

One straightforward way to improve over the generation of a single greedy solution is in some cases the repeated application of a greedy heuristic to generate a variety of different candidate solutions and then to choose the best one. Obviously, repetition in this sense is only reasonable if in the construction process different solutions can be generated. For example, for the well-known nearest neighbor heuristic for the traveling salesperson problem (TSP), n distinct nearest neighbor tours may result (assuming no random tiebreaking is done); for each of the n possible cities that may be chosen (randomly) as the initial city for the solution construction, a different tour may result. However, in other cases where the greedy construction is fully deterministic, additional randomization of the construction process, as proposed in the semi-greedy heuristics [57] and in GRASP [37, 104], may be required to generate different solutions.

Repeated construction of solutions also has inherent disadvantages. Constructing a full solution is relatively time-consuming as especially the initial construction steps require a large amount of computation when compared to later construction steps. Furthermore, no information is taken from one solution construction to another one, and thus such a repeated construction does not exploit knowledge gained from previous solutions. A method that alleviates these problems and that allows to invest, in principle, arbitrary computing times to generate different solutions by constructive heuristics is iterated greedy.

Iterated Greedy Framework

The main principle of iterated greedy is to iterate over (greedy) construction methods by first generating a complete candidate solution and then cycling through a main loop that consists of two main steps. In the first step, some solution components are removed from the current complete candidate solution s to result in some intermediate partial candidate solution s_p. We call this the *destruction step*. In the next step, starting from s_p, a construction heuristic is used to generate a new complete solution s'. We call this step the *construction step*. An acceptance test then decides from which of the two solutions, s or s', the next destruction step applies. While in the simplest case the acceptance test may accept only improved solutions, other choices may lead to more search diversification and, thus, to possibly better results when many iterations of the iterated greedy algorithm are done.

An algorithmic outline of an IG algorithm is given in Fig. 2. It starts by first generating an initial candidate solution using a procedure GenerateInitialSolution and then iterates through a main loop that consists of the application of the three procedures Destruction, Construction, and AcceptanceCriterion. Note that the construction procedures used in GenerateInitialSolution and Construction may be different and, hence, may also use different greedy heuristics. In the simplest case, however, they may be the same procedures.

Fig. 2 Algorithmic outline of iterated greedy (IG)

```
procedure Iterated Greedy
    s_0 = GenerateInitialSolution
    repeat
        s_p = Destruction(s*)
        s' = Construction(s_p)
        s* = AcceptanceCriterion(s*, s')
    until termination condition met
end
```

A simple default version of an iterated greedy algorithm could use the following choices. As constructive heuristic, one may take one that is either already available or implement a known state-of-the-art constructive heuristic. The solution destruction may delete some randomly chosen solution components, where the number d of solution components to be removed is a parameter of the algorithm. As acceptance criterion, one may force the cost to decrease by only accepting improved or equal quality candidate solutions.

The iterative process around construction heuristics gives IG some specific advantages when compared to the repeated construction of complete candidate solution from scratch. In fact, by starting from a partial solution, one may reduce significantly the time necessary to generate a new candidate solution as less constructive steps need to be done, and the time per construction decision is also reduced as the number of available solution components to choose from is smaller the larger the partial solutions. In addition, through the potential bias exerted by the acceptance criterion, the search process can more easily intensify around the best solutions found in the search process.

When trying to develop a more performing version of an iterated greedy algorithm, many different options for each of the specific operators may be taken into account. Some of the main relevant issues to be considered will be discussed in the following. Other ideas will be discussed also later when considering the relationship of iterated greedy to other methods or when discussing applications of iterated greedy algorithms.

Destruction There are a number of different possible choices for the solution destruction. A first consideration concerns the number of solution components that should be removed, as defined by a parameter d. The extreme settings would correspond to removing only a single component, that is, $d = 1$ or all of them. Even if one may argue that the resulting algorithms should be considered as iterated greedy algorithms, these parameter settings would not correspond to the main ideas underlying iterated greedy. The first case would be akin to a randomized local search while the latter to a repeated application of a construction heuristic. (We discuss these relationships in more depth in the section "Relationship to Other Approaches.") Intermediate values of d result in a trade-off between search intensification and diversification: removing a large number of solution components allows to jump to rather distant solutions in the construction phase, while removing few components leads to a more localized search.

Another choice is whether to leave the number of solution components to be removed fixed or variable during the algorithm run. In case d is left variable, a scheme of how to adapt its value is required. If the value of d is left fixed, it requires proper tuning. Possibilities for varying the value of d could be to modify this value randomly within some interval every few iterations, to choose the value according to a scheme similar as those introduced for variable neighborhood search [54], or to adapt the value of d at computation time, exploiting ideas of reactive search [11].

Once it is known how many components are to be removed, which ones should be chosen? There are a number of possible answers to this question. Intuitively, a randomized destruction is preferable over deterministic choices to reduce the danger of cycling. If a stochastic destruction is used, the simplest case is to choose components uniformly at random. More involved could be choices that take into account cost measures on the components or the partial solutions that remain, thus introducing a bias in the choice. In that case, solution components that have a strong contribution to the cost of a solution would then have a larger probability of being removed than low-cost components. Alternatively, one may use lower bounds on the partial solutions resulting after having removed a component: the smaller the lower bound, the higher the probability.

Construction One of the crucial ideas of IG is that restoring a fully specified solution is done by some form of (greedily biased) constructive mechanism. Hence, the usage of a constructive mechanism is essential. Using a random perturbation (corresponding to a move to a random solution in a large neighborhood) is more in the spirit of reduced variable neighborhood search than in the spirit of IG.

The naming iterated greedy suggests that the construction heuristics used in the algorithm are greedy construction heuristics and typically deterministic (modulo random tiebreaking). In fact, in many implementations of iterated greedy algorithms, this is also the case. However, we want to emphasize here that this need not necessarily be the case as, in principle, any suitable constructive mechanism that starting from some partial candidate solution s_p can generate a complete candidate solution—be it deterministically greedy, probabilistically greedy, or else—may be used as the underlying construction mechanism in an iterated greedy algorithm.

Among the construction rules, one may distinguish between *adaptive* heuristics and *static* ones. In the first case, the heuristic value assigned to a particular choice in the solution construction depends on the partial solution. Typically, adaptive construction heuristics will result in better-quality solutions than static ones; however, this improved solution quality is often reached at the cost of higher computation times.

In the simplest case, the solution construction is done following a deterministic construction heuristic—eterministic except of maybe random tiebreaking. Depending on the construction mechanism, it is possible to apply a deterministic rule: by applying stochastic destruction, either the order in which solution components are added is modified or, if adaptive construction heuristics are used, their heuristic evaluation.

Such basic considerations about solution construction in iterated greedy algorithms can be extended in many natural ways by adopting techniques that have been proposed in other methods. One may take inspiration from other constructive methods and use randomized selection in candidate lists built at each construction step as in GRASP algorithms, biased constructive decisions exploiting past experience such as the pheromone trails in ACO, or prohibitions by avoiding adding again solution components that have been removed in the solution destruction, taking ideas from tabu search. Another option may be to choose among different possible construction rules and use ideas from the hyperheuristics community for this task [19]. In fact, all kind of methods and techniques that are compatible with the idea of constructing solutions may be adopted within iterated greedy algorithms if this seems promising, making iterated greedy in this sense also a very flexible technique.

Acceptance criterion The acceptance criterion has a strong influence on the diversification/intensification behavior of an IG algorithm. On the extreme cases are the possibilities of accepting any new solution independent of its solution quality or to only accept solutions that improve over the previous one. There are many intermediate choices such as occasionally accepting worse solutions or allowing backtracks to previously seen solutions. A popular choice when accepting worse solutions is to use acceptance criteria from simulated annealing such as the Metropolis criterion: if a new solution is better or equal, it is accepted; otherwise, it is accepted with a probability $\exp\{(f(s) - f(s'))/T\}$, where T is a parameter called temperature. More elaborated approaches might probably make use of short-term memory as in tabu search. The acceptance criterion, whatever it might be, does not need to be applied at every iteration, i.e., a given incumbent solution can be destructed and reconstructed a number of times before deciding on its value. For the choice of the acceptance criterion, very much the same issues arise as in iterated local search [102], and an appropriate choice may be crucial to an IG algorithm's performance.

Hybridization with local search Iterated greedy algorithms can form directly the basis of hybrid algorithms that combine various search mechanisms. In fact, for constructive heuristics, a natural extension is to improve the generated solutions by the application of a (perturbative) local search method, in the simplest case this being an iterative improvement algorithm. Such an extension is also straightforward to be adopted in an iterated greedy algorithm and actually has been done in a number of such approaches. This extension results in an outline of iterated greedy as given in Fig. 3. With this additional local search phase, the IG algorithm also strongly resembles iterated local search (ILS) algorithms [102]. In fact, the destruction and construction phases implement a solution perturbation in the ILS sense. However, a minor difference is that ILS often makes use of perturbations that are randomly chosen from some large neighborhood, while in IG algorithms, an underlying constructive method is exploited. More importantly, IG can also reach very high performance when used without the local search phase, which is not necessarily

Fig. 3 Algorithmic outline of an IG with an additional local search step

end

true for ILS algorithms. More information on relations of IG to other methods is given in the section "Relationship to Other Approaches."

In any case, for an algorithm to qualify as an iterated greedy algorithm, it is necessary that one can distinguish between a clearly available construction mechanism and a clear destruction mechanism that are repeatedly applied in an alternating order. An acceptance criterion may be used in an explicit way or in an implicit way; the latter is the case, for example, if every new solution is accepted and no mentioning of an acceptance criterion is done. In that case, the acceptance criterion would correspond to a "random walk-type" acceptance criterion used sometimes in ILS algorithms [102].

Some Simple Examples of Iterated Greedy Algorithms

Let us consider a few examples of constructive heuristics for basic combinatorial problems that will illustrate throughout the chapter various details of IG algorithms. We consider here three examples for the traveling salesman problem (TSP), the set covering problem (SCP), and the permutation flow shop problem (PFSP). We first shortly introduce the problem and then describe a basic constructive heuristic and basic IG algorithms.

TSP Example

Traveling salesman problem (TSP). The TSP is given a graph $G = (N, E)$ where N is the set of $n = |N|$ nodes and E is the set of edges that fully connects the nodes. To each edge (i, j) is associated with a distance d_{ij}. Here we assume that the distance matrix is symmetric, that is, we have $d_{ij} = d_{ji}$ for all $(i, j) \in E$; this type of TSP instances is called symmetric and among the most widely studied types of TSP instances. The objective in the TSP is to determine a Hamiltonian cycle of minimal length. Such a cycle can be represented by a permutation $\pi = \langle \pi(1), \ldots, \pi(n) \rangle$, where $\pi(i)$ is the node index at position i. The objective function to be minimized is

$$\min_{\pi \in \mathcal{S}} \; d_{\pi(n)\pi(1)} + \sum_{i=1}^{n-1} d_{\pi(i)\pi(i+1)} \tag{1}$$

where $\mathcal{S}$ is the search space consisting of the set of all permutations.

Probably the best known constructive heuristic for the TSP is the nearest neighbor heuristic. It chooses randomly a first node to start from to obtain a partial tour $\langle \pi(1) \rangle$. Then at each step, it appends to the partial tour $\langle \pi(1) \ldots \pi(l) \rangle$ a still unvisited node that has minimum distance to $\pi(l)$. Once all nodes are visited, the tour is completed by closing the tour and going back to $\pi(1)$. The nearest neighbor heuristic usually contains subtours that may be close to optimal ones but also contains long edges that are added often toward the end of the construction. Empirically, for Euclidean two-dimensional TSP instances, the nearest neighbor heuristic generates tours that are about 20–40% above optimal (see [63]).

One possibility to build an iterated greedy algorithm on top of the nearest neighbor heuristic would be to remove a subtour of d consecutive cities of a tour, resulting in one subtour of $n - d$ cities and to restart the nearest neighbor heuristic from it. Another possibility would be to remove randomly cities, reconnect the remaining subtours, and then restart the nearest neighbor heuristic. However, it is unclear what the performance of such an algorithm would be.

Another simple constructive heuristic for the TSP is the random insertion heuristic (RIH). It starts by choosing randomly two nodes that are ordered arbitrarily. At each construction step, a next node is chosen randomly and inserted into a position in the current path such that the cost increase is minimum. The RIH is one of simplest heuristics for the TSP; however, it is among the best performing constructive algorithms for the TSP [63].

IG can be used on top of the RIH as follows. The first solution is constructed by RIH. The procedure Destruct would remove l nodes that are chosen uniformly at random. Next, Construct adds the removed nodes using again the same rules as in the RIH. Finally, AcceptanceCriterion could be chosen to only accept improved solutions. This means that the solution destruction would be applied to the best tour found so far. Different choices for iterated greedy algorithms based on such steps have also been experimentally examined by [117].

SCP Example

Set covering problem (SCP). The set covering problem (SCP) is given a set $A = \{a_1, \ldots, a_n\}$ of items and a set $B = \{B_1, \ldots, B_m\}$ of subsets of elements of A that covers A; in other words, we have that for each $B_i \subseteq A$ and $\bigcup_{i=1}^{m} = A$. A set B_i covers an item a_j if $a_j \in B_i$. Each set B_i has a cost of c_i. The objective in the SCP is to find a subset C of the sets in B that covers each element in A and that is of minimal total cost.

For the SCP, constructive heuristics differ in the choice of the heuristic function that is used. A standard heuristic function is to compute the cover value of the sets in B, which is defined as $\gamma_i = c_i / b_i$, where b_i is the number of items that would be covered when adding subset B_i to a current partial cover. Note that when starting with an empty solution, that is, none of the subsets B_i is chosen to be in the cover C, we have that $b_i = |B_i|$. However, each time a subset is chosen, b_i needs to be updated, taking into account the items already covered in a partial cover C_p. The cover value is an example of an adaptive heuristic, where the heuristic values

depend on the partial solution already generated. Adaptive heuristics require higher computation times than their corresponding static heuristics, which do not update heuristic values in dependence of the partial solution, but typically lead also to better-quality solutions. Once a complete cover is obtained, some of the subsets may have become redundant if all the items they cover are also covered by other subsets; removing such redundant subsets then improves the solution cost of the generated cover. Note that the removal of redundant subsets is not yet a destruction step as through the removal of redundant subsets the candidate solution remains a complete cover. The destruction step then may remove a number of subsets from a complete solution, resulting in a partial cover C_p, from which again the construction heuristic starts.

A first IG algorithm for the SCP has been proposed by [62]. They construct the first solution using a simple greedy construction heuristic [9] that at each step first selects a random, not covered item and adds the least cost subset that covers that item. Once a complete cover is found, redundant columns are removed. The solution destruction removes $k_1 \cdot |C|$ subsets that are chosen uniformly at random; here $0 < k_1 < 1$ is a parameter, and $|C|$ is the number of subsets on the cover and the cover size. The solution construction uses the heuristic based on cover values explained above. (The iterated greedy algorithm by [62] is, hence, an example where the constructive heuristics for generating the initial solution and for extending partial solutions in the main loop differ.) However, the subsets to be considered are limited to a candidate set that comprises all those subsets that have a cost less than $k_2 \cdot \max\{c_i | i \in C\}$, where $k_2 > 0$ is a parameter that influences the size of the candidate set and C is the current cover. At each step of the construction, a subset with a minimum cover value is added to the current partial solution, breaking ties uniformly at random. Once a complete cover is obtained, redundant columns are removed as explained above. The acceptance criterion of a new cover C' is based on the Metropolis condition that is frequently used in simulated annealing algorithms. This simple IG algorithm for SCP obtained very high performance, improving over several earlier proposed SCP heuristics.

PFSP Example

Permutation flow shop scheduling problem (PFSP). In the PFSP, n jobs have to be scheduled on m machines. All jobs visit the machines in the same order, each job having an operation at each machine. Time p_{ij} denotes the non-negative, known, and deterministic processing time that job j needs on machine i. In the PFSP, the same processing sequence of the jobs is maintained throughout all machines, and hence the processing sequence is obtained as a permutation of the jobs. The standard objective is to minimize the completion time of the last job in this order, which is also known as makespan ($C_{\max}$). The PFSP arises in many practical situations as it is common to have production lines where machines are disposed in series. The PFSP is a thoroughly studied problem in the scheduling literature with literally hundreds of papers published each year. The minimization of the makespan is the most used criterion in the literature, but not so in practice [45]. Some reviews on the PFSP are [44, 59, 112].

A popular and high-performing constructive heuristic for the PFSP is the NEH heuristic [87], named after the initials of the last names of the paper's authors. NEH is an insertion heuristic, a kind of heuristics that iteratively extends a permutation by inserting at each step one new element into the current partial solution. The NEH heuristic first computes for each job j its sum of the processing time $P_j = \sum_{i=1}^{n} p_{ij}$ and then orders them according to non-increasing P_j values, resulting in a sequence $\phi(1) \ldots \phi(n)$. The first two jobs according to that order are taken, their two possible sequences $\langle \phi(1)\phi(2) \rangle$ and $\langle \phi(2)\phi(1) \rangle$ are evaluated, and the better of the two is adopted. Then at each step l, the job $\phi(l)$ is considered and tentatively inserted in all possible l positions in the current partial solution $\pi(1) \ldots \pi(l-1)$. Among these tentative insertions, the one resulting in the least increase of the makespan is taken. These steps are repeated until all jobs are inserted. Note that there might be two levels of ties, both at the ordering of the P_j values and at the insertion phase. The NEH heuristic has a computational complexity of $O(n^3m)$, which is lowered to $O(n^2m)$ using the efficient implementation of [120]. There is a rich literature of methods that propose variants of the NEH heuristic, mainly proposing mechanisms to break ties or reinsertions. As shown by [112] and more recently by [39], the NEH is a state-of-the-art constructive heuristic for the PFSP.

A simple IG algorithm for the PFSP has been proposed by [114]. It is based on insertion heuristics such as NEH. In fact, this iterated greedy algorithm uses NEH to construct an initial solution. At each destruction step, it removes a number of jobs that are chosen uniformly at random from the current permutation. In the construction step, these jobs are then reinserted in the same order in which they have been removed. For the insertion of the jobs, the same procedure as described for the NEH heuristic is followed. The acceptance criterion accepts a new candidate solution using the Metropolis condition known from simulated annealing algorithms but with the temperature T set to a constant value. The performance of this simple IG algorithm was very good, outperforming many metaheuristic algorithms for the PFSP. When combined with a local search phase, the proposed IG algorithm was shown to be a new state-of-the-art algorithm for the PFSP [114]. The IG implementation of [39] has given some further improvements of the above-presented iterated greedy algorithm. Currently, one top-performing iterated greedy algorithm for the PFSP is the variant of [33], which additionally adds a local search on the partial solution that is obtained after the destruction step. Other variants of the flow shop problem have been also studied in the papers [41, 42] with very good results and in the paper of Pagnozzi and Stützle [93], which applies automatic configuration to the problem and again obtains excellent results.

Case Study: Iterated Greedy for Flow Shop Scheduling

The development of an effective iterated greedy algorithm requires the algorithm designer to choose which of the various possible implementation choices to take. In this section, we exemplify the development of an iterated greedy algorithm for the PFSP and study the impact specific alternative choices have on iterated greedy

performance. Here we examine the impact of various alternative choices for the iterated greedy algorithm by [114], which we presented in the previous section.

In particular, we consider the following design choices in our experimental analysis.

Initial solution. It may seem advisable to start from an as good initial solution as possible. For the PFSP, this would be the NEH heuristic [39, 112] using the accelerations of [120]. However, at least for some instances, it is not clear whether a random or heuristic initialization of iterated greedy provides the best results. In fact, [101] study cases in which only for hard instances and in short CPU times it is advisable to use NEH (or extensions of the NEH) to obtain competitive results.

Destruction strength. The first and foremost decision to be taken is how many elements of a complete candidate solution should be removed. Here, we consider different fixed values for this parameter d, although it may also be interesting to consider schemes of how to vary the value of d at runtime.

Destruction type. The type of destruction determines which components of the incumbent solution are removed. In the simplest case, one may remove components of a solution uniformly at random. Alternatively, one may remove blocks of consecutive elements. In this case, a random block of d jobs could be removed from the sequence. Note that for the same solution π and a block-based destruction, there are only $n - d + 1$ possible choices for the destruction move. These two latter possibilities will be examined here.

However, one may consider a biased destruction, where components of the incumbent solution may be chosen randomly but in a biased way. For the PFSP, for example, jobs generating a large idle time at machines before or after their processing might be disrupting the sequence and are therefore likely to have been misplaced. We leave the study of such a destruction operator for future work.

Construction type. Similarly to the type of destruction move, different ways of how to construct a solution could be examined. The default choice in the iterated greedy algorithm is to insert jobs using the NEH heuristic. As an alternative, we consider a random insertion of the removed jobs, which could be used if no efficient greedy heuristic is available. However, in this case, the difference between iterated greedy and ILS becomes somewhat blurry, especially when additional local search is used.

Acceptance criterion. The acceptance criterion has a direct impact on the balance between intensification and diversification of the search. A simple idea is to accept only better-quality solutions, while alternatively, one may use the Metropolis condition that occasionally also accepts worse candidate solutions.

Acceptance iterations. Instead of applying the acceptance criterion at each iteration, one may apply an acceptance criterion only each l iterations. This would correspond to accepting for a few iterations every new candidate solution that is generated and only applying the acceptance test after each sequence of l steps.

Table 1 Summary of the factors and the levels studied in the experimental analysis

Factor	Abbreviation	Level 1	Level 2
Initial solution	*Initialization*	NEH	Random
Destruction strength	*Destruct*	4	6
Destruction type	*Destruction_T*	Random	Block
Construction	*Reconstruction_T*	NEH	Random
Acceptance criterion	*Acceptance_C*	SA	Descent
Acceptance iterations	*Iterations_Acc*	1	5
Local search	*LS*	No	Yes

Local search. Finally, it is well-known that local search can have a tremendous impact on the quality of the results achieved, even though iterated greedy algorithms may reach high-quality solutions even without local search. Hence, it may be worthwhile to test the impact of an additional local search phase.

In order to study the different design and implementation alternatives, we have carried out a design of experiments (DOE) approach [85] where the previous factors are analyzed. Seven factors are coded and tested at two levels each, as summarized in Table 1. As a result, a total of $2^7 = 128$ combinations are to be tested in a full factorial experimental design. However, we use a half fractional design, which has most of the power of a full factorial one but requires only half of the runs. We use a 2^{7-1}_{VII} design, which has a high-resolution VII: interactions between four factors are aliased (confounded) with interactions between three factors, interactions between five factors aliased with interactions between two factors, and so on. As a result, we can safely study the experimental data since it is highly unlikely that two high-level interactions might be significant. More elaborated techniques for the analysis and calibration of algorithms than the simple exploratory analysis we perform here have been published elsewhere [10]. Each studied combination has been tested on 30 of the hardest instances from Taillard's benchmark (122). This benchmark is composed of 12 groups of 10 instances, each ranging from 20 jobs and 5 machines to 500 jobs and 20 machines. The instances of one particular group are denoted as $n \times m$. For the tests, we pick three of the hardest groups, namely, 50×20, 100×20, and 200×20. We are interested in these instances since for most of the remaining problems, the optimum solution is already known, and today's state-of-the-art methods are capable of obtaining near optimum solutions.

Each combination is run five independent times (replicates) with each instance. We also control the number of jobs (n) as a blocking factor with three levels in the experiment. Therefore, the experimental design contains $2^{7-1} \cdot 3 = 192$ treatments, $192 \cdot 10 = 1920$ experimental units (for ten instances), and $1920 \cdot 5 = 9600$ experiments (for five replicates).

The basic iterated greedy algorithm along with all studied alternatives has been implemented in Delphi language and run during a predefined CPU time, which is fixed to 30, 60, and 120 s for the instances of 50, 100, and 200 jobs, respectively. The machine used for the tests is a Pentium IV PC/AT computer running at 3.2 GHz

with 2 GBytes of RAM memory. The performance measure and response variable of the experimental design are the so-called relative percentage deviation (*RPD*) over the optimum or best known solution (upper bound) for each tested instance:

$$\text{Relative percentage deviation } (RPD) = \frac{Heu_{\text{sol}} - Best_{\text{sol}}}{Best_{\text{sol}}} \times 100 \tag{2}$$

where Heu_{sol} is the solution given by any of the replicates of any iterated greedy variation for a given instance and $Best_{\text{sol}}$ is the optimum solution or the lowest known upper bound for that specific Taillard's instance as of November 2015. The results are analyzed by means of the parametric ANOVA technique. Notice that in this case, the three assumptions of this parametric test (normality, homoscedasticity, and independence of the residual) have to be satisfied. In our experiment, the factor *LS* results to be extremely significant, and it creates large differences in the response variable. As expected, applying the local search results in a statistically significant difference in the average *RPD* of 1.46 considering all results, compared with the average *RPD* of 3.73 without local search. Such a large difference generates normality problems. In order to avoid this situation, we study two separate ANOVAs, one for each level of the *LS* factor.

Results of the Simple Iterated Greedy Without Local Search

All remaining factors after fixing the local search have p-values very close to zero in the resulting ANOVA table. As a result, we focus on the F-Ratio, which is the ratio between the variance generated by a given factor and the residual variance in the studied two-level interaction linear model. The higher this ratio, the more significant the factor or interaction is. Figure 4 shows the means plot for the remaining six factors in order of importance.

From Fig. 4, we can observe how all six studied factors have levels and variants that result in statistically significant differences. Observed differences in the average performance of the iterated greedy when a factor has been set to a given level or

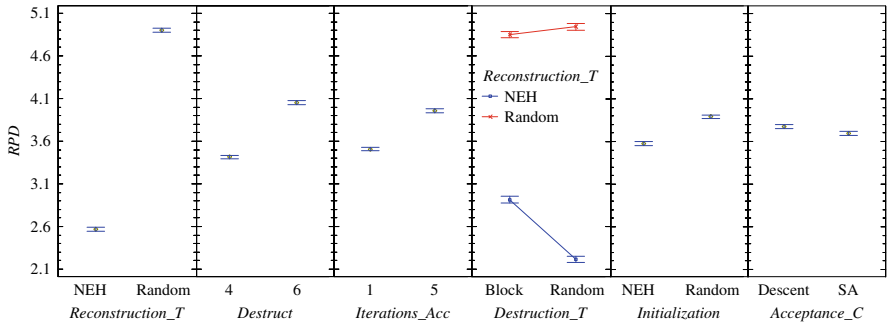

Fig. 4 Means plot of the average relative percentage deviation (*RPD*) and 99% Tukey HSD confidence intervals for the studied factors. Simple iterated greedy without local search

variant are depicted with non-overlapping confidence intervals in the plots. The importance of the F-Ratio is shown in Fig. 4 with the most significant factors to the left of the figure and the least significant to the right. As can be seen, without local search, it is clearly preferable to greedily reconstruct the solution as the difference in performance is extremely large. This is one of the main keys behind the iterated greedy algorithm. A random reconstruction of jobs means that first the jobs are randomly extracted and then randomly inserted. This is more or less a sequence of insertion moves. Too many moves (and no local search) result in an algorithm that is not performing well.

The second factor in importance is *Destruct* or d, the number of jobs to be removed in the destruction phase. Following the previous discussion, six jobs impose a rather large overall disruption, and removing only four jobs gives much better results. Notice that a similar conclusion was reached by [114] in their calibration of the iterated greedy for the PFSP. Although not shown here, removing four jobs is better for all the studied instances with 50, 100, and 200 jobs.

The third most important factor results to be *Iterations_Acc*. Among the two tested levels, applying the acceptance criterion at every iteration gives substantially better results. The analysis is continued until all factors have been fixed through the most important effects in the response variable. For example, the third most significant effect in the ANOVA is not a single factor but the interaction between factors *Destruction_T* and *Reconstruction_T*. It is shown in the fourth plot from the left in Fig. 4. We see that both factors interact greatly. When *Reconstruction_T* is set to random, the block destruction appears to be slightly better. However, when *Reconstruction_T* is set to NEH, as in the original NEH method, the destruction has to be done randomly as much better results are obtained. *Initialization* is best set at NEH, but we observe that the difference in performance with the random initialization is rather small. Finally, the acceptance criterion factor (*Acceptance_C*) is also slightly better at SA, but the difference with descent is very small, even though it is statistically significant. More specifically, the average *RPD* given by the simple iterated greedy across all factors with a SA-like acceptance criterion is 3.69%, whereas for the descent criterion, it is 3.77%. It is interesting to note that most results confirm the choices made in previous studies as in [114].

Results of the Simple Iterated Greedy with a Local Search Step

Now we proceed with the analysis of the experimental data after focusing on the results of the simple iterated greedy with the local search enabled. In this experiment, the first interesting result is that the observed differences as regards *RPD* among the levels of the factors are much smaller than in the previous one. It is safe to say that the local search is capturing much of the variability of the experiment. Figure 5 contains the means plot for the six factors, in order of importance according to their F-Ratios.

As can be seen, the relative importance of the studied factor is not the same when compared to the previous experiment without local search. The most important

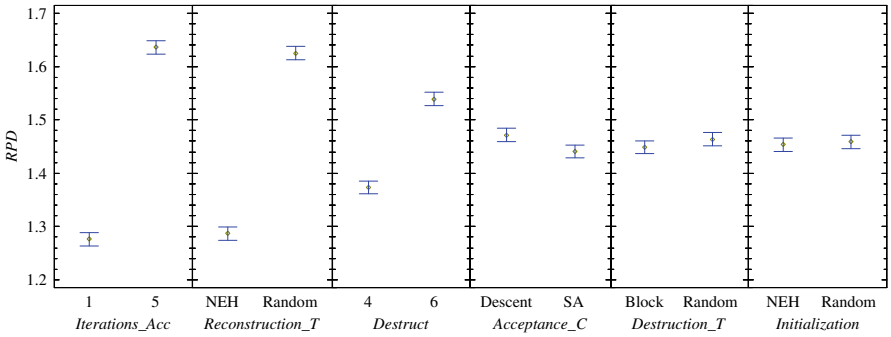

Fig. 5 Means plot of the average relative percentage deviation (*RPD*) and 99% Tukey HSD confidence intervals for the studied factors. Simple iterated greedy with local search enabled

factor is now *Iterations_Acc*. Similar to the previous experiment, applying the acceptance criterion at each iteration improves results significantly. The next factor in importance is *Reconstruction_T*. The plot is similar to the previous experiment and represents an important result. Considering that the algorithm already carries out a local search step after reconstruction, it could be argued that a random reconstruction might suffice. However, this is not the case. Carrying out a local search step from a randomly reconstructed solution yields, on average, much worse results than if the local search is carried out on a greedily (and, therefore, of higher quality) reconstructed solution. This supports the point that iterating over greedy heuristics gives very good results. The remaining factors per importance are *Destruct* and *Acceptance_C*. The last two remaining factors, *Destruction_T* and *Initialization*, are not statistically significant at a 99% confidence level as it can be seen by the fact that their corresponding means plots overlap. Hence, among the two tested types of destruction, it is not important how the jobs are removed. This is probably due to the fact that even though jobs are removed in blocks, they are reinserted one by one. As for the initialization, the advantage gained by an NEH initialization is nullified during the run of the iterated greedy algorithm, confirming the observation of [101].

As a conclusion from this study, the most significant factor is the local search and the NEH reconstruction. Most other factors have less importance. Iterated greedy can even do without a full NEH initialization for the hardest instances of Taillard in the PFSP problem.

IG Applications: Historical Development

Among the examples of iterated greedy algorithms in the section "Some Simple Examples of Iterated Greedy Algorithms," we had described an algorithm for the SCP by [62] who actually called their algorithm a *simulated annealing* algorithm. This naming is probably due to the use of the Metropolis condition as an acceptance

criterion, which was also used in the first proposals of simulated annealing [68]. This algorithm has later been extended by the same authors [18]. Somehow related is the more complex algorithm by Marchiori and Steenbeek [77] for the SCP; in this algorithm, a construction starts from a partial solution following the steps of the iterated greedy method; however, instead of obtaining the partial solution by choosing the subsets to be removed, they use a mechanism to choose the subsets of the best solution found so far that are maintained in the partial solution. Maybe surprisingly, in that paper, the proposed algorithm is viewed as an evolutionary algorithm. This algorithm is preceded by another algorithm for the unweighted SCP [76], which more directly follows the ideas of the iterated greedy method.

Interestingly, the abovementioned algorithms for the SCP are not the only ones that are directly based on the same destruction–construction process that is the basis of iterated greedy algorithms. In fact, a large number of other algorithms are based on the same principle. However, different names have been used for the underlying method or no specific name at all, which complicates the transfer of knowledge to other researchers.

Probably the earliest techniques that use some mechanism akin to the destructive–constructive moves of iterated greedy are found in the VLSI design automation community and, in particular, in the routing step, where components are connected by wires trying to obey design rules for integrated circuits. In the rip-up and reroute approach [26, 111], some routes related to bottlenecks are removed, and components are reconnected in a different order. The rip-up and reroute technique is commonly used in the design automation community, but the principle underlying this method seems not to have been generalized to the level of metaheuristic for tackling a wide variety of other optimization problems.

The possible use of destructive–constructive moves has also been mentioned earlier in the context of the type of techniques that have become known as strategic oscillation [47–49]. These types of approaches are often embedded into algorithms that make use of tabu search features to provide additional guidance to the search. Some examples of such implementations that have also a clear component related to the iterated greedy methodology are [51, 52, 71].

Among the first researchers to identify the potential of the principles underlying iterated greedy and to formulate these as a general-purpose SLS method are [117]. They called their method *ruin-and-recreate*, where the *ruin* stands for the solution destruction and the *recreate* for the reconstruction of a complete solution. (Ruin-and-recreate is protected by US patent *Optimization with ruin recreate* No. 6418398; see http://www.patentstorm.us/patents/6418398-fulltext.html.). In their seminal article, they applied ruin-and-recreate to the symmetric TSP, the vehicle routing problem with time windows, and to a network design problem, reporting good overall performance of the method. Following this work, a number of other papers have been published using the name ruin-and-recreate; however, not all papers that use the name ruin-and-recreate should be considered as iterated greedy algorithms; for example, [82, 83] essentially uses a random mutation of a current solution instead of a clearly separable destruction phase and greedy solution reconstruction.

Ahmadi and Osman [3] study the capacitated clustering $p-$median problem. Among different proposed methods and heuristics, the authors introduce a *periodic construction–deconstruction* procedure, which is basically a simple form of iterated greedy. After a given number of clusters have been built in the constructive method, some of them are randomly deconstructed, and the constructive method is reapplied.

Richmond and Beasley [107] have presented an *iterative construction heuristic* for a problem arising in ore selection. In this problem, processing options needs to be chosen for a number of mining blocks. The destruction operator deletes the processing option for some mining blocks; the size of the destruction is chosen randomly following a uniform distribution in some interval. After the reconstruction of a complete solution, the algorithm accepts only better-quality solutions as new incumbent ones. It should be clear from the description that the algorithm follows directly the very same principles of iterated greedy.

Cesta et al. [22] describe an algorithm for a capacitated scheduling problem that makes usage of the ideas underlying the concept of iterated greedy algorithms. They have developed a method that uses a greedy constructive heuristic to generate feasible schedules by introducing precedence constraints. In the destruction phase (called retraction in the chapter), they remove some of the introduced precedence relations to obtain a partial solution and then reconstruct a complete feasible one. They call their method *iterative flattening*, where flattening refers to the reduction of resource conflicts, which is an effect of the introduced precedence constraints. The term iterative flattening has gained some popularity, and several follow-up articles have been published on improvements of the algorithm [80], studies of combinations of basic algorithm components [89], or applications to other problems [90,91].

The authors of iterative flattening characterize the method in their initial paper as a local search method. Few years before, [118] has proposed the *large neighborhood search* method. The initial proposal consists in the removal of solution components and the reinsertion of solution components by using constraint programming techniques that exploit a tree search and constraint propagation techniques. Even though the method was proposed in a constraint programming framework, where a tree search is used to restore a complete solution instead of simple constructive heuristic, the latter is mentioned as one possible option. In fact, in many later articles on large neighborhood search, simple constructive heuristics are used [98], implementing, hence, directly an iterated greedy method.

Finally, the name *iterated greedy* has been used by [114] and also in [60] to denominate the type of SLS method we describe in this chapter. However, these are not the first publications that are using the name *iterated greedy*. A much earlier mentioning of the term iterated greedy is by Culberson [24]. His iterated greedy algorithm for graph coloring uses a greedy algorithm for generating a coloring, removing the color of all nodes, and then reapplying the greedy algorithm using a specific ordering of the nodes that guarantees the next generated coloring to not be worse than the previous one but potentially better. This algorithm may be seen as an extreme case of iterated greedy where the destruction operator destroys the complete solution. However, our view is rather that it is a specific algorithm that works in the way it is proposed mainly for graph coloring.

Relationship to Other Approaches

Iterated greedy is a general-purpose SLS method that has many links to other SLS methods. In the following, we discuss similarities and differences to a number of SLS methods considering other constructive methods, local search methods, and tree search algorithms. These relationships also open up many possibilities for combining techniques proposed for different methods.

Repeated (Greedy) Construction Algorithms

Iterated greedy has natural connections to other methods that repeatedly construct complete candidate solutions. A key difference between iterated greedy and few other repeated construction methods is that the solution construction in iterated greedy usually starts from a (non-empty) partial solution, while the other methods repeatedly generate new candidate solutions starting from *empty* candidate solutions.

A well-known simple such method is the greedy randomized adaptive search procedures (GRASP) that combines a greedily biased but randomized solution construction with a subsequent improvement of the generated candidate solutions by a local search procedure [37, 104]. GRASP in turn extends on some initial ideas of how to generate different solutions by a randomized greedy heuristic [57]. While GRASP does not start the construction from partial solutions, it is an example of a (simple) randomization scheme during the solution construction, which could be included directly in iterated greedy algorithms. An appealing feature of GRASP is the usage of adaptive constructive procedures, and the large number of articles on GRASP [104] may be a source for randomized greedy heuristics to be used in iterated greedy algorithms.

Many useful ideas that underlie other constructive methods may be adopted into iterated greedy algorithms. One such possibility is ways of how to improve the constructive mechanisms, for example, through look-ahead methods or, when taking look-ahead to an extreme, as advocated in the rollout [13] and pilot method [34]. In the rollout and pilot methods for each constructive decision to be taken, a full solution is constructed (or at least well approximated), and the construction decision that results in the best complete solution is taken as the next one. This process is repeated for each construction decision, resulting in a relatively time-consuming constructive approach. However, starting the rollout/pilot method from partial solutions with the resulting reduction in computation time may make this approach promising inside an iterated greedy algorithm.

Squeaky wheel optimization (SWO) [64] uses the idea of biasing the solution construction by information that was gained by analyzing complete candidate solutions. This is done by assigning priorities to specific solution components. The solution reconstruction in SWO is done, differently from iterated greedy, from empty initial solutions corresponding to a complete destruction of the current candidate solution. Within the SWO framework, Aicklin et al. [5] proposed the idea

of seeding the reconstruction of a full candidate solution by some partial solution that was obtained by removing some of the solution components of a complete candidate solution, making it a variant of iterated greedy.

A rather different way of biasing the solution construction is underlying the ant colony optimization (ACO) metaheuristic [30, 31]. In ACO, (artificial) ants implement stochastic solution construction heuristics that make their constructive decisions based on so-called pheromone information and heuristic information associated to specific solution components. The pheromone information tries to bias solution construction toward the best solutions that have been found so far. Again, differently from iterated greedy algorithms, the ants start their solution construction from empty candidate solutions. However, there have been a number of proposals in the ACO area that suggest starting the solution construction from partial solutions that are either stored [1, 2] or obtained by deconstructing complete solutions [126, 127, 134] in a way akin to iterated greedy algorithms. These approaches generally try to transfer the advantages of iterated greedy to ACO algorithms, and for several of these approaches, positive results are reported.

(Perturbative) Local Search Techniques

Iterated greedy has tight links to local search algorithms and, in particular, to very large-scale neighborhood searches [4]. In fact, as also mentioned in the section "IG Applications: Historical Development," one of the proposals of iterated greedy style algorithms called the method large neighborhood search Shaw [98]. The analogy stems from the fact that the removal of k solution components in the destruction step and the subsequent reconstruction of a complete candidate solution can be seen as a move in a large neighborhood that is implicitly defined by the number of components to be removed and/or added (Note that the number of solution components removed in a destruction step may be different from the number of solution components added in the construction step, and so we refrain from talking of k-exchange neighborhoods here. A common example where this happens is subset problems such as the SCP we discussed earlier.). The (greedy) reconstruction of a complete candidate solution typical for iterated greedy algorithms can then be seen as a heuristic examination of the neighborhood either in a fully greedy way or using randomization steps–details that simply depend on the particular design and implementation of the construction step in an iterated greedy algorithm. By varying the value of k, the size of the implicitly defined neighborhood is varied. Such changes may be done either (i) randomly within some limited range $[k_{\min}, k_{\max}]$ resembling known strategies in local search methods such as robust tabu search [121], where one tries to avoid overcommitment to a single value for a parameter, (ii) in a more systematic way such as advocated in the strategies defined for variable neighborhood search [54], or (iii) by using feedback from the search performance such as advocated in reactive search methods [11]. An interesting possibility for exploring the neighborhoods is used in the adaptive large neighborhood algorithms by [97, 110], who propose to consider different heuristics to be used in the solution

reconstruction. In their method, they additionally adapt the probability with which specific heuristics are chosen over the runtime of the algorithm based on the feedback of the search process.

An alternative to the heuristic exploration of neighborhoods provides methods that try to determine the best possible solution that can be reached from the current one, akin to best-improvement neighborhoods. In the case of large neighborhood searches, this corresponds to an exact examination of all the possible solutions that can be reached from a current partial candidate solution [4, 35]. The original proposal of large neighborhood search by Shaw [118] actually considered such an exact exploration of the resulting neighborhood by means of an constraint programming approach embedded within a branch-and-bound scheme. Due to the large variation in computation time that such a scheme however incurs, alternatives have been tested such as pure insertion-based reconstruction or limited enumeration schemes.

If we consider other local search-based SLS methods, the closest related one is certainly iterated local search [103], especially when iterated greedy algorithms exploit additional (perturbative) local search methods to improve candidate solutions, as outlined in Fig. 3. In that case, the destruction–construction cycle corresponds to what in ILS terms would be a solution perturbation. In general, it seems to be commendable in ILS to apply problem-specific perturbations whenever possible, and the destruction–construction cycle in iterated greedy introduces such problem-specific information through the use of heuristic information. Basic variable neighborhood search is an ILS-type algorithm that systematically varies the strength of the perturbation, and thus the link to iterated greedy is also immediate.

Besides the fact that complete solutions may be improved by an additional local search phase in iterated greedy algorithms, it could be worthwhile to also consider the local re-optimization of the partial solutions that are obtained during the destruction and reconstruction process. It is noteworthy that such occasional local re-optimization of partial candidate solutions has shown to be useful in a number of other contexts such as vehicle routing [21].

Tree Search Algorithms

Constructive mechanisms can be extended to an exhaustive search method by adding a simple backtracking mechanism; adding further bounding schemes, one quickly comes to methods such as branch-and-bound or, more in general, tree search techniques [60]. Hence, it is clear that iterated greedy algorithms also share some relationships to such methods.

Some links have already been mentioned in the previous section, when exact methods are exploited to generate the best possible completion of a partial candidate solution. Such a completion may be generated using tree search methods, and various of these ideas have been explored [118]. Even if tree search is used, the search need not be necessarily complete. For example, Shaw [118] has considered the usage of limited discrepancy search [58], which consists in examining a limited

number of alternative choices in the decision points during the tree generation. Any other variants such as depth-bounded discrepancy search [131] could also be interesting. Another alternative that does not seem to have been applied so far would be to apply beam search [92].

Yet another connection to tree search techniques could rely on the exploitation of lower-bound information to generate heuristic information or to prune choices that are guaranteed not to lead to improved solutions. So far, we are not aware of an exploitation of such ideas inside iterated greedy algorithms, although in other constructive SLS algorithms, such uses have been explored [14, 75].

Applications

In this section, we give a short overview of few applications of iterated greedy algorithms. Some applications have already been mentioned in the section "IG Applications: Historical Development" when discussing other methods that use the same principle as iterated greedy. Here, we focus mainly on applications that identified their algorithm as an iterated greedy algorithm. In fact, depending on the class of problems for which the respective methods have been proposed, the usage of names to refer to iterated greedy-type methods differs. For example, in the scheduling area, the excellent results of the iterated greedy algorithms for the permutation flow shop scheduling problem have spawned a lot of follow-up work on similar problems, while the name large neighborhood search is frequently found in application to vehicle routing problems, given the prominent role these algorithms have played in that domain.

Iterated Greedy for Scheduling Problems

As mentioned, iterated greedy, as defined in this chapter, was initially applied to the permutation flow shop scheduling problem by [114], and so many applications to other scheduling problems were published after that (Various applications of iterative flattening to scheduling problems have been referenced in the section "IG Applications: Historical Development."). Ruiz and Stützle [115] extended their iterated greedy algorithm to tackle the permutation flow shop scheduling problem when considering additional sequence-dependent setup times and other objectives than makespan, namely, the total tardiness. Other variants of flow shop problems have been studied for total tardiness minimization [43] and the flowtime minimization [79], blocking [106, 124], no-wait [29, 88, 95, 133], and for no-idle [105, 116, 123], and mixed no-idle [94] problems. Non-permutation flow shops were approached by [12, 17, 136]. Distributed flow shop scheduling problems have been solved with iterated greedy algorithms in [8, 40, 55, 56, 69, 74, 113]. Iterated greedy has also proven to be valuable in other optimization criteria apart from makespan, and multi-objective extensions of iterated greedy have proven to be worthwhile [23, 81, 119]. Dubois et al. [32] have embedded an iterated greedy algorithm into

the two-phase local search framework to tackle various bi-objective flow shop problems. Parallel machine problems were successfully tackled with iterated greedy algorithms [7, 36, 78, 109]. Iterated greedy algorithms are effective for various single-machine scheduling problems as shown in [28, 138]. Some other more complex problems have been studied, including job-shop scheduling with blocking constraints [100], job-shop scheduling with sequence-dependent setup times and job families [67], the optimization of manufacturing problems [137], hybrid flow shops [73, 84, 135], and real-life problems [27, 128–130].

Iterated Greedy for Routing Problems

As mentioned above, in the context of vehicle routing problems, several algorithms that follow the main structure of an iterated greedy algorithm have been applied but usually using branding under the name large neighborhood search. The article making these approaches popular has already been mentioned [118]. A major impact in that line of applications had the adaptive large neighborhood search approaches [97, 110], which led to a large number of follow-up work. Some overview is given in [98]. In fact, the usage of such iterated greedy-type methods as local searches inside SLS algorithms for vehicle routing problems is increasingly widespread and can by now be considered a standard in this area. Apart from vehicle routing, also iterated greedy approaches have been proposed to few other routing-type problems such as scheduling and routing problems of freight trains [139], in a study on a food ordering and delivery system [132], and the routing of hydrographic surveys [25]. Some few other works are in the context of TSP variants [6, 66] (Interestingly, in [6] they call their algorithm an iterated local search, but instead they do something that would be rather called an iterated greedy approach.).

Iterated Greedy for Other Problems

There have been a number of other applications where explicitly iterated greedy algorithms have been devised as the main solution techniques. Lozano et al. [70] presented an iterated greedy approach to the maximum diversity problem, where from a set of elements, a subset with maximum diversity has to be chosen. After proper tuning, the algorithm was shown to perform better than various competing algorithms and was established as a new state-of-the-art algorithm. Casado et al. [20] set up an iterated greedy to solve the minimum dominating set as obtain in graphs and derive an iterated greedy method with excellent performance within short computational times. García-Martínez et al. [46] have developed an iterated greedy algorithm enhanced by a short tabu list in the destructive phase for the quadratic multiple knapsack problem. Lozano et al. [71] have developed also another iterated greedy algorithm for the quadratic minimum spanning tree problem

obtaining excellent results on large instances. They embed the algorithm into a strategic oscillation approach by essentially extending it with tabu criteria, which led to further improvements on some problem instance classes. Early implementations of similar ideas for binary quadratic programming have been presented before [52], and Toyama et al. [125] apply iterated greedy to the same problem tackling also very large-scale instances successfully. Kang et al. [65] study the problem of allocating parallel tasks to processors in computing systems that are distributed and heterogeneous. Iterated greedy algorithms and population-based iterated greedy algorithms that exploit exact solutions to large neighborhood searches have been proposed for the maximal covering location problem [108], the goal of which is to cover clients such that the largest amount of demand possible is satisfied. Similar approaches based on population-based iterated greedy methods have been proposed by Bouamama et al [16] to maximize the sensor lifetime in a network and Lozano and Rodriguez-Tello [72] for an algorithm for the minimum S-labeling problem of a graph. A problem in market segmentation, where a company asks to partition a set of customers subject to some specific requirements related to homogeneity of customers and compactness of the areas is tackled by Huerta-Muñoz et al. [61]. The obnoxious p-median problem, where the objective is to find places to facilities that are out of some reason undesirable so that the sum of minimum distances between non-facility and the closest facility is maximized, has been tackled by two iterated greedy methods [53, 86]. Both at the time published the state-of-the-art algorithms; the later one is a variant with variable reconstruction size, which is a major advantage over the previous iterated greedy. A population-based iterated greedy algorithm has also been applied for delimiting and zoning rural settlements [99] and to the minimum weight vertex cover problem [15]. First applications of iterated greedy algorithms for machine learning tasks, in particular the generation of classification rules, have been explored [96].

Conclusions

The main principle of iterated greedy is to build a sequence of solutions by iterating over constructive algorithms through a loop of solution destructions and (re-)constructions. Deconstruction removes solution components resulting in partial solutions from which again full solutions are reconstructed. This loop may be extended by an additional local search phase, where the generated complete candidate solutions are further improved, and by many other techniques from other heuristic and exact search techniques, making iterated greedy a very flexible and malleable method.

We prefer to call this principle iterated greedy because (i) this name directly refers to what the principle implies, namely, making iterative use of construction methods, (ii) it does not obfuscate the name with natural or unnatural analogies, (iii) it is a short and punchy name describing the essence of the method, and (iv) it has

by now been used in a large number of publications. A bit unfortunate is that in the literature there have been proposed several methods under different names that make use of the same (or a very similar) principle including large neighborhood search [98, 118], simulated annealing [62], evolutionary heuristic [77], ruin-and-recreate [117], iterative construction search [107], or iterative flattening [22]. The multitude of different names for the same kind of approach can probably be explained in two ways. First, different researchers have a different perspective on the same method, and, thus, the iterated greedy principle can be viewed and proposed, for example, from the perspective of a (perturbative) neighborhood search leading to the heuristic or exact exploration of large neighborhoods or from the perspective of a (constructive) algorithm background, where the method is simply iterating through applications of constructive algorithms. Second, the method has been proposed in somewhat different communities such as ruin-and-recreate in a physics journal [117], large neighborhood search at a constraint programming conference [118], and iterative flattening at an artificial intelligence conference [22], and publications using other names have appeared in operations research journals [62, 107, 114]. It apparently has taken a significant amount of time that these ideas transpired from one community to another.

Even if this leads to some confusion and we maybe contribute to this confusion, we think that what is really important is (i) the principle underlying these methods, (ii) the fact that the iterated greedy principle can lead to very powerful algorithms, and (iii) the fact that iterated greedy is a very flexible method that can easily be combined with other techniques. By making the relationship among the different proposals clear, we hope to contribute also to a transfer of experience between these different algorithms. In any case, we hope that this review chapter will be useful for other researchers in stochastic local search methods by clearly identifying the potential of iterated greedy and in this way also contribute to its further development.

Abstract

Iterated local search is a metaheuristic that embeds an improvement heuristic within an iterative process generating a chain of solutions. Often, the improvement method is some kind of local search algorithm and, hence, the name of the metaheuristic. The iterative process in iterated local search consists of a perturbation of the current solution, leading to some intermediate solution that is used as a new starting solution for the improvement method. An additional acceptance criterion decides which of the solutions to keep for continuing this process. This simple idea has led to some very powerful algorithms that have been successfully used to tackle hard combinatorial optimization problems. In this chapter, we review the main ideas of iterated local search, exemplify its application to combinatorial problems, discuss historical aspects of the development of the method, and give an overview of some successful applications.

Keywords

Stochastic local search · Metaheuristics · Iterated local search · Local search · Perturbation · Acceptance criterion

Introduction

One important rationale of a large number of metaheuristics is to overcome the limitations of local optimality incurred by iterative improvement methods [47]. Several concepts for this task have been considered in the prolific literature on metaheuristics that include the occasional acceptance of worsening moves within a local search process, an idea underlying methods such as simulated annealing [24, 71] or tabu search [47], the usage of populations as a simple means for increasing the exploration of the search space as in evolutionary algorithms [8] or ant colony optimization [34], or the introduction of penalties in the search process as in dynamic local search methods [60].

Certainly, one of the simplest ideas is to call iterative improvement methods several times with new starting solutions to sample possibly new and better local optima. Doing so by generating new starting solutions uniformly at random from the search space is known to be an ineffective approach, especially when instance size increases [114]. Iterated local search (ILS) instead exploits the idea of generating a chain of solutions by creating new starting solutions from a perturbation of some of the previously found solutions; in this way, it creates a biased sampling of starting solutions [81]. An acceptance criterion determines whether the new locally optimal solution is taken as the new incumbent or whether the previous solution is maintained. This basic idea underlying ILS has been implemented in a number of early papers on the method [11, 12, 67, 86, 87]. The method has been extended in several directions in follow-up research, and a number of new variants

and generalizations have been considered. In fact, a first generalization is that the underlying improvement heuristic need not be necessarily an iterative improvement algorithm but can be any method that takes some solution as input and returns a possibly improved solution. Other variants concern the introduction of rather elaborate perturbation mechanisms or the consideration of different acceptance criteria. Nevertheless, what characterizes an ILS algorithm is that a chain of solutions is built through a process that involves as main sub-procedures some form of solution perturbation, an improvement method of whatever type, and an acceptance criterion.

In this chapter, we review the main ideas underlying ILS and illustrate its main principles using some example applications to well-known combinatorial optimization problems in section "Some Examples of Iterated Local Search Algorithms." We then shortly highlight, in section "Historical Development of Iterated Local Search," the main developments on the method from a historical perspective, which also shows that ILS is among the oldest metaheuristic techniques. We discuss the most relevant links ILS has to other metaheuristics in section "Relationship of ILS to ...." We end with an overview of various noteworthy applications of ILS, which complements some earlier reviews on ILS [81,82], and some concluding remarks in section "Conclusions."

Iterated Local Search

Here, we first introduce basic notions of local search and then elaborate on the main mechanisms ILS uses to steer the search process.

Local Search Heuristics

Many heuristics for tackling hard optimization problems rely on (perturbative) local search [1,60]. The idea underlying local search is to replace the current candidate solution s within a search space S of complete candidate solutions by some neighboring candidate solution. The neighborhood $N(s)$ of a candidate solution $s \in S$ is defined by all candidate solutions that can be obtained by applying specific modifications or "movements" to s.

Neighborhoods are problem specific, but for many problems, standard neighborhood concepts can be applied. One of these standard neighborhood concepts is the so-called k-exchange neighborhoods, where two candidate solutions are neighbored if they differ in at most k solution components. For implementing such neighborhoods, one needs to identify, for a given problem, appropriate solution components. Intuitively, a solution component corresponds to an atomic relationship, assignment, or selection that characterizes a candidate solution. For example, in the well-known traveling salesman problem (TSP), solution components refer to the fact that a node j is visited directly after a node i in a tour, that is, to an edge (i, j); in the quadratic assignment problem (QAP), a solution component would correspond to

the assignment of a facility to a specific location, that is, an individual assignment. In a k-exchange move for the TSP, one would change a set of k edges by a different set of k edges, and for the QAP, one would change at most k individual assignments of facilities to locations.

Of critical importance is the size of neighborhoods: Large neighborhoods have the advantage that better-quality candidate solutions may be reached in one step of the algorithm, which comes, however, with the disadvantage of increasing the time it takes to actually search for such candidate solutions in large neighborhoods. To balance these two aspects, over the years a large set of techniques have been proposed that try to either define special-purpose neighborhood structures that allow to design algorithms for searching them efficiently or to heuristically explore very large neighborhoods trying to identify good candidate solutions there but without guarantee of finding the best one. For an overview of very large neighborhood search methods, we refer to Ahuja et al. [3].

The widest spread perturbative local search method is probably iterative improvement (also called iterated descent, hill climbing, etc., in the literature). It replaces a current candidate solution by an improving neighboring one and repeats these steps until a locally optimal candidate solution has been found, that is, a candidate solution without any improving neighbor. In the following, we will indicate by $s^* \in S^*$ a locally optimal candidate solution from the set of locally optimal candidate solutions S^*; more in general, we will refer to the set S^* as the possible output set of search methods that are not necessarily iterative improvement methods. Various variants of this basic algorithm exist differing in the order in which the neighborhood of a candidate solution is searched, which neighboring candidate solution replaces the current one, and so on. The most common mechanisms for these rules are the so-called best- and first-improvement rules, which, respectively, replace the current candidate solution by a most-improving candidate solution in $N(s)$ or by the first one encountered when scanning the neighborhood. The specific choice for these pivoting rules can have a significant impact on the quality of the local optima generated and the computational effort it takes to reach local optima. Similarly, for local search algorithms, speed-up techniques such as incremental move evaluations are of crucial importance for their efficiency [1, 60].

Local optima have an ambivalent importance in optimization. When compared to the candidate solutions in the full search space S, locally optimal solutions are of, on average, much better quality, and there are much less candidate solutions in S^* than in S. Hence, identifying local optima by an iterative improvement algorithm may seem a priori a good idea. However, iterative improvement algorithms are stuck in local optima, and even when several candidate solutions in S^* are sampled independently, the so sampled local optima may still be of rather poor quality [114]. Thus, other mechanisms than independent sampling in S^* are required to allow a highly performant search process. The search for such mechanisms led to a large number of proposals and studies of general mechanisms to pursue the local search beyond the traps of local optimality [47] or on the development and study of rather different search mechanisms, such as populations, which try to focus on a more global search behavior. These mechanisms are commonly referred to as

metaheuristics [45, 46] or general-purpose stochastic local search methods [60]. Within the context of ILS, of particular relevance are trajectory-based metaheuristics that at each step modify a single solution. This includes methods such as tabu search, simulated annealing, or guided local search. Such metaheuristics can be used in a straightforward way as an improvement method in ILS algorithms.

Iterated Local Search Framework

The main principle of ILS is to generate a sequence of candidate solutions that is obtained by iterating through solution perturbations and subsequent applications of an (local) improvement method. An additional acceptance criterion decides from which candidate solution seen during the run of the algorithm this sequence is continued. Typically, the improvement method is an iterative improvement method or a trajectory-following metaheuristic such as tabu search or simulated annealing. The goal of the perturbation is to introduce a modification into the current candidate solution that is larger than the modifications that are done in the local search phase, thus effectively allowing the search to escape local optima or specific search space regions.

An algorithmic outline of ILS is given in Fig. 1. After generating an initial candidate solution and improving it by a local search, the main loop is invoked. Within the main loop, first a (typically locally optimal) candidate solution $s^* \in S^*$ is perturbed leading to a candidate solution $s' \in S$. After improving this solution and obtaining a new solution $s^{*\prime} \in S^*$, an acceptance criterion decides whether to continue the search from s^* or $s^{*\prime}$. It is also possible to consider in the perturbation and the acceptance criterion aspects of the search history, for example, to adjust the perturbation strength or the choice done in the acceptance criterion; in that case, one would extend the corresponding procedures to Perturbation(s^*, *history*) and AcceptanceCriterion(s^*, $s^{*\prime}$, *history*).

An important advantage of ILS when compared to repeatedly starting the LocalSearch method from random initial candidate solutions is that (i) intermediate candidate solutions obtained through the perturbation are often of better quality and can lead to better locally optimal solutions, and (ii) in the case of iterative improvement methods, the subsequent local search may terminate more quickly than when starting from random initial candidate solutions, leading to the exploration of a larger number of local optima within a given computation time. Hence, more local

Fig. 1 Algorithmic outline of iterated local search (ILS)

        s* = AcceptanceCriterion(s*, s*')
    until termination condition met
end
```

optima and local optima of a better average quality may be generated in an ILS algorithm, increasing the chance to find very high-quality solutions.

A further advantage of ILS is its ease of a first implementation, especially if an improvement method is already available. A first version of an ILS algorithm can be obtained by adding perturbations in some higher-order neighborhoods than the ones used in the local search and a reasonable first choice is to accept only better or equal quality solutions in the acceptance criterion. Such a version can be obtained by adding few lines of code to an existing improvement method and be the basis for an algorithm engineering effort to generate a high-performing ILS algorithm. In fact, ILS is very malleable and can range from very straightforward implementations to rather well-engineered algorithms when problem-specific details are taken into account.

Generally speaking, ILS is a modular approach, and the behavior of an ILS algorithm is determined by the four procedures GenerateInitialSolution, Perturbation, LocalSearch, and AcceptanceCriterion and their interaction. In what follows, we discuss the main issues arising for these procedures.

GenerateInitialSolution This procedure determines the starting point of the search, and it may have a significant impact during the initial search phase. Generally, candidate solutions generated by a good constructive heuristic should be preferable as often the better the quality of the initial candidate solution, the better is the quality of the local optima encountered. In addition, an iterative improvement algorithm requires usually less steps to reach a local optimum when starting from a better-quality solution. However, if the other procedures are well designed, the influence of the initial candidate solution is expected to be little especially for longer run times.

Perturbation The perturbation transforms one complete candidate solution into another complete candidate solution. Its task is to modify a current candidate solution and to generate a new, promising starting solution for the next local search application. To allow an effective escape from local optima, the perturbation should be larger than or at least different in nature from the modifications that are applied in the local search algorithm.

An important factor is the size of the perturbation, which can be measured by the number of solution components that are changed. If the perturbation is too small, it may quickly be undone by the next local search. If the perturbation is too strong, that is, too many solution components are modified, then much of the quality and the structure of the current candidate solution may be lost; in that case, the algorithm can become akin to a random restart algorithm, which is known to be usually of poor performance. Unfortunately, it depends typically on the problem and often on the specific problem instances how strong perturbations should be [81]. One possibility to adapt the perturbation strength may be either to do a proper parameter tuning, an adaptive scheme following ideas of reactive search [10], or to adapt the perturbation strength using simple schemes such as those of basic variable neighborhood search [52].

The simplest way of perturbing a candidate solution is by applying random perturbation moves. A disadvantage of choosing the perturbing moves uniformly at random is that one may lose significantly in solution quality. An alternative is to use biased perturbations and to introduce problem knowledge in this way. Biased perturbations may make use of heuristic information on the solution components that are changed. This can be done in various forms, for example, by removing preferentially solution components that have a high contribution to the cost of a candidate solution, or by introducing new solution components that have a low cost contribution. Closely related to ILS is the iterated greedy method that relies on a destruction and reconstruction cycle that is managed through constructive heuristics [110]; in fact, this cycle may be seen as a perturbation in the ILS sense. A different possibility is to introduce more complex perturbations by re-optimizing parts of a candidate solution [80] or applying data perturbations [25].

LocalSearch The local search procedure is of crucial importance for the performance of an ILS algorithm, which will benefit strongly from good choices and implementations for this procedure. A first crucial issue is the quality of the solutions that the local search algorithm produces. A priori, one may expect that the better the quality of the solutions that are generated by the local search, the better the results of the ILS algorithm. However, this reasoning would not take into account the execution time of the local search. In fact, a crucial aspect for the appropriate choice of a local search method is the trade-off between the quality of the solutions it generates and the computation time it takes to find these solutions. Given a fixed computation time, a fast local search may be applied more often and, thus, generate a larger number of candidate solutions that may be of less average quality than candidate solutions obtained by a more time-consuming local search procedure. Which choice is best depends on the particular problem or type of problem instances and has to be determined on an experimental basis.

Another important aspect is whether the local search is used as a black box or whether it is open and can be integrated in possibly more profitable ways into an ILS algorithm. One example is the exploitation of the don't look bit technique [15, 68]; we refer to section "TSP Example" for more details on this technique and how to integrate it with the perturbation. Another example requiring access to the local search is the adoption of techniques of tabu search by declaring solution components changed by the perturbation as tabu for a number of local search steps; this may help to avoid immediately undoing the perturbation.

The local search in an ILS algorithm is not limited to an improvement method, but any (even nonlocal search) method that takes as input a complete candidate solution and returns a potentially improved candidate solution upon completion could be used. Common examples include the usage of tabu search, simulated annealing, or dynamic local search algorithms as the local search. One can even think of using an ILS algorithm as the local search leading to a hierarchy of ILS algorithms [62, 81]. However, to allow a sufficient number of iterations of the ILS

algorithm, one needs to define a stopping criterion for the local search method, for example, by limiting the number of local search steps that are applied or the number of steps without improvement.

Finally, an advantage of a strong local search is that the sensitivity of the algorithm to the settings of numerical parameters is often reduced, making in this way the algorithm itself more robust. In this sense, ILS also benefits from the further development of local search techniques and the increased availability of powerful implementations based on very large neighborhoods [3].

AcceptanceCriterion One interpretation of the search behavior of ILS is that of a biased random walk in S^*, the space of local optima. The acceptance criterion has a crucial impact on the nature of this walk and, thus, the trade-off between exploration and exploitation. As the two extremes, one can have the acceptance criterion that only accepts improved solutions, leading to a search that can be characterized as a randomized iterative improvement algorithm in S^*. On the other extreme is the acceptance criterion that accepts any new solution independent of its quality, leading to a random walk in S^*. Clearly, there are many intermediate choices between these extremes, and various have been explored in the literature. One example is the Metropolis condition [95], which accepts a new, worse solution $s^{*\prime}$ with a probability $\exp\{f((s^*) - f(s^{*\prime}))/T\}$, where T is a parameter; a better or equal quality solution is accepted always. The parameter T may be left fixed throughout a run of ILS or be varied as done in simulated annealing.

Various other choices have been made such as combining short random walks with occasional backtracks to the best candidate solution found so far [26], resulting in a specific usage of the search history within the acceptance criterion. Another simple example for the usage of the search history in the acceptance criterion is the occasional restart of the search from a new initial candidate solution, which can lead to much improved algorithm behavior [117, 119].

If one is to reach high performance with an ILS algorithm, the interactions among the components need to be taken into account. The two main interactions are the following. First, the perturbation should complement the local search and ideally introduce moves that cannot be easily done by the local search. This results in two main advantages: (i) it is easier to avoid returning to the previous locally optimal candidate solution, and (ii) the structure of the candidate solution may be changed in a way that is not possible for the local search to do. Second, the acceptance criterion and the perturbation should be well balanced. In fact, both components can be biased toward a more explorative or more exploitative search behavior: large vs. small perturbations or non-strict (random walk) vs. strict (improvement) acceptance criteria. Finding the right balance between intensification and diversification of the search is one of the key issues in the design of any effective SLS algorithm, and one advantage of ILS is that the impact specific choices of the algorithm components have on this balance is rather easy to grasp. Thus, ILS is a method for which the SLS algorithm engineering process [122] can follow a well-guided direction.

Some Examples of Iterated Local Search Algorithms

We introduce example applications of ILS algorithms to well-known combinatorial optimization problems, the traveling salesman problem (TSP), the quadratic assignment problem (QAP), and the permutation flow-shop scheduling problem (PFSP). Example implementations for these ILS algorithms are available from http://iridia.ulb.ac.be/~stuetzle/Code.

TSP Example

Traveling salesman problem (TSP). The TSP is given as a graph $G = (N, E)$, where N is the set of $n = |N|$ nodes and E is the set of edges that fully connects the nodes. To each edge (i, j) is associated a distance d_{ij}. Here we assume that the distance matrix is symmetric, that is, we have $d_{ij} = d_{ji}$ for all $(i, j) \in E$; these types of TSP instances are called symmetric and are among the most widely studied types of TSP instances. The objective in the TSP is to determine a Hamiltonian cycle of minimal length. Such a cycle can be represented by a permutation $\pi = \langle \pi(1), \ldots, \pi(n) \rangle$, where $\pi(i)$ is the node index at position i. The objective function to be minimized is

$$\min_{\pi \in S} \; d_{\pi(n)\pi(1)} + \sum_{i=1}^{n-1} d_{\pi(i)\pi(i+1)} \tag{1}$$

where S is the search space consisting of the set of all permutations.

The TSP is one of the most famous examples of ILS applications, which is due to the important role it plays in the historical development of the method [11,12,67,86] and due to the very high performance ILS algorithms have reached for the TSP [4,5,56,57,68].

A basic ILS algorithm for the TSP could be the following. The initial candidate solution is generated by a constructive heuristic such as the nearest-neighbor heuristic or the greedy heuristic. For the local search, a first-improvement method in a k-edge-exchange neighborhood (typically, k equal two or three) is used. The perturbation is implemented by the so-called double-bridge move, which is illustrated in Fig. 2; the double-bridge move removes four edges and replaces them with four other edges so that in the schematic view of the move, the characteristic double bridge is formed. The acceptance criterion forces the cost to decrease, that is, only better-quality candidate solutions are accepted.

Such a basic ILS algorithm for the TSP reaches high-quality tours, but its performance can be improved by alternative choices for the components. ILS algorithms for the TSP usually benefit from a local search with better performance. For example, by replacing the local search algorithm in the two- or three-edge-exchange neighborhood with the Lin-Kernighan heuristic [77], better performance is usually achieved. It is interesting to note that the double-bridge move was considered within the Lin-Kernighan heuristic, but many implementations of it did not implement it. It is a type of move that cannot be easily achieved by a concatenation of moves in smaller neighborhoods or by the way complex moves in

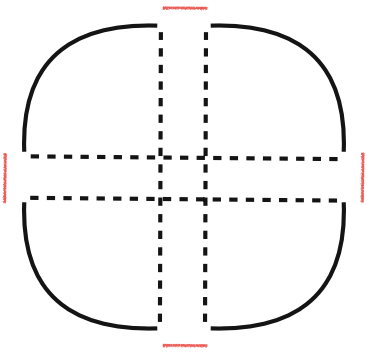

Fig. 2 Schematic view of the double-bridge move. Four edges (continuous, *red lines*) are removed from the current tour, and the four remaining tour segments are reconnected as shown by the *dashed line* in the schematic view of the move

the Lin-Kernighan heuristic are generated, and, thus, it is complementary to standard local search implementations. A main advantage of the double-bridge move is that it only leads to a small increase of the tour length as only four edges are replaced and the subsequent local search typically needs only few improvement steps to reach a new local optimum. In practice, the double-bridge move has found to be rather effective even for very large-sized TSP instances with many thousands or millions of nodes [5, 68].

For speeding up the search, direct access to the local search through the usage of the well-known don't look bit technique [15] was found to be useful. The don't look bit technique associates one such bit to each node in a TSP instance and starts a local search centered around a node for an improving move only if the don't look bit is set to one (turned on). If this local search is not successful, the don't look bit is turned off by setting it to zero. If a move improves a candidate solution, all end points of the edges involved will have set their don't look bit to one again. This technique leads to a particularly significant speed-up, when integrated with the perturbation by resetting only don't look bits to one for nodes that are directly affected by the perturbation [68] or additionally to some close-by ones [117].

An acceptance criterion that allows only moves to better or equal length tours leads to a strong intensification behavior of the search. While this results in very good performance for short and medium run times, for longer ILS runs, a stronger diversification through, say, additional restarts improves algorithm performance [117, 119].

QAP Example

Quadratic assignment problem (QAP). In the QAP we are given two matrices F and D corresponding to some kind of flow exchanged between items and a distance matrix between possible locations of the items, respectively. Let f_{ij} be the flow exchanged between items i and j and d_{kl} be the distance between locations k and l. The task in the QAP is to assign items to locations so that the cost given by the sum of flows times the associated distances is minimized. Assuming the number of items is equal to the number of locations, a candidate solution to the QAP can be represented by a permutation π, where $\pi(i)$ gives the location to which item i is assigned. The objective function to be minimized for the QAP can then be written as

$$f(\pi) = \sum_{i=1}^{n} \sum_{j=1}^{m} f_{ij} \cdot d_{\pi(i)\pi(j)} \tag{2}$$

Similar to the TSP, the QAP has played a central role in combinatorial optimization. Differently from the TSP, for which optimal solutions can be found for very large instances (the largest being solved optimally having 85,900 nodes [6]), QAP instances can only be solved optimally for relatively small instance sizes of around 30; there are only few exceptions for very particularly structured instances for which an instance of size 128 could be solved [41].

A basic ILS algorithm for the QAP can be implemented as follows. An initial candidate solution for the QAP can be generated uniformly at random, as no constructive algorithms generate generally very high-quality candidate solutions. As local search algorithm, an iterative improvement algorithm in the two-exchange neighborhood, where at each step the locations of two items are exchanged, is used. More formally, two candidate solutions π and π' are neighbored if for exactly one index pair (i, j) we have $\pi'(i) = \pi(j)$ and $\pi'(j) = \pi(i)$ and for all other indices $l \neq i, j$ we have $\pi'(l) = \pi(l)$. As a perturbation, a random move in a k-exchange neighborhood, $k > 2$, can be chosen and, as acceptance criterion, one accepts only better-quality candidate solutions.

Such a straightforward ILS version was tested by Stützle [117] and Lourenço et al. [81], and it was shown that its relative performance with respect to other choices of the main ILS components depended on the specific type of QAP instances. In fact, the specific structure of QAP instances as identified by different distributions of the entries of the flow or the distance matrices can induce widely different behavior [125]. For example, the benchmark instances that have been generated randomly assuming uniform distributions of the matrix entries result in landscapes with many local optima that are spread across the whole search space. Such a landscape requires strong search diversification, which can be achieved in ILS by using an acceptance criterion that accepts every new local optimum independently of its quality and helps to improve the performance on such instances even when using only very small perturbations [81, 118]. Differently, for randomly generated instances that resemble real-life instances, which exchange most flow among relatively few items, accepting only better-quality candidate solutions combined with some occasional restarts was found to result in high performance [81, 118]. Further studies on the QAP have shown that plain ILS algorithms reach very high performance for a variety of QAP instances and that population-based extensions of ILS algorithms are state of the art for tackling various classes of QAP instances [118].

Permutation Flow-Shop Scheduling Example

Permutation flow-shop scheduling problem (PFSP). The PFSP arises in many practical situations as it is common to have production lines where machines are disposed in series. In the PFSP are given n jobs $J_1, J_2, \ldots J_n$, each consisting of m operations that are to be executed on m distinct machines $M_1, M_2, \ldots, M_m$. Each job needs to be processed on

every machine, and all jobs pass through the machines in the same machine order, that is, first on machine M_1, next on machine M_2, and so on until machine M_m. The nonnegative, known, and deterministic processing time of job J_i on machine M_j is denoted by p_{ij}. The PFSP enforces that all jobs are processed on every machine in the same order; therefore, a permutation of the job indices is enough to define the processing sequence. In the basic PFSP, one assumes that jobs are available for processing at time zero, pre-emption is not allowed, each machine can process only one job at a time, and each job can be processed by at most one machine at a time, and that the capacity of buffers between machines is unlimited. A common objective is to minimize the completion time of the last job in the permutation, also known as makespan ($C_{\max}$).

The PFSP with the makespan objective is one of the most widely studied scheduling problems with hundreds of papers published; for reviews on it, see [40, 42, 55, 110]. Furthermore, it is the basis of many other variants and extensions.

A first ILS algorithm for this problem has been proposed by Stützle [116]. It used the NEH heuristic [102] to generate an initial candidate solution. The NEH heuristic is a state-of-the-art constructive method for the PFSP with some recent variants being proposed only in 2014 [38]. It is a heuristic that builds a schedule by inserting at each step a next job in a position of the partial schedule where it least increases the objective function value. Using the speed-up techniques proposed by Taillard [124], the NEH heuristic has a computational complexity of $O(n^2m)$. As an iterative improvement method in the ILS algorithm, the insert neighborhood was used, which exploits the same speed-ups as implemented for NEH. The insert neighborhood consists of all sequences that can be obtained by removing a job at position i and inserting it in all other possible positions; this results in a neighborhood of size $n \cdot (n-1)$. If one removes the job with index $\pi(i)$ from position i and inserts it at a position j, for $i < j$, one obtains $\pi' = (\pi(1), \ldots \pi(i-1), \pi(i+1), \ldots \pi(j), \pi(i), \pi(j+1), \ldots, \pi(n))$ and for $i > j$ one obtains $\pi' = (\pi(1), \ldots \pi(j-1), \pi(i), \pi(j), \ldots \pi(i-1), \pi(i+1), \ldots, \pi(n))$. The local search implemented in Stützle [116] used a kind of first-improvement neighborhood scan. It removes a job J_i from the sequence and checks all $n-1$ possible insertion positions; if several result in improvements, the position is taken that leads to the largest reduction in the makespan. One scan of the neighborhood consists of repetitions of this process for all possible positions i. The neighborhood scans are then repeated until a local optimum with respect to the insert neighborhood is found. As the perturbation, a mix of two contiguous swap moves, and one interchange move was proposed. In a contiguous swap move, a permutation $\pi = (\pi(1), \ldots, \pi(i), \pi(i+1), \ldots, \pi(n))$ is modified to $\pi' = (\pi(1), \ldots, \pi(i+1), \pi(i), \ldots, \pi(n))$; in an interchange move $\pi = (\pi(1), \ldots, \pi(i), \ldots, \pi(j), \ldots, \pi(n))$ is modified to $\pi' = (\pi(1), \ldots, \pi(j), \ldots, \pi(i), \ldots, \pi(n))$. A further restriction was imposed on the positions involved in the interchange move by enforcing $|i-j| \leq \max\{n/5, 30\}$ to avoid too strong disruptions. Finally, as the acceptance criterion, the Metropolis condition with a fixed temperature was suggested.

The performance of this ILS algorithm was found to be superior to the best methods for the PFSP published until then. The excellent performance was confirmed in the extensive study of heuristics for the PFSP under makespan minimization by Ruiz

and Maroto [110], where it was found to be the top-performing heuristic. However, the ILS is outperformed by the closely related iterated greedy method [111].

Historical Development of Iterated Local Search

ILS has a long history, and the ideas underlying the method can be traced back to several approaches. The most influential have been the early developments for tackling the TSP. Baum [11, 12] has proposed an algorithm he called *iterated descent*, which used an iterative improvement method based on two exchanges as the local search and random three exchanges as the perturbation and forced the tour length to decrease. His results were not very impressive, but inspired Martin et al. [86] to propose their *large-stop Markov chains* (LSMC) algorithm. The name of this algorithm stems from the acceptance criterion, which corresponds to the Metropolis condition. In first instantiations, LSMC used a three-exchange neighborhood in the local search but was later extended to use the Lin-Kernighan heuristic. One contribution of the LSMC algorithm was the introduction of the double-bridge move as the perturbation, which is used in many other ILS algorithms for the TSP. The results with the LSMC algorithm gave a major leap in the performance of TSP heuristics. Further refinements of this approach, in particular, by Johnson [67] and Johnson and McGeoch [68] on one side and Applegate et al. [4] on the other side, have defined for a long time the state-of-the-art TSP heuristics. Differences in these implementations concern, on the high-level ILS side, mainly the choices for the acceptance criteria and different choices of the perturbation operators, but decisive are also implementation details of the local search and the data structures used for tackling large instances. Noteworthy is the experimental study by Applegate et al. [5] who performed tests on very large TSP instances with up to 25 million cities and the more recent work of Merz and Huhse [94], which is particularly well suited for very large TSP instances under severe time constraints.

In a number of papers, specific choices for ILS algorithms for the TSP have been considered and analyzed. Codenotti et al. [25] study complex perturbation schemes based on data perturbation. Hong et al. [58] examined the impact the perturbation strength has on ILS performance, indicating that for some instances perturbations larger than those introduced by the double-bridge move are beneficial; they also studied population-based extensions of ILS algorithms for the TSP. Katayama and Narihisa [70] proposed to use candidate solutions different from the incumbent one to generate directed perturbations and showed that this idea can lead to very competitive results when compared to an iterated Lin-Kernighan algorithm. Stützle [117] and Stützle and Hoos [119] have analyzed the run-time behavior of ILS algorithms for the TSP, showing that the most common implementations show stagnation behavior for long runs. As a simple remedy to this behavior, they have proposed occasional restarts of the ILS algorithms [117,119]. Finally, there are some approaches for TSP solving that in their iterated version do not follow necessarily the main ILS steps but are, say, inspired from it. The most notable example is probably Helsgaun's iterated version of his Lin-Kernighan implementation [56].

It generates new starting candidate solution through a constructive mechanism, which is strongly biased toward generating a candidate solution that is close to the incumbent candidate solution.

The ILS principle has been discovered before its first applications to the TSP. Baxter [13] proposed an algorithm for a location problem that made repeated use of a data perturbation technique to create new starting solutions for a local search algorithm. However, it appears that these initial approaches have not been the main inspiring source for other ILS approaches and that this work has been overlooked for quite some time. In fact, most early ILS adaptations to problems other than the TSP seem to have been inspired by the proposals of ILS algorithms for the TSP.

Among the first problems other than TSP tackled by ILS is graph bipartitioning. Martin and Otto [84, 85] reported for specific types of graphs better performance with their ILS algorithm than for simulated annealing heuristics. Many other early applications of ILS algorithms have been for scheduling problems. Lourenço [80] presented an innovative idea that combined ILS with exact algorithms for job-shop scheduling. In her approach, the exact algorithm is used to solve exactly subproblems on one or two machines, keeping the sequence on other machines fixed; the so modified candidate solution is then used as the perturbed one.

It is important to stress that ILS algorithms have been published and made popular under a variety of different names, ranging from problem or algorithm specific names such as iterated Lin-Kernighan [67,68] or chained Lin-Kernighan [5] to generic names such as large-step Markov chains [86], chained local optimization [85], iterated descent [11, 12], iterated hill climbing [100], or others. In the local search template proposed by Vaessens et al. [129], ILS was referred to as a multilevel point-based local search. Even today, apparent variations of the ideas underlying ILS are published under new names such as breakout local search [14], creating possibly confusion with the earlier proposed breakout method [98], which relies on a different mechanism for escaping from local optima. A review and unification of the various papers published in the literature has been proposed by Lourenço et al. [81] in their 2002 book chapter on ILS. This chapter has led to a more coherent view of the method, has discussed the main ingredients of ILS algorithms, and has shown trade-offs in the design of effective ILS algorithms.

Relationship of ILS to . . .

ILS, being a relatively old method, has a number of links to other well-known methods, which we will shortly discuss in this section. We focus our discussion on relationships to simple, hybrid, and population-based metaheuristics (or stochastic local search methods), following the classification of Hoos and Stützle [60]. Within this classification, ILS belongs to hybrid SLS methods, which can be characterized as methods that interleave search steps in different neighborhoods or that combine different types of procedures in an interleaved fashion. As such, most links of ILS are within that group.

. . . Simple SLS Methods

Simple SLS methods typically move within one type of neighborhood. They can be seen as direct extensions of perturbative local searches that avoid local optima either by occasionally accepting moves to worse candidate solutions or modifications of the evaluation function during the search. Well-known examples for the former are simulated annealing [24, 71] and tabu search [47], while a well-known example for the latter is guided local search [132].

A first relation is that any of these methods may play the local search part within an ILS algorithm, replacing simpler iterative improvement methods. While iterative improvement methods do have a natural stopping condition, namely, hitting a local optimum, for simple local search methods, in principle, arbitrary computation times can be invested. This leads to the task of balancing the intensification obtained through the simple SLS method and the diversification given through perturbation steps and the acceptance criterion. A main task therefore for the algorithm designer is to determine an appropriate computation time for the SLS method to obtain a good trade-off between the computation time and solution quality.

Another relation is the usage of diversification measures in methods such as tabu search. For example, the random shake-up ideas [45] are directly linked to perturbations in ILS. The well-known reactive tabu search algorithms invoke occasional sequences of random moves to provide a means for search diversification [9], which can directly be seen as a random perturbation whose size is adjusted in dependence of features of the search process. Several ideas from the area of tabu search and, in particular, the memory usage explored there [47] may provide a source of inspiration of how to improve ILS algorithms or to define schemes for adapting parameters at run time [10].

. . . Hybrid SLS Methods

Hybrid SLS methods combine more than one basic search strategy into an overall method. For example, ILS combines typically one search strategy in the local search with a different type of search strategy in the perturbation. From a high-level perspective, one point ILS has in common with many other hybrid SLS methods is that it combines a local optimization with search steps oriented toward diversification. These diversifying steps may be based on constructive or perturbative search steps.

Considering hybrid SLS methods that obtain diversification through constructive procedures, the closest to ILS is the iterated greedy algorithm, if the latter uses a local search phase. In iterated greedy methods, a new candidate solution is obtained by removing from a complete candidate solution $s \in S$ some solution components, obtaining a partial solution s_p, from which in turn a solution construction process is performed. While such iterated greedy algorithms may result in reasonable performance without improving the newly constructed candidate solution by a local search phase, in many cases, an additional perturbative local search improves

performance. In that latter case, the destruction-construction cycle may be seen as a (directed) perturbation in the ILS sense. Another link between the two methods is to see both as creating an iterative process that in the ILS case iterates across local search applications and in the iterated greedy case iterates across applications of constructive algorithms. A different perspective on the mechanism of iterated greedy algorithms is taken by large neighborhood search techniques [115]. They consider also the removal of solution components, but then the subsequent completion of the resulting partial solution may be done with exact techniques, originally taken from constraint programming, or also constructive-type approaches. In any case, large neighborhood search interprets the completion of a partial solution as the exploration of a large neighborhood, hence the name of the method. In a sense, the application of one iteration of LNS would correspond in ILS terms to one (complex) perturbation that moves a solution $s \in S$ (typically a local optimum) to another complete candidate solution $s' \in S$. More details on iterated greedy and further related methods such as large neighborhood search can be found in the chapter on this topic by Stützle and Ruiz in this handbook. The use of constructive mechanisms to provide search diversification also underlies greedy randomized adaptive search procedures (GRASP) [36, 108], which in their basic form create many independent starting points for a local search through randomized greedy constructive searches. GRASP is clearly distinct from the basic principle underlying ILS, as it does not create a biased walk in the space of local optima. Later extensions of GRASP add various mechanisms with the goal of making it more performing. In fact, some extensions reuse parts of candidate solutions and, hence, move GRASP more toward mechanisms that underlie ILS; see Resende and Ribeiro [108] for an overview of GRASP.

The hybrid SLS method that shares most similarities with ILS is (basic) variable neighborhood search (VNS) [52, 53, 97]. VNS is based on the principle of changing the neighborhood during the search to avoid getting trapped in local minima with respect to one specific neighborhood. While the rationale of the main search mechanism underlying VNS and ILS is rather different, many instantiations of VNS, in particular those related to basic, skewed, or general VNS, can be seen directly as specific instantiations of ILS algorithms. For example, in basic VNS, an iterative improvement process is performed in the smallest neighborhood. Larger neighborhoods are explored randomly, and this random exploration is interleaved with the iterative improvement search in the smallest neighborhood. This loop corresponds to the perturbation and local search steps in ILS algorithms, where the main specificity of VNS is to modify the strength of the perturbation following some fixed scheme in which the neighborhoods are explored: The scheme could be in an increasing or decreasing order and additionally taking into account step sizes. In early instantiations of a basic VNS, only candidate solutions that improve on the incumbent candidate solution after the local search phase are accepted, while in skewed VNS worse candidate solutions are accepted depending on how far the new candidate solution is from the incumbent one. Finally, general VNS is a variation of the basic VNS schemes, where the underlying local search can be a variable neighborhood descent algorithm.

. . . Population-Based SLS Methods

Population-based SLS methods are characterized by the use of a population of candidate solutions to drive the search. As such, they are clearly distinct from ILS, which is based on modifying a single search point. In addition, several population-based search methods such as evolutionary algorithms [8] and ant colony optimization [34] do not necessarily make use of local search algorithms. However, several links exist. In fact, many population-based algorithms can profit from the introduction of a local search phase as it was clearly shown for ant colony optimization [34], for scatter search [48], and for many evolutionary algorithms resulting in methods such as genetic (or evolutionary) local search [100, 127] or memetic algorithms [99]. ILS as well as the population-based methods can in that case be seen as sampling candidate solutions in the space of local optima.

ILS and memetic algorithms are linked by taking an extreme parameterization of the latter, in particular, using memetic algorithms with a population size of one. In that case, the mutation operator takes over the role of the perturbation and the selection scheme used for population replacement the role of the acceptance criterion. The usage of only mutation to generate candidate solutions has been called parthenogenetic algorithm [67]. In fact, even when using a population size of more than one individual and excluding recombination operations, in the context of memetic algorithms, good performance results are reported for some problems [93]; mutation-only candidate solution modifications are also often used in evolution strategies.

Considering the usage of populations as a convenient means of providing search space exploration, several authors have explored population-based variants of ILS algorithms [58, 117, 118, 126]. The approaches proposed by Hong et al. [58] and Stützle [117] maintain the usual perturbation scheme, applying perturbation at each iteration to a single candidate solution. The usage of time-varying distance bounds among the candidate solutions in the population as a specific diversity mechanism was explored by Stützle [118], resulting in high solution quality for the quadratic assignment problem. Thierens [126] uses the population to (i) perturb only solution components in which pairs of candidate solutions differ, similar to what was done in the genetic transformations proposed by Katayama and Narihisa [70], and (ii) to reduce the neighborhood size during the local search.

Applications

This section summarizes some noteworthy applications of ILS in addition to those mentioned in sections "Some Examples of Iterated Local Search Algorithms" and "Historical Development of Iterated Local Search." As the number of applications of ILS has strongly increased over the recent years, we do not give here an exhaustive list but mainly refer to recent publications for illustrating the progress of ILS. Here, we mention only papers where the authors have identified their algorithms explicitly as ILS algorithms, even though a larger number of published

algorithms would fit the framework of ILS without this being made explicit in the respective papers.

Iterated Local Search for Routing Problems

Among the first explicit ILS algorithms for vehicle routing problems (VRPs) are those proposed by Ibaraki et al. [65] and Hashimoto et al. [54]. In the first paper, the authors tackle the VRP with time windows, where a dynamic programming approach minimizes the penalties for time window violations. The ILS algorithm, which used various neighborhoods in the local search, was shown to reach high performance on instances with up to 1000 customers. Hashimoto et al. [54] tackle a VRP with time windows and time-dependent travel times and costs. They introduce various speed-ups and neighborhood restrictions and show the effectiveness of their algorithm compared to previous proposals in the literature. Vaz Penna et al. [131] consider a variant where the fleet of vehicles is heterogeneous, that is, it consists of vehicles with different characteristics such as capacities. Brandão examines two variants of an open vehicle routing problem with time windows [17] and multi-depots [18]. In the first one, he applies ILS with ejection chains and the incorporation of elite solutions. On the second one, he also uses an history-based information to decrease the chance of cycling. He shows that he obtains good results on the two problems. Melo Silva et al. [92] consider a VRP where split deliveries are allowed, that is, a customer's demand may be satisfied by splitting deliveries across various vehicles or tours; they report very high performance for their algorithm improving a large number of benchmark instances. Palhazi Cuervo et al. [105] tackle the vehicle routing problems with backhauls, where in addition to the consumers who get delivered from the depot, there are also suppliers that send goods to the depot. The authors propose a structurally simple ILS algorithm, where the main ingredient is a local search algorithm that uses multiple neighborhoods and allows oscillations between feasible and infeasible candidate solutions. The problem of the paper Osorio-Mora et al. [104] is the multiple depot cumulative capacitated vehicle routing problem. The authors propose an ILS and show in an experimental analysis that it obtains state-of-the -art results. Michallet et al. [96] consider a periodic VRP with time windows under the consideration of malevolence acts, and the goal becomes spreading the repeated visits to customers across their time windows. A VRP with multiple, incompatible commodities and multiple trips per work day is considered by Cattaruzza et al. [23]. They propose an effective ILS algorithm for this problems, which is shown to perform better than previous approaches. Máximo and Nascimento [90] propose an adaptive ILS with a certain diversification control. They demonstrate that they perform better than current state-of-the-art techniques on large capacitated vehicle routing problems. In Máximo et al. [91], they further develop the adaptive ILS to surpass other algorithms for heterogeneous fleet vehicle routing problem. Nguyen et al. [103] consider a two-echelon location routing problem, where two types of trips arise. One type of trips serves from a main depot a number of subordinate depots, which have to be located appropriately, and a second type of

trips delivers goods to customers from the subordinate depots. Vansteenwegen and Mateo [130] solve a cyclic inventory routing problem for a single vehicle. The goal is to minimize the costs of the distribution and the inventory costs at the customers. An efficient ILS algorithm for this problem was shown to outperform previous approaches for this problem. Laurent and Hao [75] considered a multiple depot vehicle scheduling problem, which arises in public transport. Related to routing problems is the team orienteering problem, which arises commonly as a problem faced by tourists when planning their trips. In the paper of Fernandes Muritiba et al. [37], they tackle a generalization of the traveling repairman problem. The problem arises when maintenance is necessary when considering the travel times between cameras and the traffic flow; the objective is the minimization of the total weighted latency. They propose an ILS and a branch and cut algorithm and show in the experimental results that the heuristic algorithm reaches very good results in particular for large instances.

Iterated Local Search for Scheduling Problems

Scheduling problems have been among the first problems tackled by ILS algorithms, and by now a large number of high-performing ILS algorithms have been proposed for many variants of scheduling problems including single- and parallel-machine scheduling problems as well as scheduling problems of flow- and job-shop type.

The first applications of ILS to single- and parallel-machine scheduling problems are due to Brucker et al. [19, 20]; they have used two neighborhood structures that are nested, where the outer neighborhood essentially is used for perturbation. ILS algorithms have reached particularly excellent results for the well-known single-machine total weighted tardiness problem (SMTWTP), for which the iterated dynasearch algorithms by Congram et al. [26] and the extension thereof by Grosso et al. [50] are state-of-the-art algorithms. den Besten et al. [31] have applied an ILS with a variable neighborhood descent local search also to the SMTWTP. Later ILS algorithms have been applied to the SMTWTP with additional sequence-dependent setup times in two independent works, reaching high performance when compared to other heuristics [123, 134]. An application of ILS to the parallel-machine total weighted tardiness problem has been presented by Della Croce et al. [30]. They use generalized interchange moves, ideas from dynasearch, and new large-scale machine-based neighborhoods for the local search to improve over the current state of the art. In the paper of Queiroga et al. [107], they introduced an ILS for the batch scheduling on a single machine. A comparison of their algorithm shows that it is competitive to other algorithms for this problem.

ILS algorithms have been proposed to tackle a variety of flow-shop scheduling problems, starting with the best-known variant that considers the minimization of the makespan. The first ILS algorithm for this problem [116] has already been described in section "Permutation Flow-Shop Scheduling Example." Some issues in the design of ILS algorithms for the permutation flow-shop problem have been considered by Juan et al. [69]. ILS algorithms have been adapted by

other researchers to variants of the flow-shop scheduling problem and shown high performance for the flow-shop problem with flowtime objective [32]. Later, the authors of [32] further improve their ILS algorithm by including a multi-restart perturbation strategy, where the ILS is continued from the best of a set of perturbations obtained from a local optimum [33]. State-of-the-art results for the same flowtime objective are obtained by [106] with ILS variants, including versions that entail populations. ILS has been used to solve more complex variants of the flow-shop problem. Yang et al. [135] presented an ILS algorithm for a flow-shop variant with several stages in series, where at each stage a number of machines is available for processing the jobs. Ribas et al. [109] deal with the blocking flow-shop problem and propose an ILS procedure where the local search combines moves in different neighborhoods as does the perturbation step. M'Hallah [101] tackles the flow-shop scheduling problem with the objective of minimizing the earliness and tardiness, where due dates are distinct. An ILS algorithm is presented, which uses a variable neighborhood descent in the local search phase. Differently, the author of Ferone et al. [39] applies an ILS to a distributed assembly permutation flow-shop problem. Here, multiple production factories are concerned in the first stage, and in a subsequent second stage, they produce a final product. They consider the objective of the minimization of the makespan and propose an algorithm with a biased-randomization technique. Geiger [43] proposes the usage of an ILS algorithm for tackling the multi-objective flow-shop scheduling problem, obtaining promising solution quality despite the simplicity of the proposed approach. Finally, complex hybrid flexible flowline problems are studied by [128], where ILS approaches are intermingled with other schemes to obtain high-quality candidate solutions for scheduling problems that are very close to real settings found at production floors.

As mentioned before, the first scheduling problem tackled by ILS was the well-known job-shop scheduling problem [80]. The ILS algorithm by Kreipl [73] for the total weighted tardiness job-shop scheduling problem reached high performance, being surpassed only quite some time later by an evolutionary algorithm that integrated an ILS algorithm as the local search operator [35]. An ILS algorithm is underlying the generic approach proposed by Mati et al. [88], which tackles job-shop problems with regular objectives, that is, objectives whose values increase along with an increase of the completion times of the jobs. The proposed ILS algorithm, which uses a perturbation with a size chosen uniformly at random and an acceptance criterion that accepts every new candidate solution, was shown to reach very high performance for a number of criteria, including weighted tardiness and weighted completion time. Calmels [22] proposes an ILS for a complex scheduling problem that involves nonidentical parallel machines and tool switching. The approach uses a mixed-integer programming approach, construction heuristics, and iterated local searches, and in the experimental section he shows that the ILS is the best for large instances. The paper of Aguiar Santos et al. [2] shows an ILS search for tackling the minimization of the maximum completion time of jobs and the total delay time of the jobs in an unrelated parallel-machine scheduling problem with job deterioration. They compared their problem to two evolutionary algorithms, and they get a significantly improved performance with the multi-objective version of iterated local search.

Iterated Local Search for Other Problems

ILS algorithms have been applied to tackle many other problems, illustrating the wide range of possible applications of the ILS principle. Corte and Sörensen [29] use an ILS algorithm for designing a water distribution network, obtaining excellent computational results despite the fact that the proposed algorithm has a much simpler structure than many of the other proposed methods for the same task. Results with an ILS method for gravity-fed water distribution network design are also reported by Martinho et al. [89]. Their algorithm is shown to ameliorate on many state-of-the-art algorithms in shorter times. Grosso et al. [51] propose an ILS algorithm for the maximin Latin hypercube design problem, which consists in assigning positions to n points in a k-dimensional grid such that no two points have a same coordinate and the distance between the closest pair of points is maximized. A possibility to improve the state estimation for the monitoring of power systems is to insert power measure units into the network at appropriate positions. Hurtgen and Maun [61] propose an ILS algorithm for minimizing the size of the configuration to reach full observability of the network. While virtually all ILS applications have been to deterministic problems, Grasas et al. [49] consider adaptations for ILS to integrate simulation in order to be able to tackle stochastic combinatorial optimization problems. The approach is illustrated with some example application of the proposed SimILS framework. The integration of information from lower bounding techniques into an ILS algorithm is considered by Buson et al. [21] for solving the fixed-charge transportation problem, which extends the transportation problem by the consideration of fixed costs for sending a flow from some origin to a destination. The reduced costs from the lower bounding are used to guide a restart phase of the algorithm. Lai and Hao [74] apply ILS to obtain high-quality candidate solutions to the maximally diverse grouping problem, where the goal is to partition the vertices of an edge-weighted and undirected complete graph under some constraints on the group size. Wolf and Merz [133] develop an ILS algorithm to find a symmetric connectivity topology with minimum power consumption in wireless ad hoc networks. Benchmark results on large instances with up to 1000 nodes show that their algorithm outperforms other heuristics that were previously used to solve this problem. For the prize-collecting generalized minimum spanning tree problem with a two-level solution, the authors of Contreras-Bolton and Parada [27] introduced an ILS which proposes in the first level one vertex from each cluster and in the second level constructs a minimum spanning tree with the vertices from the first subproblem. ILS has been applied to image analysis tasks, and Cordón and Damas [28] applied it to image registration, obtaining promising initial results. Imamichi et al. [66] apply ILS as a method to improve the placement of irregular polygons in a rectangular surface with the goal of minimizing, for a fixed width, the length of the container so that no polygon overlaps with any other or protrudes the container. The proposed approach allows overlaps but tries to minimize them using nonlinear programming methods and swaps between polygons. In the paper by Schettini et al. [113], a capacitated demand-driven timetabling problem is

tackled, which also has a demand-driven nonperiodic timetabling problem for a two-directional metro line. The objective is to minimize the total passenger waiting time. They proposed an ILS and obtain excellent performance by three instance sets given by the metro of Beijing, Madrid, and Milan.

Few papers have considered the adoption of the ideas underlying ILS for tackling continuous optimization problems. Kramer [72] has explored a simple continuous optimization algorithm, which embedded Powell's methods into an ILS for continuous optimization. Liao and Stützle [76] use ILS as one of the component algorithms in their hybrid, competition-based approach for continuous optimization. This approach decides in a preliminary competition phase which of two continuous optimizers, an ILS algorithm or IPOP-CMAES [7] to execute and then, in a second phase, continues with the execution of the winning algorithm. This approach was a winner of the CEC 2013 benchmark competition for real-parameter optimization.

Conclusions

In the initial phases of metaheuristic research, many efforts were dedicated toward developing and refining new metaheuristic methods and on studying their performance and behavior. As such, the focus was on rather pure applications of the respective methods to tackle computationally hard problems. Iterated local search contributed by relying on a clear principle that is easy to identify and that leads usually to high-performing algorithms. In addition, ILS algorithms are relatively intuitive to design and at the same time malleable. Therefore, iterated local search served often as a basis for a larger algorithm engineering effort if high-performing heuristics are desired. This approach was very successful, as shown by the various problems for which ILS algorithms have been or still are state of the art. In later research efforts in the metaheuristics area, often hybrid methods were proposed that mix in one algorithm concepts from different principles to derive effective algorithms [16, 83]. Even if this trend somehow blurs the differences behind the methods, it is nevertheless important to have methods that rely on clear principles and to have knowledge of their particular strengths, which can be exploited in the design of hybrid methods.

The research in heuristic search methodologies and metaheuristics, in particular, has now reached a mature state, and fundamentally new ideas appear rarely. Within this context, ILS has a clear role as one of the main methods that offers an excellent trade-off between simplicity and flexibility. As future trends we expect on one side that the number of applications of ILS increases further, and that more complex problems and also non-combinatorial problems will be tackled by it. On the other side, as the development of effective heuristic algorithms is becoming increasingly more streamlined, we expect that the clear principles underlying ILS support well a sound algorithm engineering effort. While traditionally such an algorithm engineering effort relied in part on the manual configuration and tuning of the algorithms, over the recent years, the advent of automatic algorithm configuration

tools [59, 112, 120, 121] such as ParamILS [63], SMAC [64], or irace [78, 79] has helped to alleviate the algorithm designer from this task. In fact, we foresee that in the future, the development of effective ILS algorithms and, more in general, of any other metaheuristic algorithms will be strongly based on the exploitation of automatic algorithm configuration and design techniques.

Abstract

Memetic algorithms (MAs) provide a very effective and flexible metaheuristic approach for tackling hard optimization problems. MAs address the difficulty of developing high-performance universal heuristics by encouraging the exploitation of multiple heuristics acting in concert, making use of all available sources of information for a problem. This approach has resulted in a rich arsenal of heuristic algorithms and metaheuristic frameworks for many problems. In this chapter, we discuss the philosophy of the memetic paradigm, lay out the structure of an MA, develop several example algorithms, survey recent work in the field, and discuss the possible future directions of MAs.

Introduction

The effectiveness and efficiency of (meta)heuristics—and we may view memetic algorithms as particularly good heuristics in this sense—rests upon their ability to explore the solution space thoroughly while avoiding exhaustive or near-exhaustive searching. If we take polynomial-time computability as an approximation of tractability, then we can view a polynomial-time algorithm as a very clever search procedure; in these cases we have a small search space or can reduce the search space drastically. However, in dealing with intractable problems, reducing the search space to a reasonable size is a much more difficult task. Most centrally, we face the problem of local versus global improvement; an improvement to a solution does not give us any guarantee that we are in fact moving toward the optimum. Actually, depending upon the problem under consideration, we may be moving away from it (hence the notion of deception in search algorithms [253]) or at the very least we may be getting closer to being trapped in a nonoptimal solution for which no simple modification can lead to an improvement (i.e., a local optimum).

Thus many (meta)heuristic methods include techniques for allowing non-improving alterations to a solution or for nonlocal moves across the search space (Of course, there is some notion of locality that would put any two given solutions to a problem nearby, but we shall slip quietly past this semantic wrangling.) in order to be able to escape from local optima [27]. Perhaps the archetypic example of such a metaheuristic is the genetic algorithm (GA) [99, 113]: Inspired by the principles of natural evolution, GAs maintain a population (i.e., a multiset) of solutions that are subject to successive phases of selection, reproduction (via recombination and mutation), and replacement. The use of a population of solutions provides a better chance of avoiding local optima than maintaining a single solution. On the one hand, the search is driven by operators that (1) allow the search to take non-

improving steps, most notably in the case of mutations, and (2) allow the search to move to significantly different portions of the search space, particularly by virtue of recombination. On the other hand, selection and replacement typically work on a global (population-wise) scale, meaning that non-improving solutions have a chance of persisting for a nontrivial amount of time, hence allowing escape from local optima. However, although this heuristic structure has proven quite effective, it relies almost entirely on recombination mechanisms to improve solution quality and evolutionary processes are slow. In particular, they are also less capable of fine-tuning solutions, that is, the progress toward a fully optimized solution once the algorithm has located its basin of attraction (i.e., the region of the search space from which a series of small—local—improvements can lead to a certain local optimum—see [131, 210])—is often sluggish. This is precisely in contrast to local search (single-solution or trajectory-based) techniques which can readily locate local optima (and hence are more sensitive to them).

To address this weakness, researchers began developing *hybridized* metaheuristics [28, 30], that is, metaheuristics that combine ideas from different search paradigms and/or different algorithms altogether. The underlying idea in such approaches is obviously trying to achieve some synergetic behavior whereby the deficiencies of a certain search technique are compensated by the combination with other techniques and their advantages are boosted due to this very same combination. This strict interpretation of the term *hybrid* has been broadened with time to encompass all forms of nonblind metaheuristics (i.e., not domain independent). Under this broad interpretation, hybridization is the process of augmenting a generic (problem-independent) metaheuristic with problem- (or problem-class, i.e., domain-) knowledge. Since this augmentation is often achieved via the blend of different metaheuristic components, both interpretations are equivalent in most situations. The broad interpretation has, in any case, the advantage of fitting better into theoretical results such as those of Hart and Belew [110] and—most conspicuously—those of Wolpert and Macready [254] in the so-called *No-Free-Lunch Theorem*, which state that search algorithms perform strictly in accordance with the amount and quality of the problem knowledge they incorporate. Although these results have provoked controversy in their time and have been refined [79, 80], the bottom line remains.

Memetic algorithms (MAs) championed this philosophy. The notion of *memetic algorithm* (The term "memetic" was developed from Dawkin's [71] notion of a "meme" (from the Ancient Greek μίμημα, meaning "imitated thing") as a unit of cultural inheritance (and hence cultural evolution)—the cultural analog of a gene.) was coined in [177] to characterize and codify these hybrid approaches. The use of the term meme was intended to capture the fact that information traits in human culture are subject to periods of lifetime learning, and therefore they are different when transmitted to what they were when first acquired. This bears a strong resemblance with the Larmarckian model of evolution, whereby traits acquired during the lifetime of an individual are transmitted to its offspring. Therefore, it is not surprising that MAs are sometimes disguised under other denominations featuring the terms "Lamarckian" or "hybrid."

Although the initial conception of memetic search did not include the idea of GAs or evolutionary algorithms (EAs) whatsoever [181], it turned out that these techniques were ideal recipients for exploiting the metaphor of MAs, namely having a collection of "agents" alternating periods of self-improvement with phases of cooperation and competition, cf. [180]. In fact, early MAs mixed GAs and EAs with simulated annealing and tabu search [178, 183], eventually developing the idea that MAs are EAs endowed with some kind of local search (LS) technique, leading to the restrictive definition MA = EA + LS [206]. However, note that the central concept of MAs is not to adhere to a particular heuristic approach or metaphor, but to provide a coherent structure to employ *several* heuristics (including exact methods [29]) that employ *complementary* heuristics that exploit *all available knowledge*. We can thus state that EA + LS $\subset$ MA as a consequence of this broader definition of MAs, cf. [58]. The next section will explore the structure of MAs in more detail, with particular emphasis on the classical characterization of this paradigm. Subsequently, we will describe two examples of application of MAs to distinct combinatorial optimization problems, detailing how to deploy MAs by leveraging problem-specific knowledge in each case. Following that, we will provide an overview of recent applications of memetic algorithms across various fields and discuss the most prevalent MA architectures. We conclude this work by providing information on current trends in the development of MAs.

Structure of a Memetic Algorithm

As mentioned above, the early definitions of MAs envisioned the paradigm as a pragmatic integration of ideas from different metaheuristics. These were orchestrated in terms of a collection of search agents performing individual explorations (i.e., lifetime learning) of the space of solutions and participating in periodic phases of cooperation and competition [193]. An abstract formulation of such an approach is provided in Fig. 1. This pseudocode matches the initial conception of MAs as an inherently parallel approach in which a collection of local searchers (simulated annealing in early developments [181]) run either concurrently or physically in parallel and establish synchronization points in which information was exchanged between them. However, this depiction of MAs is still generic enough to encompass most actual incarnations of the paradigm as shown later, as it captures the essential feature of MAs, namely the carefully crafted interplay between global (population-based) and local (individual-based) search (It must be noted that we are always using the terms *global* and *local* in connection to the mechanics of the search rather than to the ability of eventually (or asymptotically) finding the global optimum. It is certainly the case that many local search approaches (simulated annealing, tabu search, etc.) are capable of escaping from local optima and navigate the search space in order to find the global optimum. However, the distinctive feature of these techniques (as opposed to, e.g., genetic algorithms) is that they do this following a trajectory-based approach.).

Fig. 1 A generic memetic algorithm

```

1   parfor j = 1,...,μ do
2       pop_i ← CREATE-SEARCH-AGENT();
3   end-parfor
4   repeat
5       parfor j = 1...μ do
6           pop_i.LEARN();
7       end-parfor
8       pop.COMPETE();
9       pop.COOPERATE();
10  until stopping criterion is satisfied;
end GENERIC-MA
```

Skeleton of a Classical Memetic Algorithm

Following early work in which the population-based aspect of MAs, namely the collection of agents and the synchronized stages of cooperation and competition, was captured by a genetic algorithm [183], the classical memetic model was cemented. The basic skeleton of such an MA is relatively straightforward, adding little additional complexity beyond that of a GA. Figure 2 provides a visual representation of the functioning of such a classical MA, and Fig. 3 gives a pseudocode sketch of the salient structure (The interested reader may find an actual implementation of this skeleton at https://github.com/Bio4Res/memetic-continuous.), using LOCAL-SEARCH as a placeholder for any particular individual improvement heuristic (see Table 1) including, for instance, a complete exact algorithm like Branch and Bound and others that guarantee the optimality of the final solution obtained when they stop. Although a small structural change to a typical GA, the inclusion of the individual improvement phase can dramatically alter its performance. This mix allows the metaheuristic to benefit from the diversity of solutions engendered by the evolutionary approach, but to avoid the lethargic pace of improvement via more directed optimization: Instead of relying on random processes subjected to fitness-based selection alone, each individual solution is optimized before the

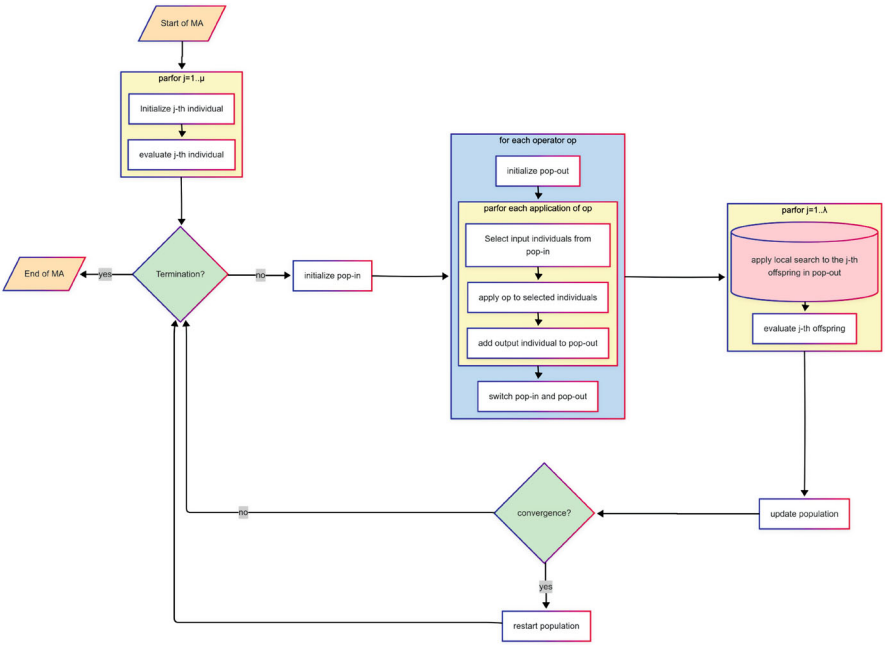

Fig. 2 A flowchart of the classical MA. Therein, μ is the population size and λ the number of offspring

evolutionary mechanism is applied (see Fig. 4b), significantly increasing the rate at which individual solutions converge to an optimum.

The structure of an MA is quite flexible, and the performance of the implementation, in terms of both solution quality and speed, can be affected by a number of factors. As an evolutionary population-based metaheuristic, the typical issues regarding choice and implementation of variation operators are inherited from the GA paradigm. Thus, it is very common to use recombination and mutation as the two primary elements to globally navigate the space of solutions (lines 8–14 in Fig. 3; see also Fig. 4). However, for those familiar with GAs, it should be readily apparent that the individual improvement phase is most likely to be the computational bottleneck—the improvement and subsequent evaluation of every individual is inherently expensive and, as shown in [170], it can easily take up to 95% of the computational cost of the algorithm. The trade-off is that, with a good choice of individual improvement heuristic, far fewer generations of mutation and recombination are required. The careful reader will also notice that the local search procedure (and, typically, any individual improvement heuristic) is highly amenable to parallelization. This helps to ameliorate the cost of individual improvement but more importantly lends the MA approach a high degree of scalability.

```
begin LOCAL-SEARCH-BASED-MA(parameters)
1  pop ← [];
2  parfor j = 1,...,parameters.μ do
3      pop_i ← INITIALIZE();
4  end-parfor
5  EVALUATE(pop);
6  repeat
7      pop-in ← pop;
8      for j = 1,...,parameters.#operators do
9          pop-out ← [];
10         parfor k = 1,...,parameters.op[j].times do
11             pop-out_k ← APPLY(parameters.op[j], SELECT(pop-in, parameters.op[j].arity));
12         end-parfor
13         pop-in ← pop-out;
14     end-for
15     parfor j = 1,...,parameters.λ do
16         pop-out_j ← LOCAL-SEARCH(pop-out_j, parameters);
17     end-parfor
18     EVALUATE(pop-out);
19     pop ← REPLACE(pop, pop-out);
20     if CONVERGED(pop) then
21         RESTART(pop, parameters);
22     end-if
23 until stopping criterion is satisfied;
end LOCAL-SEARCH-BASED-MA
```

Fig. 3 A Local Search-Based Memetic Algorithm. In addition to μ and λ (see Fig. 2), the algorithm parameters include the number of variation operators and for each of them the number of times they are applied and how many input solutions they require

Table 1 A list of some local search methods that can be used within an MA

Local search method	Description
Hill climbing	Simple neighborhood sampling (partial or complete) and selection of an improved neighbor (first one found or the best of the neighborhood explored)
Hooke-Jeeves	Continuous optimization. Derivative-free method. Pattern search
Local branching	Mixed-Integer Programming (MIP). Refinement via restricting the search space to a local neighborhood around the current solution
Lin-Kernighan Heuristic	TSP optimization. Tour reassembling
Nelder-Mead	Continuous optimization. Derivative-free method. Polytope search
Simulated annealing	Probabilistic acceptance of neighboring solutions using the Metropolis criterion, controlled by a temperature parameter. It can escape from local optima by allowing non-improving moves
Tabu search	Neighborhood exploration modulated by a tabu list of recent moves. It can escape from local optima by allowing non-improving moves
Variable neighborhood search	Systematic change of neighborhoods to conduct local search and use of perturbations to escape from local optima

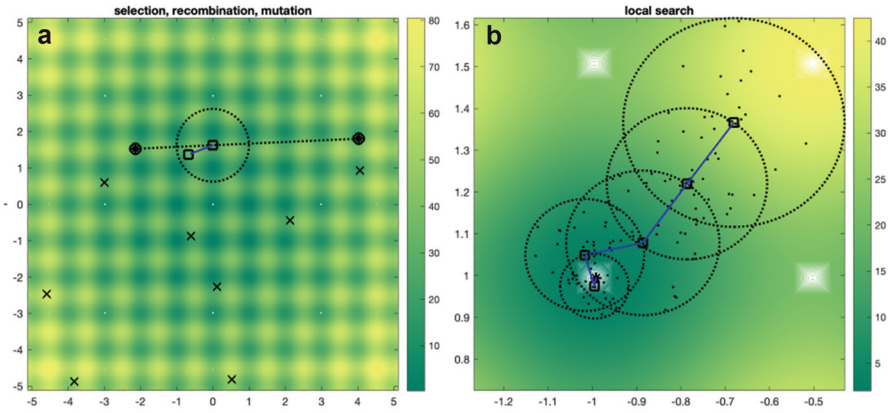

Fig. 4 Exploration done by the different components of the MA. (**a**) Population-based components. The crosses denote the current population, and the two small circles indicate selected individuals; along the line that connects them, a recombination is done (square mark), and the individual produced is mutated by selecting a random point within a certain neighborhood (represented as a dotted circle). (**b**) Local search. Focusing on the solution generated at the end of the previous subfigure, a sequence of steps is made: A number of neighbors of the current solution are selected (small dots), and the best of them is selected as the next current point (square marks). In both subfigures, the background is a contour plot of the 2D Rastrigin function. Note the different scale in either subplot

Population-Based Components

From the point of view of the different components into which a classical MA can be dissected, all of them are susceptible to encapsulating some portion of problem knowledge. Consider, for instance, recombination. This is the component that most appropriately captures the idea of agent cooperation. Such a cooperation is

typically established between a pair of agents but can in general involve an arbitrary number of *parents* [82] (notice nevertheless that in this case some forms of heuristic recombination can be very complex [60]). The generic idea of a knowledge-augmented recombination operator is to combine information pieces contained in the parents in an intelligent way. How these information pieces are defined is a problem-dependent issue that arises from the issue of representation in EAs. The underlying objective of an appropriate representation would be to have solutions described by some structured collection of objects whose values truly capture solution features of relevance (i.e., ultimately responsible for determining whether a solution is good or not). This is a substantial topic for which the interested reader is referred to, e.g., [214]. Focusing on the *smart* manipulation of these information units (however they are defined), that is, processing them in a problem-specific way instead of using domain-independent templates (such as those in [205]), the goal is picking the right combination of such units from either parent. Of course, this is easier said than done (and in fact, doing it is in general *provably* hard for arbitrary problems and/or definitions of *right* combination—see the discussion on the polynomial merger complexity class in [180, 182]), but there are numerous heuristics ideas in the literature that can be used to this end. In many cases—and following design advice already present in classical texts of hybridization pioneers, e.g., [70]—these ideas are based on the use of problem-specific heuristics such as greedy algorithms [132, 187], backtracking [55], dynamic programming [121], or branch and bound [62], just to mention a few.

Mutation is another classical operator, well known for its role of maintaining a continuous supply of genetic diversity that can be subsequently exploited by the remaining operators. Even more so, in certain EA models such as evolutionary programming [89], it actually bears sole responsibility for driving the search. Note that while this latter philosophy can also be used in an MA context—see Section "An Example Memetic Algorithm for *Weighted Constraint Satisfaction Problems*"—it is typically the case that MAs use sophisticated recombination operators such as those described before, and hence the criticism of recombination being just a disguised form of macromutation would not apply to them. Moreover, due to the presence of a local search stage in the main evolutionary cycle, one has to be careful to pick a mutation operator whose effects on solutions cannot be trivially undone by the local search, since that would defeat the very purpose of mutation. Following this line, in some cases there are MAs that even refrain from using mutation, e.g., [165, 246]. Although such a decision could be further supported by the fact that MAs usually feature a population restart procedure (see line 22 in Fig. 3), and therefore premature convergence is not so troublesome; this is not the most common course of action. An appropriate mutation operator (i.e., one that uses a neighborhood sufficiently different from that used by the local searcher) is often utilized. In fact, it is not unusual to have more than one such mutation operator, e.g., [147, 219], much like in metaheuristic approaches such as variable neighborhood search [108] (VNS). In some cases, these multiple mutation operators are used with the purpose of exerting different degrees of perturbation (i.e., *light* and *heavy* mutations) depending on the convergence of the population [90].

The restart procedure is another important element in an MA. The goal of this procedure is to perform a warm reinitialization of the population when the search is deemed stagnated (i.e., the population has converged to a suboptimal state). Of course, stagnation can be hindered by taking preventive measures such as the light/heavy mutation scheme mentioned before, the use of spatial structure in populations [238] (see also the next subsection), or some other diversity preservation policy [227]—see also [188]. However, a more drastic measure may eventually be required. For that purpose, a common approach is to keep a certain percentage of the current population and use the solution creation mechanism (the one used to create the initial population—line 3 in Fig. 3) to complete the new population. Regarding the former, they constitute a seed that allows one to keep a part of the search momentum without having to start from scratch. As to the latter, note that they need not be purely random solutions, but any available constructive heuristic can be used for this purpose, e.g., see [57, 76, 195].

The Role of Local Search

The use of local search components is one of the most distinctive elements of MAs. These components (one such component in most simple approaches, although some more advanced methods may feature multiple local search operators—see the next subsection) can take the form of any stand-alone method such as hill climbing, simulated annealing, tabu search, variable neighborhood search, etc. [194]. The choice of a particular technique must take into account two major issues, namely its parameterization and its interaction with the remaining components of the algorithm. Regarding the latter and in addition to the issues discussed above in connection with the mutation operator, one has to consider the interplay between the local searcher and the recombination operator. For example, a highly intensive local search procedure may be better suited to interact with a more diversification-oriented recombination operator; see, e.g., [91]. This heuristic recipe does not necessarily conflict with the use of a powerful recombination operator (see, e.g., [93]) but underlines that the knowledge embedded in either component, recombination operator, and local search heuristic must be complementary in terms of the effect they produce in the search dynamics (much as it was discussed for the mutation operator). An interesting analysis of these issues from the point of view of fitness landscapes is provided in [172]. Whatever the definition of the neighborhood (and note that it can be complex, even combining several simpler neighborhood schemes), it is often crucial for performance reasons to be able to evaluate solutions incrementally [109], that is, without having to resort to a full evaluation, but only by recomputing the fitness contribution of the solution components that were modified. This may require the use of appropriate data structures and is normally associated with discrete optimization (the high nonlinearity—and sometimes even the lack of a closed fitness function—often makes this complicated in continuous optimization).

The parameterization of the local search heuristic is another complex issue. We can include here both high-level algorithmic aspects such as when to apply

local search, to which solutions it should be applied, which local search operator to apply (if there are several of them), as well as low-level parameters such as the breadth (number of neighbors explored in each iteration of the local search heuristic) and depth (how many iterations of local search will be performed)—see [230]. Determining an adequate setting for these parameters is crucial for the performance of the algorithm, as it has been shown theoretically that small parameter changes can turn a problem from being polynomial time solvable with high probability to requiring super polynomial (even exponential) time [139, 229]. Unfortunately, a priori design guidelines to provably avoid this kind of behavior are ruled out by intractability results [230]. Thus, design by analogy and empirical testing appear to be the most helpful tools to approach this endeavor (although both self-parameterization and automatic tuning [164,228] are appealing alternatives that are increasingly gaining relevance). In this regard, it has been shown, for example, in several contexts that partial Lamarckism [115], that is, not applying a local search to every individual but just applying it with some probability p_{LS}, can produce notably better results than a fully Lamarckian approach [56, 124] although the best value of this parameter is problem dependent. In relation to the depth of the local search, it has also been proposed in the literature to save the state of the local search together with the solution to which it was applied, so as to resume the process from that point if necessary [175, 176].

A Note on More Advanced Memetic Algorithms

Although Figs. 1 and 3 set a basic MA framework, the structure can be made significantly more complex. As the central motivation of MAs is to exploit all available information, the restriction of any particular component would be antithetical. In addition to employing different heuristics, we can employ *multiple* heuristics in concert. We can easily combine different individual improvement heuristics, applying them to different individuals, different populations, in parallel, in sequence, or even in competition. Similarly, the population-based heuristic can employ multiple improvement techniques—such approaches are well known in the GA community.

Moscato and Tinetti [184] demonstrate a more advanced MA that uses several heuristics in concert and to achieve different goals within the algorithm. The algorithm employs *tree-structured population* where the population is divided into subpopulations of size 4, arranged in a ternary tree structure.

1. Each subpopulation divided into a *leader* node and three *supporters*. The supporters are stored one level below their leader.
2. The intermediate nodes in the tree hold an individual that is part of two populations; it is the leader of the three supporters lower in the tree and a support of its leader higher in the tree.
3. The number of subpopulation can be manipulated by adding levels to the tree.

Each individual can be optimized using a local search procedure that selects from a variety of local optimization moves; approximate 2-OPT, One-City Insertion, and Two-City Insertion [135, 150]. Genetic recombination occurs "normally" within each subpopulation with the leader individual representing the best tour in the subpopulation (note that overlap of subpopulations ensures that improvement propagates up the tree); however, the small size of the subpopulation can quickly lead to a lack of diversity, in which case the recombination mechanism switches to an external recombination procedure for the lowest level of the tree.

In this example, we can see a number of variations on the basic structure of an MA: multiple local search variants, a multipopulation variation of a GA which itself employs multiple recombination procedures. Another example of a more complex improvement strategy is given by Moscato [179], where a small population of individuals is maintained (only 16 individuals, each a binary vector), with a tabu search procedure for individual improvement. Again, in a small population, a loss of diversity is a potential drawback. To combat this, each individual notes the 16 best single-bit-flip moves available. When diversity falls below a given threshold, instead of following a simple tabu search approach, the individual i performs move i from its list of best moves. This deliberate (potentially) nonoptimal action has the effect of spreading the individuals further across the configuration space, increasing diversity. Once diversity is restored, normal tabu search optimization is restored.

The continuation of these ideas has led to the development of what are now called *self-adaptive* MAs, which allow the context-specific, dynamic application of different heuristics or tuning of search parameters by the algorithm itself. See Section "Future-Generation Memetic Algorithms".

Memetic Algorithms in Practice

In this section, we present two extended examples of MAs for specific problems—*Network Alignment* and *Weighted Constraint Satisfaction Problems*—and survey recent interesting applications of MAs in different fields.

An Example Memetic Algorithm for *Network Alignment*

The optimization version of the basic *Network Alignment* problem takes as input two networks G_1 and G_2 and asks for an injective partial mapping $f : V(G_1) \to V(G_2)$ between the vertices of the two networks that maximizes $\sum_{u,v \in V(G_1)} \tau_f(u, v)$ where

$$\tau_f = \begin{cases} 1 \text{ if } uv \in E(G_1) \text{ and } f(u)f(v) \in E(G_2) \\ 0 \text{ otherwise} \end{cases}$$

In fact, we may assume that the mapping is total and bijective by adding "dummy" vertices to the smaller network. Of course, τ_f is open to variation, as are the

precise details of f, leading to many variants of *Network Alignment*. The decision variant of *Network Alignment* is NP-complete [136] and W[1]-complete [169], suggesting, subject to standard complexity assumptions, that there is no suitably efficient exact algorithm for *Network Alignment*, making it a prime candidate for heuristic methods.

In developing an MA for this (and any) problem, we must (at a minimum) select an individual solution representation, mutation and recombination operators, and an individual improvement heuristic and its attending concerns.

For *Network Alignment*, the most direct individual representation is the mapping itself. Assuming that we have already added any necessary dummy vertices, we can represent the mapping by (for example) an array of size $|V(G_1)|$ storing a permutation of $V(G_2)$. For ease of representation, it is sufficient to assign each vertex a unique integer in the range $[0, |V(G_1)|]$. An alternative representation suitable for *Network Alignment* would be to store the alignment of the edges, making the computation of the basic fitness function simple, but the individual could be polynomially larger, affecting the efficiency of mutation, recombination, individual improvement, and even evaluation. In addition, care would need to be taken as to how to determine which vertices were aligned.

With this individual representation, a simple and reasonable mutation operator is that of a random shuffle, where each element of an individual is randomly swapped with another, randomly chosen element, with a given probability. A naïve recombination operator is, given two parents, to select a linear segment of the individual (i.e., a set of contiguous indices) and swap the mappings for those indices between the parents (with adjustment to handle the duplication of elements, etc.), producing two children. This recombination is commonly known as a Partially Matched Crossover (PMX) [100]. However, considering the problem we are trying to solve, it is easy to see that this choice may be somewhat inefficient. The *Network Alignment* problem, in essence, seeks to preserve as much topological structure (i.e., edge matchings) as possible—in this sense it is a relaxed *Graph Isomorphism* problem. Swapping a set of arbitrarily chosen indices is unlikely to preserve interesting structure, contrary to the goal of a recombination operator, which is to produce children of higher quality than their parents by mixing the better parts of the parents, aiming to place the child solution closer to the global optima. For *Network Alignment*, it is much more interesting to preserve vertices' neighborhoods in this regard. So, a better choice of recombination operator is to select a vertex and its 2-neighborhood (all vertices at distance at most 2) as the set of indices which will be swapped.

To complete the GA component, we employ a tournament selection process to choose the individuals included in the new generation and a restart mechanism, whereby the best solution is recorded and the population is restarted if no improvement has been observed after a given number of generations.

For individual improvement, we employ a local search heuristic where the neighborhood of each individual is the 2-swap neighborhood, the set of individuals obtained by swapping any two elements. The search is implemented by selecting an element in the individual and taking the optimal swap in the local neighborhood.

If this is not the identity mapping, we place the neighbors of the preimage of the swapped vertex into a list of vertices to swap. If no initial swap is found, we repeat the process with a new starting point until a swap is found or all vertices have been tested.

In combination with the skeletons given by Figs. 1 and 3, these assembled components constitute an MA for *Network Alignment*; however, the reader will notice that, even without considering more complicated approaches, there are several tunable parameters present, namely the probabilities and frequencies that control mutation and recombination (as in GAs), and more specifically for MAs, the frequency and application régime of the individual improvement step. We may choose to apply individual improvement, essentially at one extreme, regularly, to all individuals, or at the other extreme, only when evolutionary progress slows and to a select few individuals, or of course in some intermediate régime. As discussed in Section "A Note on More Advanced Memetic Algorithms", we could also take an adaptive approach, allowing the algorithm to adjust these parameters itself.

An Example Memetic Algorithm for *Weighted Constraint Satisfaction Problems*

Weighted Constraint Satisfaction Problems (WCSPs) are a general class of combinatorial problems in which (i) solutions are assignments of values to a collection of variables, each of them taken from a possibly different domain, (ii) there are hard constraints making some particular combinations of variable values infeasible, and (iii) there are some soft constraints that establish preferences between solutions. We can, for example, think of a school timetabling problem in which courses have to be fit into different time slots: No two courses can use the same time slot if they are taught by the same lecturer (a hard constraint) and lecturer preferences (e.g., teaching in the morning or in the afternoon) have to be respected if possible. In essence, both types of constraints can be represented by defining a collection of integer functions f_i, one for each constraint; these functions are used to weight the fulfillment/violation of the corresponding constraint, and therefore an objective function F (to be minimized, without loss of generality) can be built by summing them. Thus, it will typically be the case that hard constraints have a much larger weight (even infinite if violated) than soft constraints.

Formally, we can characterize a WCSP as a triplet $\langle \mathscr{X}, \mathscr{D}, \mathscr{F} \rangle$, where each $x_i \in \mathscr{X}$, $1 \leqslant i \leqslant n$, is a problem variable whose domain is $D_i \in \mathscr{D}$. Each function $f_j \in \mathscr{F}$, $1 \leqslant j \leqslant m$, has signature $f_j : V_j \to \mathbb{N}$, where $V_j \in 2^{\mathscr{X}}$ is the subset of variables involved in the jth constraint. With this formulation, a naïve evolutionary approach can be defined by using the Cartesian product $\mathscr{S} = D_1 \times \cdots \times D_n$ as search space, taking the fitness function to be $F(x) = \sum_j \hat{f}_j(x)$ (where $\hat{f}_i$ is a function that picks from its argument the variables in V_j and feeds them to f_j), and using standard operations for recombination and mutation. However, such an approach is going to perform poorly in general due to the lack of problem-specific

knowledge. A much more sensible approach can be built on the basis of (i) a smart recombination operator and (ii) a powerful local search technique.

Regarding recombination, it is very easy to define a greedy recombination mechanism for WCSPs: (1) start from a solution s with all variables unassigned, (2) sort constraints in some particular order (arbitrary or heuristically selected) $j_1, \cdots, j_m$, and (3) traverse this ordered list of constraints, checking for each j_k the variables in V_{j_k} that are still unassigned in s, constructing two (or as many as parents) candidate sets using the assigned values in s plus the values that the remaining variables in V_{j_k} take in either parent, and keeping the candidate set v minimizing $f_{j_k}(v)$ (which is subsequently used to expand the solution s). This procedure has been used, for example, in [64] for the construction of Golomb rulers and in [213] for the construction of balanced incomplete blocks, to cite only two examples.

It is possible to define a more intensive recombination approach by taking ideas from complete techniques [66]. More precisely, a complete technique can be used to explore the set of potential solutions that can be created using a given collection of parents, returning the best solution attainable. Different possibilities can be used for this purpose, such as branch and bound [62] or integer linear programming techniques [168]. A more WCSP-specific approach can be found in the use of bucket elimination (BE) [73]. BE can be regarded as a dynamic programming approach based on the successive elimination of variables and the use of an auxiliary table to store the best value of the fitness function for specific variable combinations. More precisely, BE considers some ordering of the variables (again, arbitrarily or heuristically selected—it must be noted that while the particular choice ordering is irrelevant for correction purposes, it can have a huge impact in the computational complexity of the algorithm though) $i_1, \cdots, i_n$. Then, it traverses this sequence, and for each variable x_{i_k} (1) determines the constraints $\mathscr{C} \subseteq \mathscr{F}$ in which x_{i_k} is involved, (2) computes the bucket

$$B_{i_k} = \left(\cup_{f_j \in \mathscr{C}} V_j\right) \setminus \{x_{i_k}\},$$

namely the collection of variables related to x_{i_k} in any constraint, (3) determines for each combination t of values for variables in B_{i_k} the value v_t^* for x_{i_k} such that $w = \sum_{f_j \in \mathscr{C}} \hat{f}_j(t \cdot (x_{i_k} = v))$ is minimal, and (4) removes $\mathscr{C}$ from $\mathscr{F}$ and adds a new constraint f' with domain $V' = B_{i_k}$ defined as $f'(t) = \sum_{f_j \in \mathscr{C}} \hat{f}_j(t \cdot (x_{i_k} = v_t^*))$. When all variables have been eliminated, the optimal cost w is found, and one only has to trace the process (using the auxiliary table) to determine the best assignment of variables [95]. This procedure has been used with great success in [93] to solve *Maximum Density Still Life Problem* in conduction with a local search procedure based on tabu search.

A potential drawback of recombination schemes such as those defined above is scalability: The use of an exact technique for recombination is less costly than using it to solve the problem completely from scratch, but its cost will nevertheless

grow with the problem size until becoming impractical at some point. To alleviate this problem, we can play with the granularity of the representation [61], that is, grouping variables into larger chunks which are subsequently used as basic units for the purposes of constructing solutions (hence reducing the number of potential solutions attainable and therefore the computational cost of the exact technique). In the context of the BE method described previously, this approach is termed mini-buckets [77] and can be readily applied to the recombination mechanism described above [95]. Another source of difficulties is the existence of symmetries or partial isomorphisms between solutions. This scenario is typical in many WCSPs in which variables or groups thereof can be relabeled without altering the solution. In such a situation, recombination can reduce to macromutation unless it is effectively capable of identifying correspondences between variables in different parents. This is, for example, done successfully in [173] in the context of clustering genomic data. Of course, it may be very complex, in general, to find a perfect match between variables in an arbitrary WCSP with symmetries. In problems for which this is deemed too complicated or time consuming, it must be noted that a recombination-less MA—essentially a population of local searchers subject to interleaved phases of self-improvement and competition via selection/replacement, much in the line of go-with-the-winner approaches [5]—can also provide acceptable results. This is, for example, the case of the *Social Golfer Problem*, a WCSP with a large degree of symmetry that was successfully attacked using a memetic evolutionary programming approach [63] (an MA propelled by selection, mutation, and local improvement).

A Brief Survey of Recent Memetic Algorithm Applications

In recent years, MAs have become a significant part of the optimization toolkit and have become particularly well used in recent years. As a rough gauge, the number of academic papers (Found via searching Scopus (https://www.scopus.com) and the Web of Science (https://www.webofscience.com) for relevant papers with the phrase "memetic algorithm" in their title, abstract, or keywords.) published is approximately 238 per year on average during the last decade, with thousands of academic publications in total since 1998 (between ∼3200 and ∼3900 depending on the source). These publications have attracted an interest that is well represented by the number of citations received (see Fig. 5). The total number of citations ranges between ∼77000 and ∼86000 depending on the source, and the field has a h-index between 113 (Scopus) and 118 (WoS), thus underpinning the traction of this area. Possibly the most interesting aspect of this growing interest in MAs is the diversity of techniques and application areas. This will be shown next.

Memetic Algorithms in the Wild

While many algorithms developed in the areas of Computer Science and Optimization are demonstrated via application to practical problems drawn from a

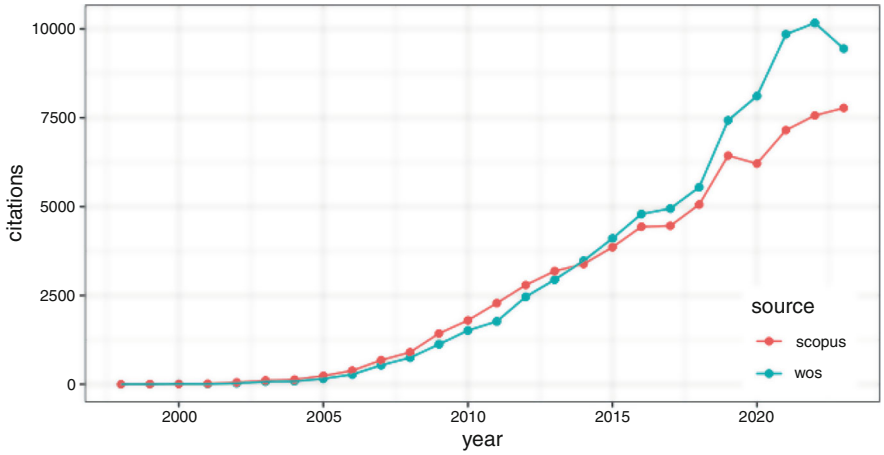

Fig. 5 Number of citations per year to academic papers dealing with MAs

variety of areas, a more reliable indicator of the effectiveness of a technique is the adoption of the technique as a tool within the communities from which the problems are drawn. Here, we briefly survey some of the areas in which MAs have been successfully applied. Table 2 gives an overview of the breadth of application areas for MAs, with recent references. Of course, this table is far from exhaustive, even within the application areas mentioned. In fact, in some areas the number of memetic applications has deserved individualized treatment in specialized surveys, e.g., scheduling and timetabling [58], engineering and design [41], bioinformatics [24], etc. The reader is also referred to application-oriented surveys in which MAs are also features, such as [225] (for feature selection), [127] (for flexible job shop), [49] (for IoT network topology), and [122] (for multiple sequence alignment), just to name a few. The breadth of the application areas suggests a significant generality and flexibility in the memetic paradigm.

Memetic Speciation

Along with a wide set of application areas, MAs have also embraced many forms, employing a wide variety of combinations of population-based heuristics and individual improvement heuristics. Table 3 lists some of the more prominent combinations, with examples of references for each (see also the annotated references in Table 2). Not only are different combinations of population-based heuristics and individual improvement heuristics extant, but also more exotic MAs that use heuristics of only one type or multiple heuristics of each type exist. The adaptability of MAs to parallel implementation also encourages the use of multiple different types of heuristics simultaneously—the exploitation of *all* available knowledge is, after all, the central idea of the memetic paradigm.

If we examine some of the more recent trends, it is interesting to see that the use of several neighborhood structures is becoming increasingly popular. As already anticipated in [178,184] (where agents used different local search techniques for the TSP), this can enhance the final performance of an MA. Quite interestingly, some of them involve some sort of learning or adaptation procedure to guide the basic search mechanisms [48]. A special case of these is those that involve reinforcement learning and their variants [226,251,278,284]. In particular, Q-learning seems to be a very popular option in this regard [52,144,146,160,201,244,262,269,274].

We have also identified numerous recent combinations with mathematical programming techniques, such as linear programming [242], mixed integer linear

programming [1], constraint programming [11], dynamic programming [273], chance-constrained programming (in the form of an adaptive differential evolution algorithm with Q-learning) [144], or continuation Newton methods with deflation techniques for global optimization [163]. This is certainly the tip of the iceberg. Several techniques under the denomination of *matheuristics* can to some extent fall under the umbrella of the broad definition of MAs, since they are based on a population-based strategy with refinements using these mathematical programming methods. Other methods involve large neighborhood search which is explored via solving a mixed-integer programming subproblem (similarly, others use variable neighborhood search to provide exploration and rigorous local optimization of a population). Finally, there are several complete memetic algorithms [66] in which exact solvers are available to some of the agents in the population. In that way, one or more agents running branch and bound, or branch and cut and price method, for instance, are dedicated to solve large-scale integer programming problems, while other agents use independent search procedures guided by constructive heuristics or local search ones. We are confident that readers will recognize the memetic approach in some of these new procedures and reviewing all this material is a bit

out of the scope of this current review, but it shows a great promising new area of development for more powerful MAs now that computational resources allow these more complex search strategies.

Future-Generation Memetic Algorithms

Back in the days when MAs were just a nascent approach for optimization, different visions of what MAs would be in the future were foreseen. Among these, perhaps the one that has come closest to reality refers to the self-⋆ capabilities [23] of the paradigm and more precisely to self-generation properties. Early works envisioned that the algorithm could work on two timescales, one in which the solutions would be optimized and another in which the problem solving strategies used to optimize the solutions themselves would be optimized [180]. In essence, this has been a long standing goal in metaheuristics. It is widely acknowledged that designing an effective problem-solving technique is in itself a difficult task. Attempting to transfer a part of this design effort to the actual metaheuristic is just the logical course of action [65]—see, for example, the corpus of research in hyperheuristics [44, 67]. This latter approach is actually related to what has been termed meta-Lamarckian learning [196], a memetic approach in which a collection of local searchers is available and there is a decision-maker that decides which of them should be applied to specific solutions based on different criteria (e.g., the past performance of each local searcher, the adequacy of the current solution for being improved by a certain local searcher according to past experience, etc.). Multi-memetic or multi-meme algorithms provided a much more general approach [137, 138, 140]. In this approach, an encoding of a local searcher (ranging from the definition of the neighborhood or pivot rule used, up to a full algorithmic description of the procedure) is attached to each solution and evolves alongside it. Thus, the algorithm looks not only for improved solutions but also for algorithmic structures capable of improving the latter. The next natural step is to detach these memes from the genes and have them evolve in separate populations [220–222], paving the way for the emergence of complex structures of interacting memes [50]. An overview of adaptation in MAs is provided in [197]. This view of memes as explicit representations of problem-solving strategies that interact in a complex and dynamic way within an evolutionary context for optimization purposes leads to the notion of memetic computing [191, 198]—see [189] for a literature review on memetic computing.

Also related to the design of the problem solver, albeit not in an autonomic way, transfer learning and knowledge sharing are techniques that are being attempted, with varied results, to transfer knowledge between problem instances. Other more recent techniques suggest looking back at the transformation between problems, prototypical of the NP-completeness proofs, for instance, and using different transformations than the standard ones to speed up the convergence of memetic algorithms to optimal solutions. An interesting example can be found in [6] in which massive speedups have been obtained, thus allowing to solve very challenging

Hamiltonian cycle problems using a memetic algorithm for the TSP. In addition, other learning techniques are being used to predict suitable algorithm configurations or help design local search operators based on the identifying characteristics of the problem instance.

Another dimension along which some early ideas (far-fetched at their time) about MAs may become a reality is parallel computing. The deployment of metaheuristics in parallel and/or distributed environments is by no means new [4] and has been extensively used since the late 1980s; see, for example, [186, 232]. However, the continuous evolution of computational platforms is dragging these parallel modes along, forcing them to adapt to new scenarios. Thus, while early work often assumed dedicated local area networks, nowadays we have emerging computational environments such as peer-to-peer networks [174] and volunteer computing networks [215], which are much more pervasive, of a larger scale and inherently dynamic. The complex and dynamic structure of these computational substrates is undoubtedly a challenge. Fortunately, population-based metaheuristics have been shown to be intrinsically robust on a fine-grain scale [129] and can be endowed with appropriate churn-aware strategies if required [192]. They are therefore ripe for being deployed on these platforms to exploit the possibilities they offer. In this line—and connected to the previous discussion on meme evolution and interaction—some initial concepts revolving around "meme pools," that is, repositories of problem solving methods to be used synergistically, acquire a new scope more akin to service-oriented architectures [96]. Furthermore, to build on the idea of automated self-design of the MA requires the ability to keep or gather some sort of distributed knowledge about the state of the search and make design decisions on its basis. Some ideas from multi-agent systems and epistemic logic were proposed as potential tools for this purpose [59], but the concept is still largely unexplored.

There are a number of recent areas that we consider that are going to expand the types of MA we will see in the near future. One is the use of reinforcement learning within the memetic strategy. This could help to adaptively select or generate individual search operators for the agents based on a learning outcome from the previous search experience. This assumes that the strategy is not optimal and needs to be constantly varied over time. Another one is the use of either deep learning, symbolic regression, or continued fraction regression to approximate objective function (or guiding or fitness function) such that they can act as surrogate models in high-dimensional and computationally expensive instances of problems. Since the introduction of the CONCORDE algorithm for the TSP, it was clear that the use of dynamic programming algorithms can help optimally solve some tasks, such as finding the best possible offspring after a recombination step [62]. The exact optimization of these subproblems can give fantastic leaps of performance to memetic algorithms that also incorporate stochasticity in other parts of their design. There are also opportunities for the development of MAs (and GAs) on a small scale. Any use of recombination operators is naturally limited by the expectation that the recombination step will be performed many, many times during a run of the algorithm. This leads to the requirement that a recombination operator be able to be

implemented very efficiently. Traditionally, this would mean at most linear or close to linear time in the size of the individual (of course, ideally constant time). This immediately rules out the possibility of optimal recombination strategies for many problems, as such strategies are typically NP-hard. Parameterized complexity, for example, offers an opportunity to exploit the naturally arising parameters in many recombination strategies. If such parameters are small, or can be made small, then we may effectively reduce the complexity of optimal recombination to polynomial time [60, 83–85]. For further reading on the challenges raised by evolutionary approaches to optimization, many of the problems posed in [59] remain open.

In general, these trends discussed above lead to increasingly complex algorithmic architectures. In this context, and very much in the same vein as deep learning algorithms, which use multiple processing layers to learn data representations with multiple levels of abstraction [141], the notion of *deep memetic algorithm* [10] can be considered as an MA with multiple interconnected layers or components, each of them encapsulating the knowledge or tools required to tackle some computational issue or some problem specificity.

Conclusion

Since their primordial conception in the late 1980s, MAs have developed to become one of the most adaptable and flexible metaheuristic approaches available. Although many heuristic techniques perform well for some problems, the No-Free-Lunch Theorem [254] guarantees that their performance falters on the majority of problems. MAs, with their insistence on adaptability and utilitarianism (both on the part of the algorithm and the implementer), are free to exploit the performance of multiple approaches and choose the best suited for the problem at hand.

This adaptability, efficiency, and amenability to the current availability of large-scale parallelism, including traditional parallel architectures along with GPU computing, cloud, and peer-to-peer approaches, along with a tendency toward modularity in implementation, has led to their adoption across a broad range of fields with excellent results. Research on MAs has grown dramatically since its inception. With nearly 4000 academic papers published to date, the field is vibrant and dynamic. More importantly, MAs can be regarded as a methodological approach that can complement and cooperate with the many effective tools currently existing in the heuristic toolbox and can be helpful as a framework for articulating complex synergistic heuristics whenever the target problem thus requires.

Abstract

Particle swarm optimization has captivated the scientific community for three decades. Its effectiveness and efficiency have made it a significant metaheuristic approach in various scientific fields dealing with complex optimization problems. Its simplicity makes it accessible to nonexpert researchers, while its flexible operators and the ease of integrating new procedures allow its application to a wide range of problems with diverse characteristics. Additionally, its inherent decentralized nature facilitates easy parallelization, enabling it to leverage modern high-performance computing systems, effectively. The present work introduces the basic concepts of particle swarm optimization and presents several popular variants that have opened new research directions by incorporating novel ideas into the original algorithm. The focus is on conveying the essential information of these algorithms rather than delving into all the details. A comprehensive list of references and sources is provided for further inquiry, making this text a valuable starting point for researchers interested in the development and application of particle swarm optimization and its variants.

Keywords

Particle swarm optimization · Swarm intelligence · Metaheuristics · Nature-inspired algorithms · Stochastic search · Optimization · Computational intelligence

Introduction

Particle swarm optimization (PSO) was introduced in the pioneering works of Russell C. Eberhart and James Kennedy in 1995 [44, 80]. At that time, the widespread success of evolutionary algorithms (EAs) motivated researchers worldwide to develop and experiment with novel nature-inspired methods. Beyond the interest in genetic algorithm procedures that dominated EAs, new paradigms from nature became subjects of investigation. In this context, the hierarchically organized societies of simple organisms such as ants, bees, and fishes—known for their limited range of individual responses but fascinating collective behaviors—immediately attracted scientific interest.

Simulations of such organism populations exhibited traits of intelligent behavior and remarkable problem-solving capabilities [17]. The underlying mathematical models shared concepts with particle physics, enriched with elements from probability theory and stochastic processes. This theoretical background, along with

the notable potential for developing powerful optimization metaheuristics, led to the emergence of a new category of algorithms known as *swarm intelligence* (SI) [17, 45, 46].

PSO holds a prominent position among SI algorithms. It was inspired by simulators of social behavior that implemented rules such as neighbor velocity matching and acceleration by distance. These properties were sufficient to produce swarming behavior in groups of simple agents. The initial models were refined to fit the framework of optimization algorithms. The first PSO models introduced the innovation of using difference vectors among population members to sample new points in the search space. This approach diverged from the established procedures of EAs, which mostly relied on sampling new points from explicit probability distributions [163]. Nevertheless, it proved influential, as another algorithm with a similar structure, differential evolution [174], appeared in the literature almost concurrently with PSO. Additional advantages of PSO include the ease of adapting its operators and procedures to match the specific requirements of a problem, as well as its inherent decentralized structure that promotes parallelization.

PSO has rapidly gained wide recognition due to its effectiveness, efficiency, and easy implementation. This is evident from Fig. 1, which shows the number of scientific works including the term "particle swarm" in their titles from 1995 to 2024, as retrieved by the Scopus search engine in May 2024. The numbers encompass all sources indexed by Scopus, including journals, conferences, books, and other publications.

The present chapter aims to introduce the basic concepts of PSO and present several of its most influential variants, selected based on their novelty at the

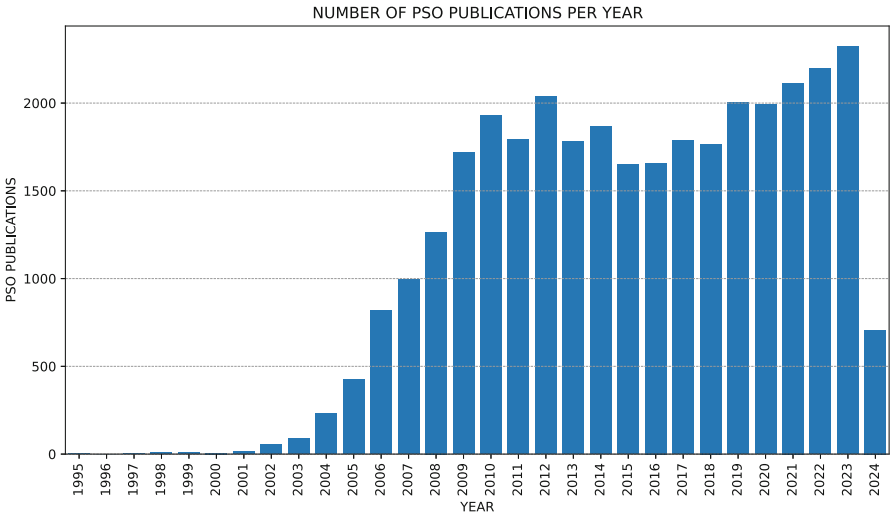

Fig. 1 Number of publications with the term "particle swarm" in the title. (Source: Scopus search engine, May 2024)

time of development, popularity, and potential to inspire new research directions. Naturally, the selection of variants cannot be exhaustive, nor can the presentation be comprehensive within the limited scope of a book chapter. Therefore, only basic information is provided here, while further details can be found in the cited references and sources. Thus, the present text is intended to serve as an "Ariadne's thread" for researchers interested in PSO.

The rest of the chapter is organized as follows: Section "Basic Model" introduces a basic PSO model that serves as a reference point for the variants discussed. Section "Convergence and Parameter Setting" outlines the theoretical properties of PSO, including convergence, parameter settings, special features, and performance-enhancing techniques. Section "Enhanced and Specialized PSO Variants" presents several essential PSO variants. Section "Applications and Further Resources" briefly comments on PSO applications. Finally, the chapter concludes in section "Conclusions." An appendix at the end of the text offers additional sources for further inquiry and experimentation with PSO.

Basic Model

PSO was primarily developed for optimization in real-valued search spaces. For this reason, the general d-dimensional bound-constrained optimization problem:

$$\min_{\vec{x} \in \mathcal{X}} f(\vec{x}), \tag{1}$$

where:

$$\mathcal{X} = \left[x_1^{\min}, x_1^{\max}\right] \times \cdots \times \left[x_d^{\min}, x_d^{\max}\right] \subset \mathbb{R}^d, \tag{2}$$

is henceforth considered as the reference problem for the presentation of the algorithm. In case of different search spaces, explicit definitions will be given. The only necessary assumption regarding the objective function is the availability of its value $f(\vec{x})$ for every point $\vec{x} \in \mathcal{X}$. Smoothness properties such as continuity and differentiability are not required.

The main search mechanism of PSO is based on a group of *search agents*, called *particles*, which iteratively move in the search space $\mathcal{X}$. The particles retain in an external memory the best positions they have ever visited in $\mathcal{X}$. Each particle's move is stochastically biased towards its own findings as well as promising regions of the search space discovered by the rest of the particles. This implicit information exchange scheme is responsible for the emergent convergence properties of the whole group, which is accordingly called a *swarm*.

Putting it formally, let A_i denote the ith particle (search agent) and let:

$$\mathcal{S} = \{A_1, A_2, \ldots, A_N\} \tag{3}$$

be a swarm of size N (the ordering of the particles is irrelevant). Also, let $I = \{1, 2, \ldots, N\}$ be the set of all particle indices, $D = \{1, 2, \ldots, d\}$ be the set of coordinate directions' indices, and t denote the algorithm's iteration number. Then, each particle can be defined by four essential elements:

$$A_i^{(t)} = \left\langle \vec{x}_i^{(t)}, \vec{v}_i^{(t)}, \vec{p}_i^{(t)}, NB_i^{(t)} \right\rangle, \qquad i \in I.$$

The first vector:

$$\vec{x}_i^{(t)} = \left(x_{i1}^{(t)}, x_{i2}^{(t)}, \ldots, x_{id}^{(t)} \right)^T \in \mathcal{X},$$

defines the *current position* of the particle in $\mathcal{X}$ at iteration t (with T denoting the transpose). Frequently, the term "particle" is used to define solely the current position $\vec{x}_i$. However, in our opinion, the use of this term to define the search agent with all its components promotes a more compact presentation, while it is aligned with the notation in similar SI algorithms (e.g., the term "ant" is similarly used to define search agents in ant colony optimization [17]).

The second vector:

$$\vec{v}_i^{(t)} = \left(v_{i1}^{(t)}, v_{i2}^{(t)}, \ldots, v_{id}^{(t)} \right)^T,$$

is an adaptable position shift, also called *velocity*, which is responsible for the particle's move. The third vector:

$$\vec{p}_i^{(t)} = \left(p_{i1}^{(t)}, p_{i2}^{(t)}, \ldots, p_{id}^{(t)} \right)^T \in \mathcal{X},$$

is the particle's *best position*, i.e., the best position it has ever visited in $\mathcal{X}$ up to iteration t. For the reference optimization problem of Eq. (1), the best position corresponds to the particle's previous position with the smallest objective value, i.e.:

$$\vec{p}_i^{(t)} = \arg \min_{\left\{ \vec{x}_i^{(k)},\ k \leqslant t \right\}} f\left(\vec{x}_i^{(k)} \right).$$

The best position plays the role of an attractor that biases the particle's velocity towards the promising regions it has discovered in $\mathcal{X}$. However, this sole information would render each particle an isolated search agent that produces trajectories solely by oscillating around its best visited points.

For this reason, in addition to its own discoveries, each particle has an implicit information-exchange mechanism with the members of a subset of the swarm, called its *neighborhood*. The neighborhood can be simply defined as a subset of the indices set I:

$$NB_i^{(t)} \subseteq I,$$

and its cardinality is usually called the *neighborhood size*. In most PSO variants, the best position in the neighborhood of the particle, i.e.:

$$\vec{p}_{g_i}^{(t)} = \arg \min_{\left\{\vec{p}_j^{(t)},\ j \in NB_i^{(t)}\right\}} f\left(\vec{p}_j^{(t)}\right),$$

is used as the second attractor for biasing the particle's search direction.

Based on the descriptions above, the basic update scheme for the particle current positions and velocities is componentwisely defined as follows:

$$v_{ij}^{(t+1)} = \chi\, v_{ij}^{(t)} + \mathcal{C}_1\left(p_{ij}^{(t)} - x_{ij}^{(t)}\right) + \mathcal{C}_2\left(p_{g_i j}^{(t)} - x_{ij}^{(t)}\right), \tag{4}$$

$$x_{ij}^{(t+1)} = x_{ij}^{(t)} + v_{ij}^{(t+1)}, \tag{5}$$

where $i \in I$ and $j \in D$. The scalar parameter χ is called the *inertia weight* or *constriction coefficient* and its role is discussed in section "Convergence and Parameter Setting." The stochastic terms $\mathcal{C}_1$ and $\mathcal{C}_2$ follow the uniform distribution:

$$\mathcal{C}_1 \sim \mathcal{U}(0, c_1), \qquad \mathcal{C}_2 \sim \mathcal{U}(0, c_2), \tag{6}$$

where c_1 and c_2 are predefined parameters, called the *acceleration constants*, which control the magnitude of attraction towards $\vec{p}_i^{(t)}$ and $\vec{p}_{g_i}^{(t)}$, respectively. The first difference term $\left(p_{ij}^{(t)} - x_{ij}^{(t)}\right)$ is called the *cognitive term* because it involves only the particle's own information. Correspondingly, the second difference term $\left(p_{g_i j}^{(t)} - x_{ij}^{(t)}\right)$ is called the *social term* since it involves information provided by other particles.

After updating all current positions, the best positions of the particles are also updated as follows:

$$\vec{p}_i^{(t+1)} = \begin{cases} \vec{x}_i^{(t+1)}, & \text{if } f\left(\vec{x}_i^{(t+1)}\right) \leqslant f\left(\vec{p}_i^{(t)}\right), \\ \vec{p}_i^{(t)}, & \text{otherwise,} \end{cases} \qquad i \in I. \tag{7}$$

The algorithm is executed until a predefined stopping condition is fulfilled. The presented basic PSO model is also known as the *canonical particle swarm* [79] and it is summarized in the pseudocode of Fig. 2. The discussion on initialization, search space boundary violation, and stopping conditions is postponed until the next section.

A number of issues arise regarding essential choices that need to be made prior to the application of the basic PSO algorithm. Specifically, the practitioner shall address the following questions:

1. How shall the parameters N, χ, c_1, c_2 be set?
2. How shall the neighborhoods be defined?

```
begin CanonicalPSO(𝒳, N, d)
  while stopping criterion not satisfied do
    for i = 1, ..., N do
      for j = 1, ..., d do
        Update v_ij by using Eq. (4)
        Check for velocity boundary violation and correct if needed
        Update x_ij using Eq. (5)
        Check for search space boundary violation and correct if needed
      end-for;
    end-for;
    for i = 1, ..., N do
      Update p⃗_i according to Eq. (7)
    end-for;
  end-while;
  return best solution;
end CanonicalPSO
```

Fig. 2 Pseudocode of the canonical PSO

3. How shall the boundary violations be handled?
4. How shall the swarm be initialized?
5. What stopping conditions shall be used?

Apparently, each decision can have significant impact on the algorithm's performance. For this reason, careful settings that take into consideration the potential impact on PSO dynamic are required.

A number of PSO variants have been developed on the basis of using alternative techniques for configuring the algorithm. Further discussion on these issues is provided in the next section. Canonical PSO has constituted the starting point for further developments and enhancements for more than two decades. Yet, it still remains a popular piece of the state-of-the-art due to its verified effectiveness and efficiency in numerous applications [140, 147, 164].

Convergence and Parameter Setting

Over the past decades, a large number of PSO variants have been proposed. In most cases, the motivation for further research stemmed from the necessity for more efficient variants that address the weaknesses of earlier versions. At the core of these enhancements are the answers to the fundamental questions posed in section "Basic Model" concerning the configuration and parameter settings of PSO.

In the following paragraphs, the most significant developments in PSO are highlighted, along with insights and suggestions for its configuration.

Early Precursors

Early precursors of PSO [44, 80] were not as sophisticated as the canonical PSO defined in section "Basic Model." In fact, they were mostly based on a simplified version of Eq. (4) with $\chi = 1$ and $NB_i = I$, i.e.:

$$v_{ij}^{(t+1)} = v_{ij}^{(t)} + \mathcal{C}_1 \left(p_{ij}^{(t)} - x_{ij}^{(t)} \right) + \mathcal{C}_2 \left(p_{gj}^{(t)} - x_{ij}^{(t)} \right), \tag{8}$$

$$x_{ij}^{(t+1)} = x_{ij}^{(t)} + v_{ij}^{(t+1)}, \tag{9}$$

with $i \in I$, $j \in D$, and $\vec{p}_g^{(t)}$ the best position (also called the *overall best*) discovered by any particle up to iteration t:

$$\vec{p}_g^{(t)} = \arg \min_{\left\{ \vec{p}_k^{(t)},\, k \in I \right\}} f\left(\vec{p}_k^{(t)} \right). \tag{10}$$

Obviously, the magnitude of the particles' position shifts depends on the values of the parameters c_1 and c_2 that determine the stochastic terms $\mathcal{C}_1$ and $\mathcal{C}_2$ in Eq. (6).

In [76] the trajectories of the particles were studied by further simplifying the system. The use of the previous velocity $\vec{v}_i^{(t)}$ in the update equation of the current velocity results in an oscillatory move of the particle around the weighted average of the two best positions:

$$\vec{\bar{p}}_i^{(t)} = \frac{1}{\mathcal{C}_1 + \mathcal{C}_2} \left(\mathcal{C}_1 \vec{p}_i^{(t)} + \mathcal{C}_2 \vec{p}_g^{(t)} \right). \tag{11}$$

The overall best particle, for which it holds that $\vec{p}_i^{(t)} = \vec{p}_g^{(t)}$, updates its velocity as follows:

$$v_{ij}^{(t+1)} = v_{ij}^{(t)} + \mathcal{C} \left(p_j^{(t)} - x_{ij}^{(t)} \right), \tag{12}$$

where $j \in D$, $\mathcal{C} = \mathcal{C}_1 + \mathcal{C}_2$, and $\vec{p}^{(t)} = \vec{p}_g^{(t)}$.

Considering the trivial case of a single particle and a constant best position $\vec{p}$, it was shown [76] that the particle's trajectory becomes highly dependent on the values of $\mathcal{C}$, as shown in Fig. 3. Values higher than 4.0 are detrimental for the algorithm's convergence, since the velocity can grow arbitrarily large (notice the scaling difference in the vertical axis for $\mathcal{C} = 4.0$ in Fig. 3). This problem was called the *swarm explosion effect* and it was verified also in [121, 122], emphasizing the necessity for a control mechanism to amplify the velocities.

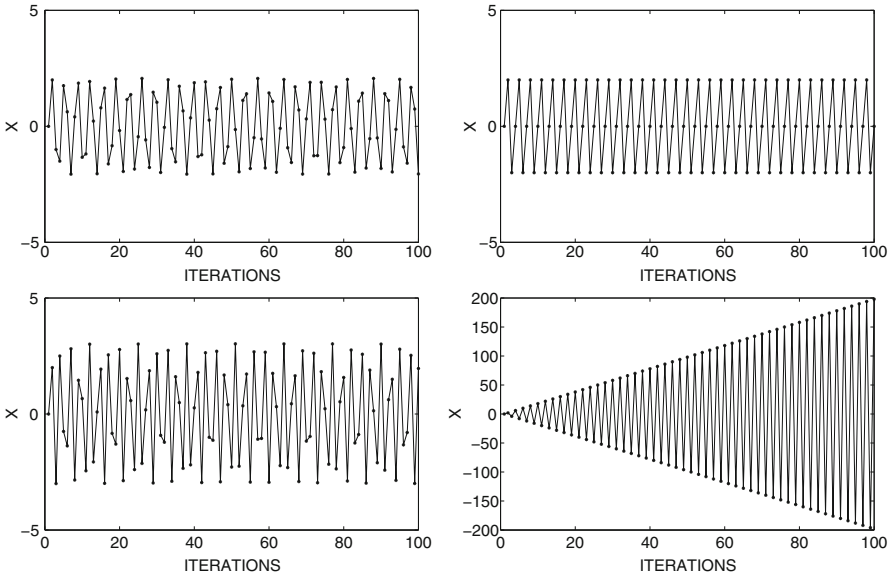

Fig. 3 Particle trajectory for fixed value $\mathcal{C} = 2.5$ (upper left), 3.0 (upper right), 3.5 (lower left), and 4.0 (lower right)

Velocity Clamping and Inertia Weight

The swarm explosion effect in early PSO variants led to the first significant improvements i.e., *velocity clamping* and the introduction of the *inertia weight*. Since the main problem was the arbitrary grow of the velocities, a straightforward solution was their explicit restriction in acceptable values. Specifically, a maximum value $v_j^{\max}$ was imposed on the absolute value of each velocity component:

$$-v_j^{\max} \leqslant v_{ij} \leqslant v_j^{\max}, \quad \text{for all } i \in I, j \in D.$$

If a velocity component v_{ij} escapes from the prescribed interval, it is set equal to the violated boundary value. This way, the particles are prohibited from taking large steps that may frequently send them out of the search space. The value $v_j^{\max}$ can be arbitrarily defined by the user or be set as a fraction of the search space along the jth coordinate direction:

$$v_j^{\max} = \lambda_j \left(x_j^{\max} - x_j^{\min} \right), \qquad j \in D, \ \lambda_j \in (0, 1). \tag{13}$$

Naturally, prior information regarding the number and density of the minimizers of the objective function facilitates the proper setting of the maximum velocity. For example, in cases of extremely large number of minimizers or very narrow regions of attraction around them, smaller velocities can offer better search accuracy [170]. Equation (13) is used also in modern PSO variants, usually assuming identical λ_j for all $j \in D$. Velocity clamping is applied in line 5 of the pseudocode of canonical PSO in Fig. 2.

Although velocity clamping has proved to be effective in hindering divergence, it can hardly produce convergent behavior of the particles. Obviously, convergence can be achieved by gradually diminishing the velocities. This way, the particles would perform decreasing oscillations around the attractors and, eventually, settle on a point. This was achieved by introducing an inertia weight w on the velocity update of Eq. (8) [168], as follows:

$$v_{ij}^{(t+1)} = w v_{ij}^{(t)} + \mathcal{C}_1 \left(p_{ij}^{(t)} - x_{ij}^{(t)} \right) + \mathcal{C}_2 \left(p_{gj}^{(t)} - x_{ij}^{(t)} \right), \tag{14}$$

$$x_{ij}^{(t+1)} = x_{ij}^{(t)} + v_{ij}^{(t+1)}. \tag{15}$$

The parameter w shall be properly set such that the impact of the previous velocity $\vec{v}_i^{(t)}$ declines during the execution of the algorithm. This can be achieved by setting either a fixed value $w \in (0, 1)$ or assuming a decreasing scheme between two extreme values $w_{\max}$ and $w_{\min}$, during the algorithm's run. For example, if $t_{\max}$ is a predefined maximum number of iterations, a linearly decreasing inertia weight may take values as follows:

$$w(t) = w_{\max} - \frac{t}{t_{\max}} \left(w_{\max} - w_{\min} \right).$$

Figure 4 illustrates swarm diversity in terms of the average standard deviations per coordinate direction of the particles, without inertia weight as well as with a linearly decreasing inertia weight, for a well-known optimization problem.

Velocity clamping and the introduction of inertia weight boosted PSO research due to the improved convergence properties of the derived variants. Both these improvements are still used in modern PSO approaches [140]. Further information and enhancements can be found in relevant works [21, 99, 156, 183, 207].

Stability Analysis

The empirical analysis of particle trajectories in [76, 121, 122] and their implications in PSO modeling and parameter setting motivated the systematic theoretical investigation of the algorithm. The first breakthrough appeared in 2002 due to M. Clerc and J. Kennedy who conducted a convergence and stability analysis of the algorithm in multidimensional search spaces [29].

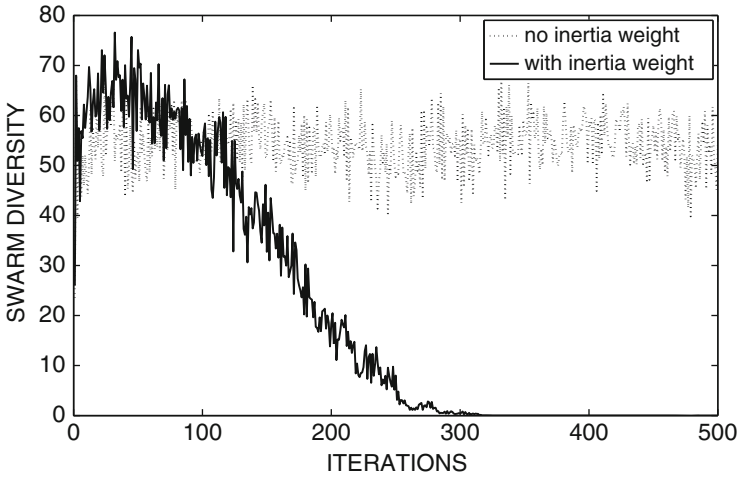

Fig. 4 Swarm diversity with (solid line) and without (dotted line) inertia weight while minimizing the 2-dimensional Rosenbrock function using 20 particles with $c_1 = c_2 = 2$, $v^{\max} = 50$, $w_{\max} = 1.2$, and $w_{\min} = 0.1$

The authors used as starting point the early model of Eqs. (8) and (9) with velocity clamping. The initial model was manipulated according to Eq. (12) and further simplified by assuming 1-dimensional particles without stochasticity, i.e., the two stochastic acceleration terms were assumed to be equal and fixed, $\mathcal{C}_1 = \mathcal{C}_2 = \mathcal{C}$. After dropping some indices and making proper algebraic manipulations, the 1-dimensional update rules can be rewritten in the form [29]:

$$v^{(t+1)} = v^{(t)} + \mathcal{C} y^{(t)}, \tag{16}$$

$$y^{(t+1)} = -v^{(t)} + (1 - \mathcal{C}) y^{(t)}, \tag{17}$$

where $y^{(t)} = \bar{p} - x^{(t)}$, with $\bar{p}$ being the (currently fixed) aggregate best position defined in Eq. (11) (note that all vectors currently collapse to scalars). This discrete system can be written also in matrix form:

$$P_{t+1} = M\, P_t = M^t\, P_0,$$

where:

$$P_t = \begin{pmatrix} v^{(t)} \\ y^{(t)} \end{pmatrix}, \qquad M = \begin{pmatrix} 1 & \mathcal{C} \\ -1 & 1 - \mathcal{C} \end{pmatrix}.$$

Then, the behavior of the system depends on the eigenvalues of M, which are given as:

$$\lambda_{1,2} = 1 - \frac{\mathcal{C}}{2} \pm \frac{\sqrt{\mathcal{C}^2 - 4\mathcal{C}}}{2}.$$

The previously identified critical value $\mathcal{C} = 4$ (recall Fig. 3) [76, 122] appears again as the limit between the case of two different real eigenvalues, one eigenvalue of multiplicity 2, and two complex conjugate eigenvalues $\lambda_{1,2}$.

For the case of $\mathcal{C} \in (0, 4)$, the eigenvalues become complex [29]:

$$\lambda_1^t = \cos(t\theta) + i\ \sin(t\theta), \qquad \lambda_2^t = \cos(t\theta) - i\ \sin(t\theta),$$

and the system exhibits cyclic behavior for $\theta = (2\kappa\pi)/t$. On the other hand, $\mathcal{C} > 4$ does not produce cyclic behavior. Instead, it is proved that P_t has monotonically increasing distance from the origin [29]. Finally, the limit case $\mathcal{C} = 4$ produces (*i*) oscillatory behavior $P_{t+1} = -P_t$ if P_0 is an eigenvector of M or (*ii*) linearly increasing or decreasing $\|P_t\|$ for $y_0 > 0$ or $y_0 < 0$, respectively.

The investigation was further extended to the continuous case by transforming the simplified model into the following recurrent equation [29]:

$$\vec{v}^{(t+2)} + (\mathcal{C} - 2)\vec{v}^{(t+1)} + \vec{v}^{(t)} = 0,$$

which in turn becomes a second-order differential equation:

$$\frac{\partial^2 \vec{v}}{\partial t^2} + \ln(\lambda_1\lambda_2)\frac{\partial \vec{v}}{\partial t} + \ln(\lambda_1)\ln(\lambda_2)\vec{v} = 0,$$

where λ_1 and λ_2 are the solutions of:

$$\lambda^2 + (\mathcal{C} - 2)\lambda + 1 = 0.$$

Thus, the quantities $\vec{v}^{(t)}$ and $\vec{y}^{(t)}$ take the following general form [29]:

$$\vec{v}^{(t)} = c_1\lambda_1^t + c_2\lambda_2^t,$$
$$\vec{y}^{(t)} = \left(c_1\lambda_1^t(\lambda_1 - 1) + c_2\lambda_2^t(\lambda_2 - 1)\right)/\mathcal{C}.$$

The parameters c_1 and c_2 depend on the initial vectors $\vec{v}^{(0)}$ and $\vec{y}^{(0)}$. Following a similar analysis as for the discrete case shows that the system explosion depends on whether the condition $\max\{|\lambda_1|, |\lambda_2|\} > 1$ holds or not [29].

Subsequently to the analysis above, the employed simplified model was generalized in order to approximate the actual model of PSO. A number of extended models were accordingly developed and studied in [29]. The outcome of the study was an effective model, namely, the canonical PSO model of Eqs. (4) and (5), accompanied with a proposed parameter setting [29]:

$$\chi = 0.729, \quad c_1 = c_2 = 1.49, \tag{18}$$

derived from closed-form formulae that retain the convergence behavior of the system. This parameter setting has become the most common choice in off-the-shelf PSO approaches in numerous applications [140].

The theoretical analysis of PSO in [29] was succeeded by new theoretical studies such as [67, 73, 148, 161, 190, 195]. These developments increased our understanding of the algorithm's dynamic. Also, they added merit that, along with its easy implementation and the reported excellent results in various applications, eventually placed PSO in a salient position among other established population-based optimization algorithms such as genetic algorithms and evolution strategies. Moreover, the motion dynamic of the canonical PSO model motivated approaches that spare function evaluations by taking advantage of the continuous particle movement [196].

Concept of Neighborhood

Information exchange among the particles is a concept of major importance in PSO. In the canonical PSO of Eqs. (4) and (5), the ith particle adopts the best position $\vec{p}_{g_i}$ of its neighborhood NB_i as an attractor for its move, besides its own best position. This way, the neighborhood structure determines communication channels among the particles and, consequently, the information flow in the swarm. Without communication, collective behavior cannot emerge and the swarm is downgraded to a group of isolated search agents with limited search capabilities.

Obviously, the characteristics of the neighborhood play a major role in PSO dynamics [77, 175]. The neighborhood structure defines the communication channels among the particles, while neighborhood size controls the influence of the swarm on each particle. Since the particles are attracted towards the best positions of their neighbors, it is easily comprehended that neighborhoods with a large number of particles and dense communication channels are more inclined towards intensification of search around the best detected positions in the search space. This is ascribed to the rapid diffusion of the discovered good solutions to the particles and their consequent attraction towards them.

However, this also renders the particles prone to get stuck in deep local minima that are possibly detected in early iterations of the algorithm's run. Such minima in the swarm are typically updated less frequently than shallow minima. Hence, they can impose stronger attraction on the particles. On the other hand, less crowded neighborhoods with sparse connections among the particles exhibit slower information diffusion in the swarm. In this case, the particles are gradually acquainted with good solutions, retaining higher diversity and exploration capability.

The discussion above suggests that a proper neighborhood configuration shall be carefully selected, as it is highly responsible for the diversification versus intensification (also known as exploration vs. exploitation) trade-off of the algorithm. To this end, prior knowledge on the studied problem can be valuable. For example, smooth functions with one or few minima may be properly handled through intensification-oriented neighborhoods, while rugged landscapes with a plethora of minimizers,

possibly dispersed at distant parts of the search space, may require exploration-oriented approaches.

In early PSO variants, each particle was assumed to be connected with all the rest, i.e.:

$$NB_i^{(t)} = I, \quad \text{for all } i \in I,$$

and the selected best position from the neighborhood was the swarm's overall best defined in Eq. (10). Also, the neighborhoods were time-invariant, i.e., they remained unchanged throughout the algorithm's run (hence we can neglect t in $NB_i^{(t)}$ notation). This PSO model was also called the *global PSO model* or simply the *gbest model*. The interconnection among the particles can be elegantly represented by undirected graphs where nodes denote the particles and edges denote communication channels. The corresponding structure is called the *neighborhood topology*. Apparently, the gbest model corresponds to a fully connected graph since all particles communicate with each other. This topology is illustrated in the left part of Fig. 5.

The tendency of the gbest model to rapidly converge towards the most promising detected solutions and easily get stuck in local minima led to further experimentation with sparsely connected models. The outcome of these efforts was the *local PSO model* or *lbest model*, which assumes neighborhoods that are proper subsets of I:

$$NB_i \subset I, \quad \text{for all } i \in I.$$

The most effective and easily implemented topology of this form is the *ring*, which is depicted in the right part of Fig. 5. In this scheme, the particles are assumed to lie on a ring according to their indices, i.e., neighboring particles have neighboring indices. Then, each particle is set to communicate only with its immediate neighbors on the ring. The number of neighbors for each direction (front and back) is called *neighborhood radius*. Thus, a neighborhood of radius $r < N$ of the ith particle is defined as the set:

$$NB_i = \{i - r, i - r + 1, \ldots, i - 1, i, i + 1, \ldots, i + r - 1, i + r\},$$

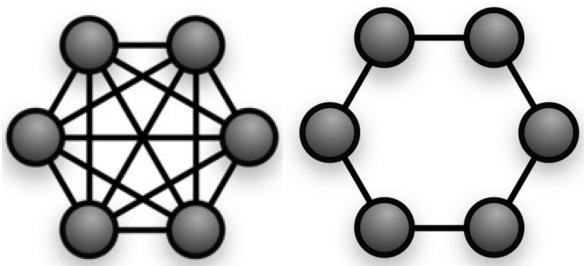

Fig. 5 Graphical representation of the fully connected (left) and the ring (right) neighborhood topology

where the indices are assumed to recycle after index N, i.e.:

$$j = \begin{cases} j, & \text{if } 1 \leqslant j \leqslant N, \\ j \bmod N, & \text{if } j > N, \\ N - |j|, & \text{if } j < 1, \end{cases} \qquad \text{for all } j \in NB_i.$$

Differences in diversity between the gbest model and the lbest with ring topology of radius $k = 1$ is indicatively depicted in Fig. 6 for a single run on a well-known optimization test problem.

The ring topology has become a standard for lbest PSO implementations due to its successful application in various problems [140]. There is also a multitude of alternative topologies that have drawn attention, such as random [175], hierarchical [63], and dynamic [24], but with limited number of applications. Also, the concept of neighborhood has offered motivation for the development of new PSO variants with sophisticated computational budget allocation based on the information carried by the neighborhoods rather than the particles [173].

Initialization, Stopping Conditions, and Boundary Violation

A basic requirement in the design and development of stochastic optimization algorithms such as PSO is their robustness under random initialization in the search space. In practice, this implies that mild perturbations on random initial positions of the particles shall correspond to similar performance profiles of the algorithm.

In benchmarking studies, it is commonly assumed that there is no information available regarding the problem at hand. This is usually called the *black-box optimization problem*. In such cases, there is no reason for purposely biasing particle initialization in specific areas of the search space. Consequently, random and uniform initialization of the particles is the typical procedure followed in most studies, i.e.:

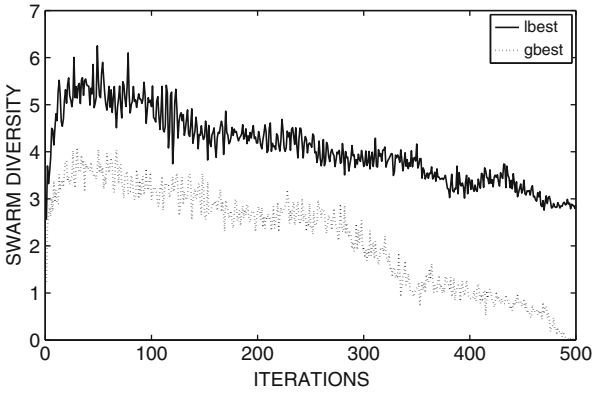

Fig. 6 Swarm diversity for the lbest (solid line) and gbest (dotted line) PSO model on the 10-dimensional Rastrigin function using 20 particles

$$x_{ij}^{(0)} = p_{ij}^{(0)} \sim \mathcal{U}\left(x_j^{\min}, x_j^{\max}\right), \qquad \text{for all } i \in I, j \in D.$$

Accordingly, the velocities are randomly initialized as follows:

$$v_{ij}^{(0)} \sim \mathcal{U}\left(-v_j^{\max}, v_j^{\max}\right), \qquad \text{for all } i \in I, j \in D.$$

Naturally, if there is prior information regarding promising regions of the search space, the distributions can be properly adapted to favor the sampling of particles in those regions.

The effect of initialization has been studied in a number of works for different PSO variants [33, 40, 49, 61, 134, 157, 181, 210], offering further insight and suggestions for specialized initialization in specific applications. Nevertheless, random initialization remains the standard approach also due to (*i*) its minor implementation effort and (*ii*) the availability of uniform random number generators in almost all programming languages and hardware platforms.

In contrast to initialization, which is based on problem characteristics, termination conditions are rather user-dependent and resource-dependent [140]. The most common termination criteria that can be found in the relevant literature are as follows:

1. Convergence in search space
2. Convergence in function values
3. Limitations in computational budget
4. Search stagnation

The first two stopping criteria entail information on the position of the global minimizer or its objective function value, respectively. Naturally, this information is not always available. However, in some cases relevant bounds can be estimated for the solution or its objective function value. Then, the user can set the algorithm to stop as soon as it reaches those bounds with a prespecified tolerance. The underlying stopping condition can have the following form:

$$\texttt{IF} \quad \left(\left\|\vec{p}_g^{(t)} - \vec{x^*}\right\| \leqslant \varepsilon_x \quad \texttt{OR} \quad \left\|f_g^{(t)} - f^*\right\| \leqslant \varepsilon_f\right) \texttt{ THEN STOP}$$

where $\vec{x}^*$ and f^* are the targeted solution vector and function value, respectively, and ε_x, ε_f, are the corresponding user-defined tolerances.

The last two stopping criteria in the above list are more common than the first two in PSO literature. Computational budget limitations are typically imposed by the maximum available time that can be spent for solving a problem. This quantity can be explicitly expressed either as wall-clock/CPU time or as the number of function evaluations performed by the algorithm. For benchmarking purposes, the latter is preferable since even the same algorithm executed on the same computer

at different time instances may result in different running times. This is due to irrelevant procedures that may be concurrently running on the same computer.

On the other hand, the search stagnation criterion can prematurely stop the algorithm even if the computational budget is not exceeded. Successful application of this criterion is based on the existence of a proper stagnation measure. Typically, the number of subsequent iterations without improvement of the best solution and/or the dispersion of the particles' current (or best) positions in the search space are used for this purpose.

The aforementioned criteria can be combined in joint stopping rules as follows:

$$\texttt{IF} \quad (t \geqslant t_{\max} \quad \texttt{OR} \quad t_{\text{fail}} \geqslant t_{\max\text{fail}} \quad \texttt{OR} \quad dv(t) < dv_{\min}) \ \texttt{THEN STOP}$$

where t stands for the iteration number, t_{fail} is the number of subsequent non-improving iterations, and $dv(t)$ is a measure of particle dispersion (for example, the average standard deviation per coordinate component). Overall, the user shall pay special attention to the selection of stopping criteria in order to avoid unintentional premature termination of the algorithm. Further developments on this issue can be found in [85].

Another topic of interest lies in handling boundary violations. More specifically, after the particle update of Eqs. (4) and (5), some components of the new position may violate the corresponding boundaries of the search space. The most popular approach to restrict the particle in the search space is to set the violated components equal to the value of the violated boundary:

$$x_{ij}^{(t)} = \begin{cases} x_j^{\max}, & \text{if } x_{ij}^{(t)} > x_j^{\max}, \\ x_j^{\min}, & \text{if } x_{ij}^{(t)} < x_j^{\min}, \\ x_{ij}^{(t)}, & \text{otherwise}, \end{cases} \tag{19}$$

while simultaneously setting the corresponding velocity component $v_{ij}^{(t)}$ equal to zero. Different boundary handling techniques such as absorbing, bouncing, and cyclic search spaces are also used although less frequently. A survey on such techniques can be found in [123].

Performance-Enhancing Techniques

The canonical PSO has offered satisfactory performance in various problems. However, it may exhibit declining performance in special problems such as the detection of multiple local/global minima, constrained, or discrete problems. In such cases, the user can either change the algorithm by introducing new, specialized operators or incorporate external techniques to tackle the problem's peculiarities.

There are established techniques that have been successfully used with canonical PSO. Transformations of the objective function have been used for the alleviation of local minima and the detection of multiple minimizers. Rounding has been used

for solving discrete optimization problems, while penalty functions can address constrained optimization problems. In the following paragraphs, basic techniques that have been combined with the canonical PSO model are presented. Specialized variants of the algorithm with ad hoc operators for similar purposes are presented in subsequent sections.

Alleviating Local Minimizers

In problems with a multitude of local and/or global minimizers, stochastic optimization algorithms such as PSO may approximate a different minimizer in each independent run. Frequently, the detected solutions are sub-optimal, while the user either needs more than one such solution or requires the globally best one. *Multistart techniques* where the algorithm is subsequently restarted from different initial conditions have been proposed for such cases and discussed in classical optimization texts [189]. However, these approaches cannot guarantee that an already detected minimizer will be avoided after restarting the algorithm.

An alternative approach consists of transforming the objective function into a new one that excludes the already detected solutions. Well-known examples of this type are the *filled functions* [51]. Similar techniques have been developed and successfully used with PSO [129, 134]. The *stretching* technique consists of a two-stage transformation of the objective function:

$$F_1(\vec{x}) = f(\vec{x}) + \gamma_1 \|\vec{x} - \vec{x}^*\| \left[1 + \text{sign}\left(f(\vec{x}) - f(\vec{x}^*)\right)\right], \tag{20}$$

$$F_2(\vec{x}) = F_1(\vec{x}) + \gamma_2 \frac{1 + \text{sign}\left(f(\vec{x}) - f(\vec{x}^*)\right)}{\tanh\left(\mu\left(F_1(\vec{x}) - F_1(\vec{x}^*)\right)\right)}, \tag{21}$$

where $f(\vec{x})$ is the original objective function, $\vec{x}^*$ is the best detected solution of the algorithm so far, and the sign function is defined as follows:

$$\text{sign}(\vec{z}) = \begin{cases} -1, & \text{if } \vec{z} < 0, \\ 0, & \text{if } \vec{z} = 0, \\ +1, & \text{if } \vec{z} > 0. \end{cases}$$

As soon as a local minimizer (or generally a sub-optimal solution) is detected, the first transformation stretches the objective function upwards, while the second one transforms the detected solution $\vec{x}^*$ into a local maximizer. Under proper parameter setting, stretching has the ability to remove higher local minima than the detected solution $\vec{x}^*$ while leaving unchanged all lower minima as well as the global one. This is illustrated in Fig. 7 for a 1-dimensional instance of a well-known test function. Thus, it can be very useful in problems with a multitude of local minima that can mislead the algorithm after its re-initialization. Of course, if a better solution is found in a subsequent application of the algorithm, it can simply replace $\vec{x}^*$ in Eqs. (20) and (21).

It shall be noted that the application of stretching on a global minimizer eliminates all other minimizers. For this reason, stretching is inappropriate for

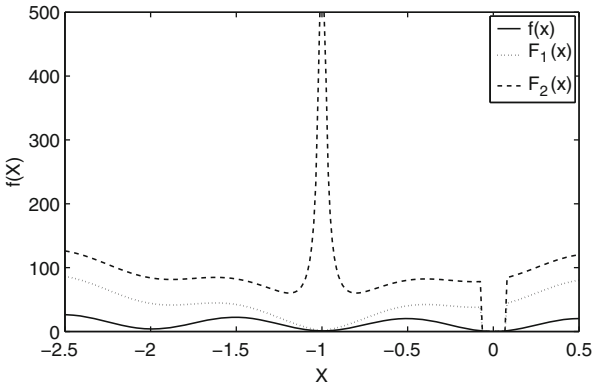

Fig. 7 The stretching technique applied on the 1-dimensional Rastrigin function for the local minimizer $\vec{x}^* = -1$ and parameters $\gamma_1 = \gamma_2 = 20$, $\mu = 0.1$

detecting multiple global minimizers (see next section for a relevant technique that tackles this problem). Also, similarly to its filled function predecessors, stretching may introduce new local minima around the point of application $\vec{x}^*$ [135]. This is also known as the *Mexican hat effect* and has been addressed in [204] through proper parameterization. Naturally, the application of stretching is not limited to the canonical PSO, as it can be incorporated to any PSO variant, even to different algorithms [57].

Detecting Multiple Minimizers

Deflection [106] is a technique that works similarly to stretching but it has only local effect on the objective function. Thus, it can be applied in cases where multiple solutions of the problem are needed. Deflection has been used with PSO for detecting many global and/or local minimizers with promising results [135].

Let $f(\vec{x})$ be the objective function and $\vec{x}_1^*, \ldots, \vec{x}_k^*$, be k previously detected solutions. Then, the objective function is transformed as follows:

$$F(\vec{x}) = \frac{f(\vec{x})}{\prod_{i=1}^{k} T_i\left(\vec{x}, \vec{x}_i^*, \lambda_i\right)}, \tag{22}$$

where T_i is defined as [135]:

$$T_i\left(\vec{x}, \vec{x}_i^*, \lambda_i\right) = \tanh\left(\lambda_i \|\vec{x} - \vec{x}_i^*\|\right), \tag{23}$$

and λ_i are relaxation parameters, $i = 1, 2, \ldots, k$. The idea behind this transformation is similar to stretching, i.e., the transformation of detected solutions into local maximizers. However, deflection changes the objective function only locally, around the point of application. The magnitude of change depends on the parameters λ_i that need proper tuning. Also, deflection requires strictly positive objective functions in order to achieve the desirable effect. In cases where the problem at hand is not

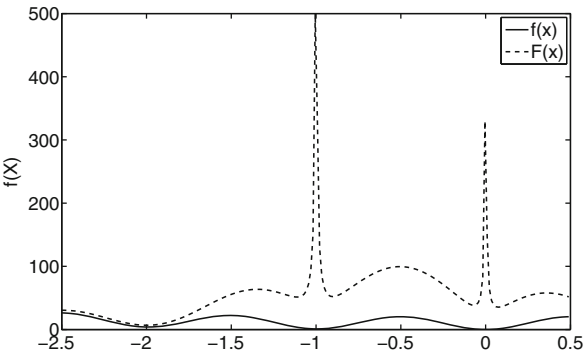

Fig. 8 The deflection technique applied on the 1-dimensional Rastrigin function for the local minimizer $\vec{x}_1^* = -1$ as well as the global minimizer $\vec{x}_g^* = 0$ and parameters $\lambda_1 = \lambda_g = 1$

strictly positive, it can be simply shifted to positive values by using $f(\vec{x}) + c$ instead of $f(\vec{x})$, with a sufficiently large bias $c > 0$.

Figure 8 illustrates deflection for the 1-dimensional instance of the Rastrigin test function. The Mexican hat effect appears also in deflection, although its impact can be controlled with proper selection of the parameters λ_i. Moreover, deflection can be combined with a *repulsion* technique that prevents the particles from visiting the neighborhoods of detected solutions and possibly get trapped in the artificially introduced local minima [135, 140]. Combined with PSO, deflection offered previously undetected solutions in computationally challenging problems [170].

Penalty Functions for Constrained Optimization Problems

In constrained optimization problems, the objective function is accompanied by a set of constraints that need to be satisfied at the final solution. In general, such a problem is defined as:

$$\min_{\vec{x} \in \mathcal{X}} f(\vec{x}) \quad \text{subject to} \quad C_i(\vec{x}) \leqslant 0, \quad i = 1, 2, \ldots, k, \tag{24}$$

where $C_i(\vec{x})$ are inequality constraints. Different constraint types can be transformed in the above form as follows:

$$C_i(\vec{x}) \geqslant 0 \;\Leftrightarrow\; -C_i(\vec{x}) \leqslant 0,$$
$$C_i(\vec{x}) = 0 \;\Leftrightarrow\; C_i(\vec{x}) \geqslant 0 \;\text{ and }\; C_i(\vec{x}) \leqslant 0.$$

Penalty functions have been widely used in constrained problems. The main goal is to penalize all solutions that lie in the infeasible region, such that the algorithm will be implicitly directed into the feasible search space.

The general form of a penalty function for the problem of Eq. (24) is defined as:

$$F(\vec{x}) = f(\vec{x}) + P(\vec{x}),$$

where:

$$P(\vec{x}) = \begin{cases} \alpha > 0, & \text{if } C_i(\vec{x}) > 0 \text{ for at least one } i, \\ 0, & \text{otherwise.} \end{cases}$$

In the simplest case, the penalty term $P(\vec{x})$ can be a constant for all infeasible solutions. This is not always a suitable choice since it neglects the magnitude of constraint violation. Also, it does not provide any information to the algorithm regarding the distance of the infeasible solutions from the feasible region. Thus, the penalty term is recommended to take into consideration the number of violated constraints as well as the degree of violation. Moreover, the magnitude of penalties can be time-varying, starting with mild penalties in early iterations and becoming strict in later ones.

The canonical PSO has been combined with a penalty function defined as follows [132, 212]:

$$F(\vec{x}) = f(\vec{x}) + h(t)H(\vec{x}), \tag{25}$$

where:

$$H(\vec{x}) = \sum_{i=1}^{k} \theta\left(q_i(\vec{x})\right) q_i(\vec{x})^{\gamma(q_i(\vec{x}))}, \tag{26}$$

and:

$$q_i(\vec{x}) = \max\left\{0, C_i(\vec{x})\right\}, \qquad i = 1, 2, \ldots, k.$$

The weight $h(t)$ controls the impact of the penalty term $H(\vec{x})$ with respect to iteration t. The degree of violation is accounted in $q_i(\vec{x})$ and manipulated with the power function $\gamma(q_i(\vec{x}))$ as well as with the multistage assignment function $\theta\left(q_i(\vec{x})\right)$. An alternative penalty function was proposed in [31]:

$$F(\vec{x}) = f(\vec{x}) + H(\vec{x}),$$

with:

$$H(\vec{x}) = w_1 H_{\text{NVC}}(\vec{x}) + w_2 H_{\text{SVC}}(\vec{x}),$$

where $H_{\text{NVC}}(\vec{x})$ is the number of violated constraints and:

$$H_{\text{SVC}}(\vec{x}) = \sum_{i=1}^{k} \max\left\{0, C_i(\vec{x})\right\},$$

is the sum of violations. The weights w_1 and w_2 can be either fixed or time-varying and they determine the importance of each penalty term.

The canonical PSO updates its best positions according to Eq. (7) by comparing objective values, solely. However, it is commonly desirable to allow only feasible best positions in order to avoid oscillations of the particles in the infeasible space. On top of that, the final solution shall be feasible and, thus, the particles shall eventually concentrate their search efforts in the feasible region.

In the penalty functions presented above, it is still possible that an infeasible solution has lower function value than a feasible one and, therefore, be preferable for inclusion in the best positions. In order to prevent such undesirable inclusions, a set of rules can be imposed in the selection procedure:

1. Between feasible solutions, the one with the smallest objective value is preferable.
2. Between a feasible and an infeasible solution, the feasible one is always preferable.
3. Between two infeasible solutions, the one with the smallest penalty term $H(\vec{x})$ is preferable.

These selection rules combined with the penalty function approach have been used with PSO in constrained optimization problems with promising results [115, 146].

Solving Discrete Problems

The canonical PSO was initially introduced as a continuous optimization method and its operators are designed to work on real-valued search spaces. In Mathematical Programming literature, integer optimization problems can also be solved through continuous algorithms by extending the discrete problem to a continuous one and rounding the solutions to the nearest integers. Such approaches have been used with branch and bound algorithms combined with quadratic programming solvers [87, 108].

A similar approach has been used also with PSO for solving integer problems [86]. Specifically, the particles are let to assume real vectors in their current positions, although they are rounded to the nearest integer vector when evaluated with the objective function. Also, the rounded integer vectors are preferable as best positions, since the final solution shall be integer. Putting it formally, if $\vec{x}_i = (x_{i1}, x_{i2}, \ldots, x_{id})^T$ is the ith particle, then its objective value is $f(\vec{x}_i) = f(\vec{z}_i)$, where the integer vector $\vec{z}_i = (z_{i1}, z_{i2}, \ldots, z_{id})^T$ is defined as:

$$z_{ij} = \lfloor x_{ij} + 0.5 \rfloor, \qquad i \in I, \ j \in D.$$

Rounding has effectively worked for various problems of integer and mixed integer type [86, 115, 126, 146]. Note that, in mixed integer problems, no additional representation effort is needed to distinguish between real and discrete coordinate

components. The algorithm can work by simply rounding the coordinate components that correspond to integer variables.

An issue that shall be taken into consideration when rounding is that the velocities may become rather small, resulting in search stagnation due to the inability of producing different integer components. This potential deficiency can be tackled by restarting the current positions of the particles (and possibly the best positions except the overall best) as soon as stagnation is identified. Alternatively, gradual truncation of the particles in less decimal digits can be applied as the number of iterations increases [86].

Another interesting category of problems with discrete search spaces comprises of *permutation problems*. In such problems, the main goal is the detection of an optimal permutation of fixed elements (numbers, items, indices), and they are frequently met in Combinatorics and Operations Research [16]. Such problems can be tackled through real-valued algorithms by using the *smallest position value* (SPV) representation scheme [184]. Specifically, let an ordered set:

$$\mathcal{Z} = \{Z_1, \ldots, Z_d\}$$

consisting of elements $Z_i, i \in D$. Then, the components of a real-valued particle are defined as numerical weights that denote the priority of the corresponding elements according to a predefined mapping. For example, the components of the ith particle $\vec{x}_i = (x_{i1}, x_{i2}, \ldots, x_{id})^T$ can be mapped as follows:

$$\begin{array}{lcccc} \text{Ordered list of elements:} & Z_1 & Z_2 & \cdots & Z_d \\ & \updownarrow & \updownarrow & & \updownarrow \\ \text{Particle components (weights):} & x_{i1} & x_{i2} & \cdots & x_{id} \end{array}$$

Then, the weights (particle components) are sorted in ascending order and the corresponding permutation is received by rearranging the elements, accordingly:

$$\begin{array}{rcccc} \text{Sorted particle components (weights):} & x_{ik_1} & x_{ik_2} & \cdots & x_{ik_d} \\ & \updownarrow & \updownarrow & & \updownarrow \\ \text{Corresponding permutation:} & Z_{k_1} & Z_{k_2} & \cdots & Z_{k_d} \end{array}$$

Thus, each particle corresponds to a permutation received after sorting its components. The goal of PSO is to find the appropriate weights that produce optimal or near-optimal permutations. A commonly used search space for the particles in such problems is $\mathcal{X} = [0, 1]^d$, i.e., the weights are all assumed to lie in the interval $[0, 1]$. Obviously, there is an infinite number of weight vectors that correspond to each permutation, since the produced permutation depends only on the relative ordering of the weights rather than their actual decimal values. SPV has been successfully combined with PSO in various permutation problems [83, 137, 185, 186].

Enhanced and Specialized PSO Variants

This section is devoted to PSO variants that stemmed from the canonical PSO as improvements or specialized modifications for specific problem types. The pluralism in literature renders a complete presentation impossible. For this reason, a selection was made based on the novelty introduced by each method as well as its influence for further developments. Chronological order of the methods' appearance was retained whenever possible.

Binary PSO

The first *binary PSO* (BPSO) variant was developed in 1997 [81]. Instead of using rounding for transforming the real-valued parameters into binary ones, the algorithm introduced a new interpretation of the velocities. More specifically, each component of the velocity vector is considered as the input of a sigmoid function that determines the state (0 or 1) of the corresponding coordinate component of the particle. Thus, the velocity $\vec{v}_i$ of the ith particle is updated according to Eq. (4), while its current position is updated as follows [81]:

$$x_{ij}^{(t)} = \begin{cases} 1, & \text{if } \mathcal{R} < S\left(v_{ij}^{(t)}\right), \\ 0, & \text{otherwise,} \end{cases} \tag{27}$$

for all $i \in I$, $j \in D$, where $\mathcal{R} \sim \mathcal{U}(0, 1)$ is a random variable. The sigmoid is defined as:

$$S(x) = \frac{1}{1 + \exp(-x)},$$

clamping the velocity in the range $[0, 1]$ so it can be translated to a probability value. The rest of the algorithm follows the basic rules of the canonical PSO.

The algorithm was demonstrated on a set of test problems with promising results. It also exhibits conceptual similarities with reinforcement learning approaches as it was shown in [93]. BPSO is still considered as the basis for the development of contemporary ad hoc binary PSO variants for specific applications [14, 19, 70, 119, 151, 211].

Guaranteed Convergence PSO

The *guaranteed convergence PSO* (GCPSO) was introduced in 2002 [193] based on the observation that small velocities can prohibit the convergence of the gbest PSO with inertia weight. This is ascribed to the cancellation of the attraction forces of

the overall best particle towards its best positions, along with small velocities that essentially immobilize it in the long run.

The problem was solved by modifying the position update of the overall best particle, denoted with the index g, as follows [193]:

$$x_{gj}^{(t+1)} = p_{gj}^{(t)} + \chi\, v_{gj}^{(t)} + \rho^{(t)}(1 - 2\mathcal{R}), \tag{28}$$

where $j \in D$, $\rho^{(t)}$ is a *scaling factor*, and $\mathcal{R} \sim \mathcal{U}(0, 1)$ is a random variable. The rest of the particles are updated with the standard rules of Eqs. (4) and (5). The scaling factor is dynamically adjusted according to the number of consecutive successes and failures in improving the overall best:

$$\rho^{(t+1)} = \begin{cases} 2\,\rho^{(t)}, & \text{if } m_{\text{suc}}^{(t)} > T_{\text{suc}}, \\ 0.5\,\rho^{(t)}, & \text{if } m_{\text{fail}}^{(t)} > T_{\text{fail}}, \\ \rho^{(t)}, & \text{otherwise}, \end{cases}$$

where $m_{\text{suc}}^{(t)}$ and $m_{\text{fail}}^{(t)}$ are counters of the consecutive successes and failures at iteration t, respectively, and T_{suc}, T_{fail} are the corresponding user-defined thresholds. The counters are reset whenever the row of consecutive successes or failures is interrupted by a failure or success, respectively.

Convergence of GCPSO was proved and the values $\rho^{(0)} = 1$, $T_{\text{suc}} = 15$, and $T_{\text{fail}} = 5$ were recommended in [193], where GCPSO was shown to be very promising on typical benchmark problems.

Bare Bones PSO

The *bare bones PSO* (BBPSO) was introduced in 2003 [78] as a simplification of the canonical PSO. Its main feature is the replacement of the velocity update of Eq. (4), with Gaussian sampling around the best positions. Specifically, the current position of each particle is updated by sampling the Gaussian distribution:

$$x_{ij}^{(t+1)} \sim \mathcal{N}\left(\mu_{ij}^{(t)}, \sigma_{ij}^{2\,(t)}\right), \tag{29}$$

where:

$$\mu_{ij}^{(t)} = \frac{1}{2}\left(p_{gj}^{(t)} + p_{ij}^{(t)}\right), \qquad \sigma_{ij}^{2\,(t)} = \left|p_{gj}^{(t)} - p_{ij}^{(t)}\right|,$$

and g stands for the index of the overall best particle. The rest of the canonical PSO procedures such as the best position update and boundary violations handling are retained.

BBPSO aimed at offering a very simple, parameter-free PSO variant. Its properties were studied in [124, 150] and it was extended for applications in various scientific fields [15, 20, 84, 192, 219–221].

Fully Informed PSO

The *fully informed PSO* (FIPS) was introduced in 2004 [111] as a variant of the canonical PSO that extends the concept of neighbor influence. In FIPS each particle is influenced by all its neighbors and not only the best one. The particle update scheme of Eqs. (4) and (5) is replaced by the following update rule:

$$x_{ij}^{(t+1)} = x_{ij}^{(t)} + \chi \left(x_{ij}^{(t)} - x_{ij}^{(t-1)} \right) + \sum_{k \in NB_i} \mathcal{C}_k \left(p_{kj}^{(t)} - x_{ij}^{(t)} \right), \tag{30}$$

where $i \in I$, $j \in D$, NB_i is the ith particle's neighborhood of size s_i, and $\mathcal{C}_k \sim \mathcal{U}(0, c/s_i)$ is a random variable. Applying the analysis of [29] in FIPS, the default parameter setting of Eq. (18) becomes $\chi = 0.729$, $c = 2.992$ [79].

FIPS introduced a novel point of view for the concept of neighborhood. The social influence was enhanced, providing additional attractors to the particles. The outcome is a stochastic move around a stochastic average of the best positions of all neighbors. However, this also implies the dependency of the algorithm's performance on the selected neighborhood topology. For example, in the gbest PSO model where the neighborhood of each particle is the whole swarm, the particle move tends to become nearly random [79].

A multitude of neighborhood structures (more than 1000) were tested in [111] and interesting conclusions were derived regarding the potential of FIPS to improve the canonical PSO. Potential superiority was also verified in the use of FIPS to address a clustering problem [109].

Quantum PSO

Quantum PSO (QPSO) was introduced in 2004 [177], placing the algorithm into a new framework. In QPSO, the swarm is considered as a quantum system where each particle possesses a quantum state while moving in a *delta potential well* (DPW) towards a position $\vec{p}$. The quantum state depends on the employed wave function.

Borrowing from previous PSO analyses such as [29], the aforementioned position $\vec{p}$ is defined as in Eq. (11). Depending on the considered potential, different variants of QPSO can be defined. Three established approaches are the following [112, 177, 179]:

1. Delta potential well:

$$\vec{x}_i^{(t+1)} = \vec{p}^{(t)} \pm \frac{\ln\left(\frac{1}{\mathcal{R}}\right)}{2\,q\,\ln(\sqrt{2})} \left\| \vec{x}_i^{(t)} - \vec{p}^{(t)} \right\|, \tag{31}$$

2. Harmonic oscillator:

$$\vec{x}_i^{(t+1)} = \vec{p}^{(t)} \pm \frac{\sqrt{\ln\left(\frac{1}{\mathcal{R}}\right)}}{0.47694\,q} \left\| \vec{x}_i^{(t)} - \vec{p}^{(t)} \right\|, \tag{32}$$

3. Square well:

$$\vec{x}_i^{(t+1)} = \vec{p}^{(t)} + \frac{0.6574}{\xi\,q} \cos^{-1}\left(\pm\sqrt{\mathcal{R}}\right) \left\| \vec{x}_i^{(t)} - \vec{p}^{(t)} \right\|, \tag{33}$$

where $i \in I, \mathcal{R} \sim \mathcal{U}(0, 1)$ is a random number, and ξ, q are user-defined parameters. Despite its identified parameter sensitivity, the algorithm has been embraced from the scientific community and also extended to a number of interesting applications [23, 30, 53, 62, 68, 101, 208, 218].

Unified PSO

The *unified PSO* (UPSO) was introduced in 2004 [136] as a PSO variant that harnesses the gbest and lbest PSO models in a unified scheme. The motivation behind its development lies in the inherent intensification properties of the gbest model and the corresponding diversification properties of the lbest model. Thus, their combination can form variants with different trade-offs of these two properties.

UPSO is based on the update equations of the canonical PSO with constriction coefficient. Specifically, let:

$$\mathcal{L}_{ij}^{(t+1)} = \chi\, v_{ij}^{(t)} + \mathcal{C}_1 \left(p_{ij}^{(t)} - x_{ij}^{(t)}\right) + \mathcal{C}_2 \left(p_{g_i j}^{(t)} - x_{ij}^{(t)}\right), \tag{34}$$

denote the velocity update of Eq. (4) for the lbest PSO model, where g_i is the index of the best neighbor of the ith particle and $j \in D$. Also, let:

$$\mathcal{G}_{ij}^{(t+1)} = \chi\, v_{ij}^{(t)} + \mathcal{C}_3 \left(p_{ij}^{(t)} - x_{ij}^{(t)}\right) + \mathcal{C}_4 \left(p_{gj}^{(t)} - x_{ij}^{(t)}\right), \tag{35}$$

be the corresponding velocity update for the gbest PSO model, i.e., g denotes the overall best particle. Then, the basic UPSO scheme is defined as [136]:

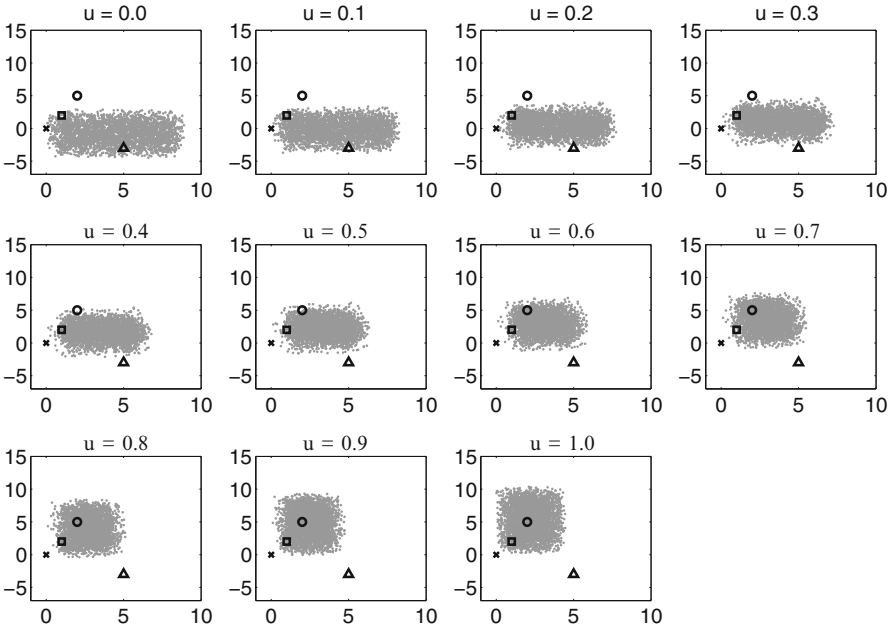

Fig. 9 The distribution of 3000 possible new positions (light grey points) of the 2-dimensional particle $\vec{x}_i = (0, 0)^\top$ (cross) with own best position $\vec{p}_i = (1, 2)^\top$ (square), neighborhood best position $\vec{p}_{g_i} = (5, -3)^\top$ (triangle), and overall best $\vec{p}_g = (2, 5)^\top$ (circle), for different values of $u \in [0, 1]$. For simplicity, the velocity vector is set to $\vec{v}_i = (0, 0)^\top$

$$v_{ij}^{(t+1)} = u\, \mathcal{G}_{ij}^{(t+1)} + (1 - u)\, \mathcal{L}_{ij}^{(t+1)}, \tag{36}$$

$$x_{ij}^{(t+1)} = x_{ij}^{(t)} + v_{ij}^{(t+1)}, \tag{37}$$

where $i \in I$, $j \in D$, and $u \in [0, 1]$ is a user-defined parameter called the *unification factor*, which controls the influence of the gbest and lbest term. Obviously, $u = 0$ corresponds to the lbest model, while $u = 1$ corresponds to the gbest model. All intermediate values define UPSO variants that combine the diversification/intensification properties of the two models. Figure 9 illustrates the distribution of new positions of a particle for different values of the unification factor.

In addition to the main UPSO model, an alternative with increased stochasticity was proposed in [136]. It came in two forms, namely:

$$v_{ij}^{(t+1)} = \mathcal{R}\, u\, \mathcal{G}_{ij}^{(t+1)} + (1 - u)\, \mathcal{L}_{ij}^{(t+1)}, \tag{38}$$

which is mostly based on the lbest model, and:

$$v_{ij}^{(t+1)} = u\, \mathcal{G}_{ij}^{(t+1)} + \mathcal{R}\,(1-u)\, \mathcal{L}_{ij}^{(t+1)}, \tag{39}$$

which is based on the gbest model [136]. The stochastic parameter $\mathcal{R} \sim \mathcal{N}(\mu, \sigma^2)$ is normally distributed and imitates the mutation operators in evolutionary algorithms.

Theoretical properties of UPSO were studied in [26, 136], while a thorough investigation of its parameter setting and adaptation was offered in [138]. Its performance has been studied on various problems with promising results [6, 52, 56, 83, 116, 117, 140, 191].

Cooperative PSO

Cooperative population-based algorithms [152] promote cooperation between population members towards a common goal. Cooperation can be either explicit through direct communication among them or implicit through a shared memory where information is deposited. Cooperation can be considered in a multi-population or single-population framework. In the first case, each population usually operates on a subspace of the original search space, e.g., on one coordinate direction of the solution vector. Its individuals carry partial solutions that are combined with those of the other populations, forming complete solutions. In the second case, the individuals usually carry complete solution information that is combined with the rest by using special recombination schemes [152].

In the context of PSO, one of the first notable attempts to design a *cooperative PSO* (CPSO) took place in 2004 [194]. This CPSO consists of d swarms (where d denotes the problem's dimension), each one comprising N_k particles, $k \in D$, i.e., according to Eq. (3):

$$\mathcal{S}^{[1]} = \left\{A_1^{[1]}, \ldots, A_{N_1}^{[1]}\right\}, \quad \ldots, \quad \mathcal{S}^{[d]} = \left\{A_1^{[d]}, \ldots, A_{N_d}^{[d]}\right\}.$$

Each swarm probes only one coordinate direction of the solution vector, applying any PSO variant (canonical PSO was used in the specific version). The evaluation of the particles with the objective function requires complete d-dimensional solutions. Thus, two main issues need to be addressed:

1. How shall particles from different swarms be selected to form complete solutions?
2. How shall particles be awarded or penalized for their contribution in solution quality?

These critical decisions have direct impact on the algorithm's performance and, thus, require special care.

In [194] two alternative schemes were proposed. The first scheme, denoted as CPSO-S$_k$, introduced a *context vector* $\vec{z}^*$ for the evaluation of the particles. This vector constitutes an external memory where each swarm $\mathcal{S}^{[k]}$ participates with its

1-dimensional overall best at the corresponding kth direction component:

$$\vec{z}^* = \left(\vec{p}_g^{[1]}, \vec{p}_g^{[2]}, \ldots, \vec{p}_g^{[d]}\right),$$

where $\vec{p}_g^{[k]}$ is the overall (1-dimensional) best of the kth swarm [194]. Then, the evaluation of the ith particle of the kth swarm is performed by replacing the kth swarm's best in $\vec{z}^*$ with its own information:

$$f\left(\vec{x}_i^{[k]}\right) = f\left(\vec{z}_{[i,k]}^*\right),$$

where:

$$\vec{z}_{[i,k]}^* = \left(\vec{p}_g^{[1]}, \ldots, \vec{p}_g^{[k-1]}, \vec{x}_i^{[k]}, \vec{p}_g^{[k+1]}, \ldots, \vec{p}_g^{[d]}\right),$$

where $\vec{x}_i^{[k]}$ is the current position of the particle under evaluation. Naturally, instead of the overall bests of the swarms, randomly selected best positions can be used in the context vector. Also, swarms of higher dimension can be used. However, both these alternatives can radically change the algorithm's performance. Obviously, the context vector $\vec{z}^*$ constitutes the best approximation of the problem's solution in CPSO-S$_k$.

The second variant from [194], denoted as CPSO-H$_k$, combines CPSO-S$_k$ with the canonical PSO and applies each algorithm alternatively at each iteration. In addition, information exchange between the two algorithms was considered by sharing half of the discovered solutions between them. The experimental assessment revealed that both CPSO-S$_k$ and CPSO-H$_k$ are promising, paving the way for further developments such as [66, 176, 180, 203, 222].

Comprehensive Learning PSO

The *comprehensive learning PSO* (CLPSO) [91] was proposed in 2006 as an alternative for alleviating premature convergence in gbest PSO that can be attributed to the use of the overall best solution in velocity update. In CLPSO, each particle can use the best position of any other particle to individually update the velocity vector components, according to a probabilistic scheme.

More specifically, the velocity update of Eq. (4) is replaced with the following [91]:

$$v_{ij}^{(t)} = \chi\, v_{ij}^{(t)} + \mathcal{C}\left(p_{q_{[i,j]}j} - x_{ij}^{(t)}\right), \tag{40}$$

where $j \in D$, $i \in I$, and $q_{[i,j]} \in I$ is the index of the particle that is used for the update of the jth velocity component of the ith particle. Naturally, this particle can be either the ith particle itself or another particle from the swarm. This decision is

probabilistically made according to predefined probabilities $\rho_1, \rho_2, \ldots, \rho_d$:

$$q_{[i,j]} = \begin{cases} i, & \text{if } \mathcal{R} \leqslant \rho_j, \\ \text{TOURN}\left(I'\right), & \text{otherwise,} \end{cases} \qquad \text{for all } j \in D,$$

where $\mathcal{R} \sim \mathcal{U}(0,1)$ is a uniformly distributed random variable, $I' = I \setminus \{i\}$, and $\text{TOURN}\left(I'\right)$ is an index selected from I' through *tournament selection* [91]. The latter requires the random selection of two particles from the set I'. The best between them, i.e., the one with smallest objective value, is the winner and participates in the update of v_{ij}.

In the case where $q_{[i,j]} = i$, for all $j \in D$, one of the components of v_{ij} is randomly selected and determined anew by using another particle. The indices $q_{[i,j]}$ are updated for each particle after a number of non-improving iterations. CLPSO has been extensively studied in [91]. A number of improvements, modifications, and applications in various fields have been proposed in [54,55,59,94,104,205,215,217].

TRIBES

The *TRIBES* algorithm was proposed in 2006 [27] as a novel PSO variant with self-adaptation capability. It is based on a special communication scheme between the neighborhoods, and it can admit the update rules of any PSO variant. In TRIBES, the ith particle is called *informant* of the jth particle if it shares its best position for the update of the latter. Accordingly, a *tribe* can be defined as a subset of the swarm, where each one of its members is informant of all the rest in the same tribe. Obviously, the swarm is the union set of all tribes.

Each tribe must have at least one communication channel with another tribe. In other words, between any two particles there shall be at least one path that connects them in the neighborhood's graph [27]. Also, the algorithm is self-adaptive, i.e., existing tribes can be deleted or new tribes can be generated. Hence, the communication channels between tribes change dynamically. The goodness criterion for the tribes is related to the performance of their members-particles. More specifically, they are characterized as *neutral* if they have not improved their best position in the last iteration, *good* if improvement was achieved in the last iteration, and *excellent* if improvement was achieved for more than one consecutive iterations. Accordingly, a tribe TR that contains s_{TR} particles is characterized as follows:

$$TR \text{ is } \begin{cases} \text{good}, & \text{if } N_{TR}^{\text{good}} > \mathcal{R}, \\ \text{bad}, & \text{otherwise,} \end{cases}$$

where N_{TR}^{good} is the number of good particles in tribe TR, and $\mathcal{R}$ is a randomly selected integer in $\{0, 1, \ldots, s_{TR}\}$. Moreover, additional rules are applied for the generation or elimination of particles and tribes:

1. The worst particle of the best tribe can be eliminated, inheriting its communication channels to the best particle of its tribe.
2. If a tribe consists of only one particle, it is eliminated if it has an informant with better performance.
3. Each tribe that was characterized as "bad" generates two new particles. The first one is randomly generated within the whole search space. The second one is randomly generated in the sphere centered on the best position of the best informant of the tribe's best particle, with radius equal to the distance between the latter and the sphere's center.

Adaptations are recommended to occur after a number of iterations so that the algorithm can deploy its dynamic [27]. Promising results were received with TRIBES under various settings [27]. Although TRIBES is a rather controversial PSO variant, it has contributed towards the development of self-adaptation mechanisms [33–35], while it was also enhanced for various applications [39, 171].

Niching PSO

Niching algorithms are applied on multimodal optimization problems where the main goal is the identification of multiple global/local minima. In such problems, the algorithms must be capable of identifying minima and retaining them until the end of the search. Although transformation techniques such as the one presented in section "Detecting Multiple Minimizers" can be used for this purpose, alternative algorithmic models that do not use external procedures have been developed.

Two efficient *niching PSO* approaches are the *speciation-based PSO* (SPSO) [128] and the *fitness Euclidean-distance ratio PSO* (FERPSO) [88]. In SPSO, the swarm is divided into subswarms, which are considered as species represented by the dominant (best) particle in the subswarm. A niche radius is also specified to define the size of species. Special procedures are applied for determining species and their seeds, while the global best particle is replaced by the species best or species seed. Also, all particles in the same species use the same neighborhood best at each iteration.

On the other hand, FERPSO is based on the lbest PSO model of Eqs. (4) and (5) [88], where the neighborhood's best $\vec{p}_{g_i}$ is taken as the particle that maximizes the *fitness Euclidean-distance ratio* (FER), defined as:

$$FER_{i,k} = \frac{\alpha \left[f(\vec{p}_i) - f(\vec{p}_k) \right]}{\| \vec{p}_i - \vec{p}_k \|}, \qquad k \in I,$$

where the scaling factor α is defined as:

$$\alpha = \frac{\sqrt{\sum_{l=1}^{d} \left(x_l^{\max} - x_l^{\min}\right)^2}}{f\left(\vec{p}_g\right) - f\left(\vec{p}_w\right)},$$

with $\vec{p}_g$ and $\vec{p}_w$ being the swarm's best and worst particles, respectively [88]. The effectiveness of both SPSO and FERPSO has led to further enhancements such as [89, 90, 100, 153, 162].

Standard PSO

The *standard PSO* (SPSO) was introduced in an attempt to define a baseline for the development and assessment of new PSO variants. Although there have been various versions (2006, 2007, and 2011), only SPSO-2011 [28] is presented here as it cures a number of weaknesses identified in the previous versions.

A feature of SPSO-2011 is the independence on the coordinate system. Let:

$$\mathcal{P}_{ij}^{(t)} = x_{ij}^{(t)} + \mathcal{C}_1 \left(p_{ij}^{(t)} - x_{ij}^{(t)}\right), \tag{41}$$

$$\mathcal{L}_{ij}^{(t)} = x_{ij}^{(t)} + \mathcal{C}_2 \left(p_{g_i j}^{(t)} - x_{ij}^{(t)}\right), \tag{42}$$

with $j \in D$, be two points for the ith particle that are a little "beyond" its own best position and its neighborhood best position, respectively, at iteration t. Then, the center of gravity between the two points and the current position of the particle is defined as:

$$\mathcal{G}_i^{(t)} = \frac{1}{3}\left(\vec{x}_i^{(t)} + \mathcal{P}_i^{(t)} + \mathcal{L}_i^{(t)}\right). \tag{43}$$

A new point $\vec{x'}_i^{(t)}$ is randomly (not necessarily uniformly) generated in the hypersphere $\mathcal{H}_i^{(t)}$ with center $\mathcal{G}_i^{(t)}$ and radius equal to its distance from the actual $\vec{x}_i^{(t)}$:

$$\vec{x'}_i^{(t)} \in \mathcal{H}_i^{(t)}\left(\mathcal{G}_i^{(t)}, \left\|\mathcal{G}_i^{(t)} - \vec{x}_i^{(t)}\right\|\right). \tag{44}$$

Then, the update equations of SPSO-2011 are given as follows [28]:

$$v_{ij}^{(t+1)} = \chi\, v_{ij}^{(t)} + x'^{(t)}_{ij} - x_i^{(t)}, \tag{45}$$

$$x_{ij}^{(t+1)} = x_{ij}^{(t)} + v_{ij}^{(t+1)}, \tag{46}$$

where $i \in I$ and $j \in D$. The rest of the algorithm follows the Canonical PSO approach. The particles are bounded in the search space according to Eq. (19). The

algorithm's parameters were studied in [216], while a thorough theoretical analysis was provided in [18].

Hybrid PSO

Hybrid optimization methods represent an advanced approach that integrates various techniques to leverage their respective strengths and mitigate their weaknesses. These methods are particularly beneficial for addressing complex and high-dimensional optimization challenges, as they enhance efficiency, accuracy, and robustness, yielding superior solutions compared to a singular method.

Although PSO is effective for many problems, its performance can be further enhanced by integrating different methods. A common approach involves hybridizing PSO with gradient-based methods, which utilize gradient information to enhance the search process and improve convergence rate. In the MEMPSODE software package [197], PSO was integrated with gradient-based optimization and direct search approaches.

Metaheuristics such as differential evolution (DE), simulated annealing (SA), ant colony optimization (ACO), variable neighborhood search (VNS), and genetic algorithms (GA) have been effectively integrated with PSO [7, 65, 107, 110, 172], enhancing its global search capability while preventing it from being trapped in local optima. The integration of different metaheuristics can be accomplished in various ways. For instance, in HGAPSO, a hybrid PSO-GA approach, the top half of the best-performing individuals (called elites) in the population is treated as a swarm, and it is improved through PSO at each iteration. The remaining half of the population is generated by applying crossover and mutation operations to the enhanced elites [72]. The method aims at deriving benefits from the search capability of PSO as well as the diversity introduced by genetic operators, resulting in a robust optimization strategy.

In recent years, integrating PSO with machine learning techniques has led to significant advancements in optimization. The relevant literature can be broadly divided into two categories, namely, (*i*) studies where a machine learning method enhances PSO and (*ii*) studies where PSO improves the performance of machine learning techniques. In the former category, machine learning methods are utilized to find promising areas for further exploration, dynamically adjust the parameters of PSO, or initialize the particles [92, 141, 169]. These methods result in more intelligent and adaptive optimization strategies, thereby significantly enhancing the efficiency and effectiveness of the search process.

In the latter category, PSO is utilized to enhance feature selection, optimize the hyperparameters of machine learning models, or fine-tune neural network architectures [3, 213]. The last case, referred to as neural architecture search (NAS), is considered to be a crucial advancement because, nowadays, there is ongoing need for more sophisticated network designs that can adapt to diverse and complex datasets while minimizing computational costs. Recently, PSO was applied to optimize a convolutional neural network (CNN) block to produce

specialized architectures for image classification [198]. The optimized block was repeated multiple times to enhance the capacity of the final network, resulting in promising outcomes in terms of classification accuracy, number of parameters, and computational cost. Furthermore, the transferability of the evolved block on two additional datasets was considered, demonstrating its successful adaptation to similar domains and promising results on different datasets.

Hybrid methods have offered a robust and adaptable approach for addressing complex optimization problems, leading to more efficient and successful solutions. A multitude of PSO hybridizations for diverse problems is reported in [2, 9, 107, 172, 206].

Memetic PSO

The term *memetic algorithm* [118] is used to describe hybrid algorithms that consist of population-based metaheuristics with additional local search or learning mechanisms. Early *memetic PSO* (MPSO) schemes appeared in 2005 [97], hybridizing PSO with the Solis and Wets local search approach. Later, different schemes were proposed using alternative local search algorithms such as the random walk with direction exploitation and the Hooke and Jeeves method [143, 144]. Further enhancements and applications can be found in [10, 60, 95, 102, 114, 167, 201].

Besides the choice of the appropriate local search algorithm, which is mostly problem-dependent, additional decisions shall be taken prior to the application of MPSO [140]:

1. When to apply local search?
2. Where to apply local search?
3. What computational budget shall be devoted to local search?

A straightforward choice is the application of local search on each new best position of the particles and/or on their current positions at each iteration until a local minimum is detected. Naturally, this approach would require excessive computational resources that are hardly available in practice.

For this reason, the following strategies were proposed in [143] after empirical evaluations on established test problems:

(S1) Application of local search on the overall best position $\vec{p}_g$, whenever it changes.
(S2) For each best position $\vec{p}_i$, $i \in I$, local search is applied with a predefined probability $\rho > 0$.
(S3) Local search is applied both on $\vec{p}_g$ and some randomly selected best positions $\vec{p}_i, i \in I$.
(S4) Local search is applied on $\vec{p}_g$ as well as on the best positions $\vec{p}_i$ that lie in adequate distance from $\vec{p}_g$, e.g., $\|\vec{p}_g - \vec{p}_i\| > \varepsilon$, where $\varepsilon > 0$ is a predefined distance usually defined as a fraction of the search space.

Shannon's information entropy, employed as a measure of information diversity of the swarm, was employed in [142] along with the above schemes in order to make swarm-level decisions on the application of local search. Further details and extensive results are reported in [140], where it was shown that MPSO outperforms the canonical PSO (as expected), but also its gbest model could outperform the lbest model of canonical PSO. The latter result suggests that local search applied as above can be beneficial for both PSO's intensification and diversification properties.

Opposition-Based PSO

The opposition-based algorithms are based on the concept of opposite point [155]. If $\vec{x} = (x_1, \ldots, x_d)^T$ is a point in the search space $\mathcal{X}$ defined as in Eq. (2), then its opposite is defined as a point $\vec{x'} = (x'_1, \ldots, x'_d)^T$ with $x'_j = x_j^{\min} + x_j^{\max} - x_j$, for all $j \in D$. Evaluating both points simultaneously and keeping the best one can accelerate the optimization procedure [155].

This scheme was adapted in the framework of PSO, producing the *generalized opposition-based PSO* (GOPSO) [202]. In GOPSO, there are two swarms, $\mathcal{S}$ and $\mathcal{S}'$, comprising the particles and their opposites, respectively. The initial positions $\vec{x}_i^{(0)}$, $i \in I$, of $\mathcal{S}$ are randomly initialized, while for $\mathcal{S}'$ the initial positions $\vec{x'}_i^{(0)}$ are obtained as follows [202]:

$$x'^{(0)}_{ij} = \mathcal{R}\left(\alpha_j^{(0)} + \beta_j^{(0)}\right) - x_{ij}, \tag{47}$$

where $i \in I$, $j \in D$, $\mathcal{R} \sim \mathcal{U}(0, 1)$, and $\alpha_j^{(0)} = x_j^{\min}$, $\beta_j^{(0)} = x_j^{\max}$. Subsequently, both swarms are evaluated and merged. The N best particles are then selected to form the initial swarm of GOPSO.

At each iteration, a probabilistic decision is taken. The algorithm, with a user-defined probability $\rho > 0$, either chooses to update the boundaries $\alpha_j^{(t)}$, $\beta_j^{(t)}$, as follows [202]:

$$\alpha_j^{(t)} = \min_i \left\{x_{ij}^{(t)}\right\}, \qquad \beta_j^{(t)} = \max_i \left\{x_{ij}^{(t)}\right\}, \tag{48}$$

or applies the update equations of the canonical PSO defined in Eqs. (4) and (5). The procedure continues with the best positions update of Eq. (7). The new overall best undergoes also a mutation procedure where its components are perturbed with random numbers following a Cauchy distribution [202].

Experimental results suggested that GOPSO can be competitive to other PSO variants [202]. A number of different opposition-based approaches have been proposed in various application fields [4, 37, 42, 74, 75, 103, 165, 188, 200, 223].

PSO in Noisy Environments

Noisy problems habitually arise in real-world engineering applications. The use of measurement instruments or approximations through inaccurate mathematical models impose uncertainty on the objective values. Thus, noise tolerance is a desirable property for metaheuristic optimization algorithms such as PSO. In [131] the gbest PSO model was studied on a number of test problems contaminated by Gaussian noise, exhibiting promising behavior. Various other studies followed in subsequent years [13, 125, 154].

A common technique for tackling noisy problems is the reevaluation of the objective function at each point. Specifically, if the objective function is given as:

$$f'(\vec{x}) = f(\vec{x}) + \mathcal{R},$$

where $\mathcal{R}$ is a random variable following some (usually Gaussian) distribution, then PSO evaluates the particles by using:

$$F(\vec{x}) = \frac{1}{M} \sum_{m=1}^{M} f'^{(m)}(\vec{x}),$$

where $f'^{(m)}(\vec{x})$ is the mth reevaluation of $\vec{x}$ using $f'(\vec{x})$. Reevaluation serves as a mean for approximating the expected value of the noisy objective function, i.e., $F(\vec{x}) \approx \mathbb{E}(f'(\vec{x}))$. Accuracy increases with the number M of reevaluations, although it also increases the computational cost.

Thus, the trade-off between better estimations of the objective values and the corresponding computational burden shall be tuned. In such cases, specialized techniques such as the *optimal computing budget allocation* (OCBA) [22] have been used to optimally allocate the reevaluation budget in order to provide reliable evaluation and identification of the promising particles [125]. Such techniques can be used along with parameter tuning [13] or learning strategies [145] for improved results. Also, they do not require modification of the algorithm. In different approaches, specialized operators have been developed with remarkable success [64, 182].

Multiobjective PSO

Multiobjective optimization (MO) problems consist of a number of objective functions that need to be simultaneously optimized. In contrast to the definition of Eq. (1), a multiobjective problem is defined as the minimization of a vector function [32]:

$$\vec{f}(\vec{x}) = (f_1(\vec{x}), f_2(\vec{x}), \ldots, f_K(\vec{x}))^\top,$$

possibly subject to constraints $C_i(\vec{x}) \leqslant 0$, $i = 1, 2, \ldots, m$. Typically, the objective functions $f_k(\vec{x})$ can be conflicting. Thus, it is highly improbable that a single solution that minimizes all of them can be found. For this reason, the main interest in such problems is concentrated on the detection of *Pareto optimal* solutions. These solutions are nondominated by any other point in the search space, i.e., they are at least as good as any other point for all the objectives $f_k(\vec{x})$. Formally, if $\vec{x}$, $\vec{y}$ are two points in the search space $\mathcal{X}$, then $\vec{f}(\vec{x})$ is said to dominate $\vec{f}(\vec{y})$, and we denote $\vec{f}(\vec{x}) \prec \vec{f}(\vec{y})$, if it holds that:

$$f_k(\vec{x}) \leqslant f_k(\vec{y}), \text{ for all } k = 1, 2, \ldots, K,$$

and:

$$f_{k'}(\vec{x}) < f_{k'}(\vec{y}), \text{ for at least one } k' \in \{1, 2, \ldots, K\}.$$

Thus, $\vec{x}^* \in \mathcal{X}$ is a Pareto optimal point if there is no other point $\vec{y} \in \mathcal{X}$ such that $\vec{f}(\vec{y}) \prec \vec{f}(\vec{x}^*)$. Obviously, a whole (even infinite) set $\{\vec{x}_1^*, \vec{x}_2^*, \ldots\}$ of Pareto optimal solutions may exist. The set of all the corresponding function value vectors $\{\vec{f}(\vec{x}_1^*), \vec{f}(\vec{x}_2^*), \ldots\}$ is called the *Pareto front*.

There are two main approaches for tackling MO problems. The first one aggregates the objectives into a single one and solves the problem with the typical methodologies for single-objective optimization. The second approach requires vector-evaluated operators and it is based on the concept of Pareto dominance. In the context of PSO, early aggregation-based approaches were developed in 2002 [133], where the canonical PSO was used for the minimization of a weighted aggregation of the objective functions:

$$F(\vec{x}) = \sum_{k=1}^{K} w_k \, f_k(\vec{x}), \qquad \sum_{k=1}^{K} w_k = 1.$$

Both a *conventional weighted aggregation* (CWA) approach with fixed weights and a *dynamic weighted aggregation* (DWA) approach [71] were investigated with promising results. Obviously, the detection of many Pareto optimal solutions through weighted aggregation requires multiple runs of PSO, as a single solution of $F(\vec{x})$ is obtained per run. From a computational point of view, this is a drawback since the swarms have the ability to simultaneously evolve many solutions. Nevertheless, it is still considered as a popular approach in various applications mostly due to its simplicity.

A *vector-evaluated PSO* (VEPSO) was also proposed in [133] and parallelized later in [130]. VEPSO uses a number of K swarms, one for each objective f_k. The kth swarm $\mathcal{S}_k$ is evaluated only with the corresponding objective f_k, $k = 1, 2, \ldots, K$. The swarms are updated according to the gbest model of the canonical PSO, although with a slight modification. Specifically, the overall best that is used for the velocity update of the particles in the kth swarm comes from another

swarm. Clearly, this is a migration scheme aiming at transferring information among swarms. The donator swarm can be either a neighbor of the kth swarm in a ring topology scheme as the one described in section "Concept of Neighborhood" or it can be randomly selected [133]. VEPSO was studied on standard MO benchmark problems with promising results [130].

There is a large number of developments and applications on multiobjective PSO approaches in the relevant literature [1, 5, 35, 36, 38, 41, 43, 69, 96, 98, 105, 209, 214, 224]. The interested reader can find comprehensive surveys in [139, 158].

Applications and Further Resources

It would be futile to even try to enumerate all published applications of PSO. From the year 2005 onwards, more than 400 papers on PSO applications appear each year, spanning various scientific and technological fields. Computer Science concentrates the majority of these works (29.6%), especially in the fields of machine learning, data mining, and robotics. Engineering follows closely (27.8%), with numerous works in intelligent systems, forecasting, and energy handling.

A fraction of these applications was cited in the previous sections. In addition, the interested reader can refer to devoted survey papers such as [147], which was probably the first notable attempt to collect and categorize PSO applications. An analytical survey was published in [164], where a huge number of PSO-based applications was categorized along with more than 100 PSO variants. Further applications are reported in relevant books such as [140]. The appendix at the end of the present chapter contains a number of resources for further inquiry on PSO-based developments.

Conclusions

PSO has been established as one of the most popular metaheuristic optimization algorithms. Its popularity stems from its nice performance and adequate simplicity that renders it usable even by nonexpert researchers. In the previous sections, a number of variants and enhancements was presented. This is only a small fraction of the existing PSO-related literature, which counts thousands of papers. Thus, a reasonable question would be how much room is left for further developments on PSO. In the author's opinion, there is still fertile ground for new developments.

Despite the numerous research contributions, there are open problems regarding the pursuit of intelligent behavior and self-adaptation. Moreover, the evolution of computer and web technologies always introduces new challenges on the design and development of algorithms that can take full advantage of their properties to solve problems of increasing complexity. For example, the GPU computing paradigm and modern multicore desktop systems can offer computational power comparable to small- and medium-size clusters. Cloud computing and ubiquitous computing environments are other examples. Also, new ad hoc operators and procedures for

specific problems are expected to appear, especially in fields related to artificial intelligence.

Closing this chapter, the authors would like to quote Albert Einstein's words to motivate new researchers towards unconventional thinking, which was the main ingredient for the development of PSO so far:

"You will never solve problems using the same thinking you created them with."

Abstract

This chapter presents POPMUSIC, a general decomposition-based framework within the realm of matheuristics that has been successfully applied to various combinatorial optimization problems. POPMUSIC is especially useful

for designing heuristic methods for large combinatorial problems that can be partially optimized. The basic idea is to optimize subparts of solutions until a local optimum is reached. Implementations of the technique to various problems show its broad applicability and efficiency for tackling especially large-size instances.

Keywords

Decomposition method · Matheuristics · Large neighborhood search · Large scale optimization

Introduction

A natural way to solve large optimization problems is to decompose them into independent subproblems that are solved with an appropriate method. However, such approaches may lead to solutions of moderate quality since the subproblems might have been created in a somewhat arbitrary fashion. While it is not necessarily easy to find an appropriate way to decompose a problem a priori, the basic idea of POPMUSIC is to locally optimize subparts of a solution, a posteriori, once a solution to the problem is available. These local optimizations are repeated until a local optimum is found (and possibly beyond). POPMUSIC stands for "Partial OPtimization Metaheuristic Under Special Intensification Conditions" [33]. It is a template, or framework, for creating heuristics repeating partial optimization on a solution. To apply this template, special conditions must be fulfilled. Among these conditions, it is supposed that a solution is composed of parts that can be optimized almost independently. Thus, POPMUSIC may be seen as a "general purpose" framework which does not need too many problem-specific adaptations if a reasonable way of decomposing a problem, or a given incumbent solution, is at hand so that it can be readily applied to a wide spectrum of problem classes.

POPMUSIC typically applies to large-size problem instances, but the template was also applied successfully to smaller instances. Typical real-life problems usually contain a very large number of elements. The POPMUSIC template proposes a solution for dealing with problem instances of that size.

Next we describe the POPMUSIC template followed by a survey of several successful applications as well as an overview on a few related approaches.

POPMUSIC Template

The idea of decomposing problems of large size into smaller subproblems easier to solve is certainly very old [8]. In the context of metaheuristics and matheuristics, this can be accomplished, for instance, by using given incumbent solutions and

optimizing parts of them. In general terms, one may distinguish soft fixing and hard fixing to attain problems of reduced size that may be solved separately. While in *hard fixing* some of the decision variables of a given problem are directly excluded (e.g., by fixing them to a certain value), *soft fixing* refers to adding, say linear, constraints to the model to cut out all solutions from a problem that are beyond a certain distance from a given solution. In that way, the search can be intensified around those parts of a solution space that are not cut out.

To exemplify the POPMUSIC template in detail, we resort to the capacitated vehicle-routing problem (CVRP) as one of the first specific applications of the template [29]. We emphasize this as POPMUSIC can be well illustrated on the CVRP. In its simplest version, it consists of finding a set of vehicle tours, starting from a depot, servicing customers asking given quantities of goods and coming back to the depot. Knowing the vehicle capacity and all distances between clients, a set of tours, visiting each customer exactly once, is searched in such a way that the total distance of the tours is minimized.

If a solution is available, a tour can be considered as a part of the solution. Each tour can be interpreted as being independent from the others and can be optimized independently. Optimizing a tour consists of finding an optimal trip (or tour) of a traveling salesman problem (TSP). Since the number of customers on a tour of a CVRP is limited and exact codes for the traveling salesman problem are available and efficient up to few dozens of cities and beyond [9], the optimization of single CVRP tours can be considered as a simple task.

Now, if we consider the subset of customers delivered by a subset of tours of a given solution, it is also possible to optimize independently the delivery of this subset of customers. So, a subset of parts of a solution creates a subproblem that can be optimized independently from the remaining of the problem. For a CVRP, such a subproblem is a CVRP of reduced size.

If an optimization method is available that can treat CVRPs with up to r tours efficiently, larger instances can be tackled by repeating optimizations on subproblems containing up to r tours. The POPMUSIC template suggests a tactic for building subproblems that can be potentially improved. Instead of generating any subproblem with r parts, as done by matheuristics like large neighborhood search (LNS), POPMUSIC introduces a notion of proximity between parts. Subproblems are built by first selecting a part called a *seed part* and r of its closest parts. Figure 1 illustrates the principle of the generation of a subproblem containing six tours.

Given a solution composed of p parts, there are only p subproblems composed of $r < p$ parts that can be so built, instead of the $\frac{p!}{(p-r)!\cdot r!}$ possible ones. In contrast to the LNS template where the user must choose at each step how to build a subproblem and when to stop the optimization process, POPMUSIC-based approaches have a natural stopping criterion: When the p subproblems are solved optimally or with satisfaction, the process can be stopped.

To be specific, in the POPMUSIC template, it is supposed that a solution s can be decomposed into p parts $s_1, \ldots, s_p$ and that a proximity measure between two parts has been defined. Let U with $|U| =: p$ be the set of parts that have not been used as seed part for building a subproblem. Initially, U contains all p parts and U

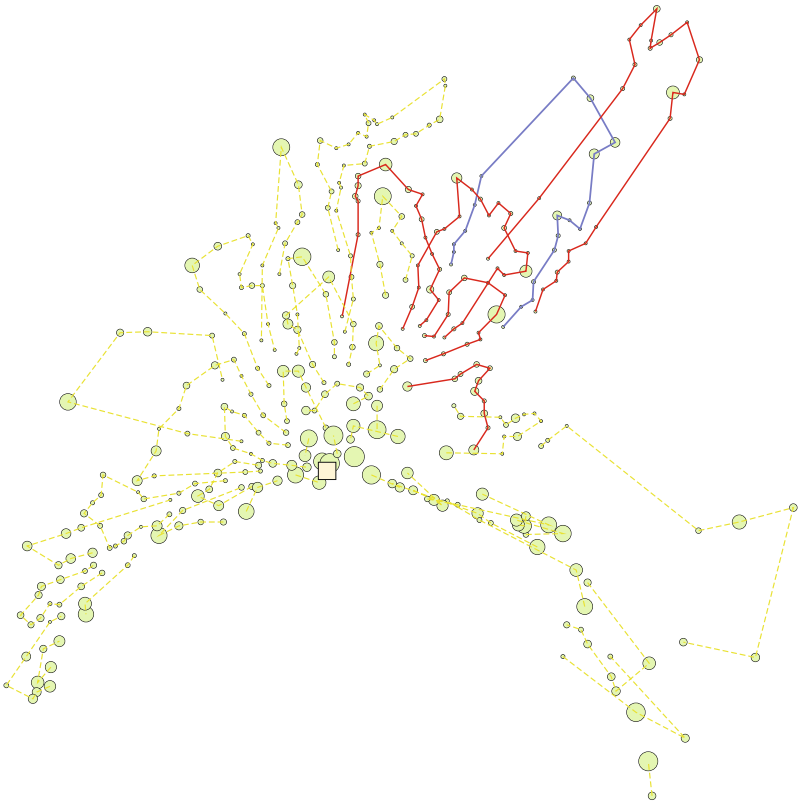

Fig. 1 For the vehicle-routing problem, the definition of a part can be a vehicle tour. In this figure, the size of the disks represents the customers' demand, and the trips from and to the depot (square) are not drawn. Here, the proximity between parts is measured by the distance of their center of gravity. A subproblem is a smaller VRP composed of the customers serviced by six tours

is empty at the end. Let $m(R)$ be an optimization method that allows to optimize a subproblem R composed of r parts. With these hypothesis, the POPMUSIC template can be expressed by Algorithm 1.

POPMUSIC can be seen from different perspectives: As mentioned above, it can be considered as a large neighborhood search [26] or as a soft fixing approach. In this case, the neighborhood considered consists of finding the best way to reshape the elements of r parts. The neighborhood is qualified as large, in contrast to local search that modifies only few elements of a solution at each step, allowing explicitly a complete examination of the neighborhood. When all the elements of r parts must be optimized, it is not possible to proceed to an explicit examination of the whole neighborhood, since its size is much too large. So, either an exact method is used, making POPMUSIC a matheuristic (see [22]), or an approximate algorithm is used, typically based on a metaheuristic.

Algorithm 1: POPMUSIC template

Input: Initial solution s composed of p parts $s_1, \ldots, s_p$, sub-problem optimization method m
Output: Improved solution s
$U = \{s_1, \ldots, s_p\}$
while $U \neq \emptyset$ **do**
    Select $s_g \in U$ `//` s_g`: seed-part`
    Build sub-problem R with the r parts of s that are the closest to s_g
    Optimize R with method m
    if R *improved* **then**
        Update solution s
        Remove from U the parts that do not belong to s anymore
        Insert in U the parts of optimized sub-problem R
    else `//` R `not improved`
        Remove s_g of U
    end
end

Deriving a specific POPMUSIC implementation is described by means of a specific application in the next section.

POPMUSIC Adaptation for Location Routing

The POPMUSIC template requires the programmer to define five components: the *initial solution*, a *part*, the *proximity* between parts, the *seed-part* choice, and an *optimization method*. This section illustrates how these components can be implemented for a location-routing problem (LRP). Very briefly, an LRP is a vehicle-routing problem with several depots where the location of the depots must be decided in addition to the building of vehicle tours.

Initial Solution

A key point for the treatment of large problem instances is to analyze the algorithmic complexity of each step of the solution method. Examining the POPMUSIC template, the first question is about the number of times the `while` loop at line 1 is repeated. Numerical experiments on different problems—unsupervised clustering [30], map labeling [3], location routing [4], berth allocation [17, 20]—have shown that this loop is repeated a number of times that grows quasi-linearly with the problem size. This behavior is typical for local searches based on standard neighborhoods where the theoretical exponential complexity is not observed. To lower the algorithmic complexity, the other steps of the template must be carefully designed.

The step that looks most complex is naturally the optimization of subproblems at line 1. Indeed, the computational time for optimizing a subproblem with r parts grows very fast with r, for instance, exponentially if an exact method is used.

The user can control the computational time by modifying the unique parameter r of POPMUSIC template. Let us suppose that the user has fixed the value of r to a value for which the subproblems are sufficiently large for getting solutions of good quality while limiting the computational time of the optimization method. If r is fixed, solving a subproblem takes a constant time—maybe large, but constant. So, if the use of an efficient optimization method is a key point of the POPMUSIC template, this is not an issue for limiting the algorithmic complexity.

The choice of the seed part can be implemented in constant time, for instance, by making a random choice or by storing set U as a stack or a queue. So, the key points for limiting the algorithmic complexity of a POPMUSIC implementation is to use an appropriate technique for producing the initial solution and for building subproblems from a seed part. Indeed, without an appropriate data structure, building a subproblem can take a time proportional to the problem size, leading to a global complexity being at least quadratic.

Alvim and Taillard [4] have presented how to build in $O(n^{3/2})$ a solution to a location-routing problem while building a data structure allowing to build a subproblem in $O(r)$. The idea of the construction is the following: Let us suppose that it is possible to advise a distance measure between the entities of the problem. For the LRP, this distance is part of the problem data: It is simply the distance between customers. The entities of the problem are grouped into $\sqrt{n}$ clusters by means of a heuristic method for the p-median problem. Although NP-hard, the p-median problem can be approximately solved with an empirical complexity of $\overline{O}((p \cdot n + (\frac{n}{p})^2)$, where p is the number of clusters desired. In this problem, the clusters are built by choosing p central elements and assigning all remaining elements to the closest center. By choosing $p = \sqrt{n}$, it is possible to cut a problem of size n into $\sqrt{n}$ clusters containing approximately $\sqrt{n}$ elements in $\overline{O}((n^{3/2})$. This method is illustrated in Fig. 2.

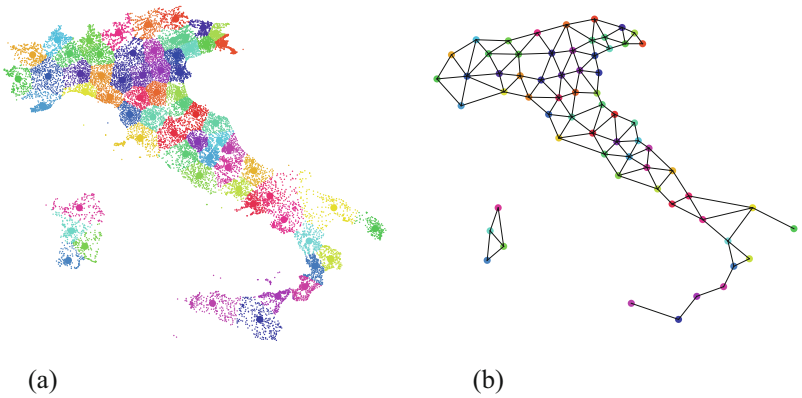

Fig. 2 Illustration of the decomposition of a problem into $\sqrt{n}$ clusters and building a proximity network between the clusters. (**a**) Problem decomposition into clusters. (**b**) Building proximity network

Then, all centers can be compared 2 by 2 to create proximity relations. Figure 2b illustrates the proximity relation obtained by considering that clusters a and b are neighbors if an entity of one of these clusters has the center of the other one as second closest center. Each cluster can then be decomposed into $O(\sqrt{n})$ clusters to create a total of $O(n)$ small clusters containing a constant number of elements. So, it is possible to create proximity relations between every entity of a problem of size n in $O(n^{3/2})$. In the context of the LRP, a vehicle tour can be assigned to the entities of a small cluster. The proximity relations can be exploited in POPMUSIC for finding efficiently the r parts that are the closest from a seed part.

However, if no versatile method for finding incumbent solutions is at hand, any type of heuristic or even a randomized approach may be used to derive them.

Part and Subproblem Definitions

The definition of a part strongly depends on the problem under consideration and on the procedure available for optimizing subproblems. For vehicle-routing problems, [4, 24, 29] have defined the customers serviced by a vehicle tour as a part. This definition is justified by the fact that the subproblems built around a seed part are smaller VRPs or multi-depot VRPs that can be efficiently optimized with a metaheuristic-based algorithm, like a basic tabu search or genetic algorithm hybridized with a variable neighborhood search. Several definitions have been adopted for the proximity between parts: For Euclidean instances, the distance between the center of gravity of tours can be used; generally, the technique presented in section "Initial Solution" can be used for defining the proximity.

Seed-Part Selection

Very few works have studied the impact of the seed-part selection procedure. In many applications, subproblems are generated around a seed part arbitrarily chosen in U (next available, random one, ...). Preliminary results in [4] have shown that a set U managed as a stack (last part entered in U is selected) seems to be better than an arbitrary selection.

Empirical Complexity

In [4], problem instances 10000 times larger than those usually treated in the literature have been tackled. As mentioned above, the most complex part is the generation of an initial solution in $O(n^{3/2})$. The subproblem optimization is less complex, almost linear. Figure 3 shows the evolution of the computational effort as a function of problem size for different POPMUSIC phases. The increase of computational time is higher for the steps of generating the initial solution (solving a p-median problem with two levels, as presented in section "Initial Solution") than

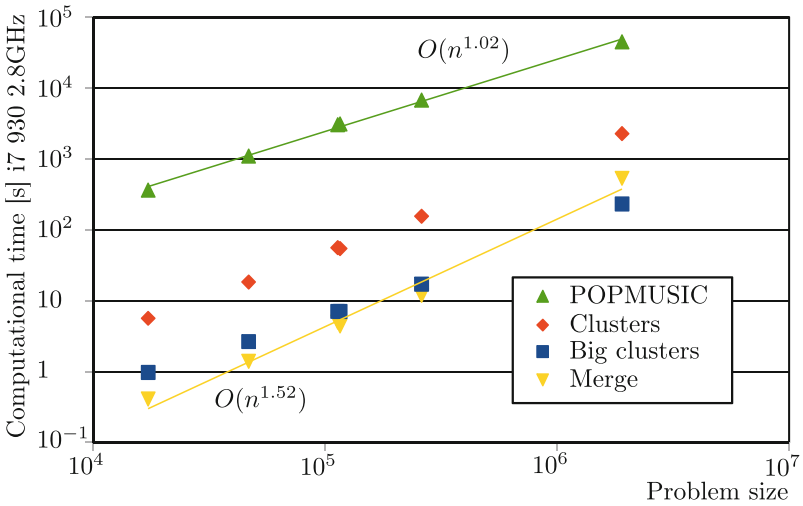

Fig. 3 Evolution of the computational effort as a function of problem size for various parts of the algorithm: building large clusters, decomposing large clusters into small ones containing subsets of customers that can be delivered by the same vehicle, finding positions for the depots and optimizing subproblems

for the subproblem optimization. However, this last phase still takes most of the computational effort, even with instances with two millions of entities.

POPMUSIC Applications

While we have used the CVRP and a location-routing problem to clarify concepts, in this section, we summarize a few additional successful applications of POPMUSIC. Other applications not specifically mentioned refer, e.g., to the turbine runner balancing problem [33] or the p-cable trench problem [19].

Application of POPMUSIC as Matheuristic for the CVRP

Recently, [27] precisely adapted POPMUSIC for the capacitated vehicle-routing problem (CVRP) using a branch-cut-and-price algorithm, which combines column and cut generation with several additional mechanisms to optimize the subproblems. These authors propose a variant for constructing subproblems:

Each customer takes turns playing the role of a seed. Then, all other customers are listed in ascending order based on their distance from the seed customer. As long as the subproblem contains a number of customers not exceeding a threshold α, the route containing the next closest customer to the seed is added to the subproblem—provided it is not already included. Thus, the parameter r, which fixes the number

of routes, is replaced by α, which sets the maximum number of customers in a subproblem.

To avoid unnecessary optimization attempts, the set of previously optimized subproblems is stored. Additionally, a variant of the POPMUSIC framework is proposed in this chapter, with the idea of increasing α by a quantity δ once each customer has played the role of a seed.

POPMUSIC has also been adapted to a variant of the CVRP, namely the multi-depot cumulative capacitated vehicle-routing problem, by Lalla-Ruiz and Voß [18].

Application of POPMUSIC to the TSP

A very simple way to apply the POPMUSIC framework to the traveling salesman problem (TSP) is to consider each city as a part and measure proximity between two cities by the number of edges that separate them in the tour to be optimized.

With this definition, a subproblem is a path that can be optimized while keeping its two endpoint cities fixed. This approach was studied in [32].

This proximity definition allows for the re-optimization of a tour with a linear empirical computational effort. However, its drawback is that it cannot "untangle" crossings between edges separated by a number of cities greater than the subproblem size.

The biggest challenge in applying POPMUSIC to the TSP is, therefore, obtaining an initial solution that lends itself well to further optimization. Taillard [31] proposed an $O(n \log n)$ approach that generates solutions for gigantic instances (with billions of cities). While the solution quality is relatively modest, it is significantly better than that of the nearest-neighbor heuristic, for example.

The main advantage of this method is its ability to quickly identify a very limited subset of edges that include those of excellent solutions, even for non-Euclidean instances. This property is leveraged in the latest versions of the LKH software [14, 15], which are currently among the best freely available solvers for this class of problems.

Application of POPMUSIC to Clustering

The POPMUSIC template is particularly well adapted to solve large clustering problem instances. The goal of clustering is to create groups of entities as well separated as possible while containing entities as homogeneous as possible. This means that metrics are available for measuring the similarity or the dissimilarity between elements. If the number of clusters is relatively large, using the POPMUSIC template is interesting. In this case, a part of a solution can be constituted as the set of entities belonging to the same cluster. The measure of the separation between groups can be used for defining the proximity between parts.

This technique was successfully applied to unsupervised clustering with centroids (sum-of-squares clustering, p-median, multisource Weber) in [30]. Figure 4 illustrates the construction of a subproblem from a solution to a p-median problem.

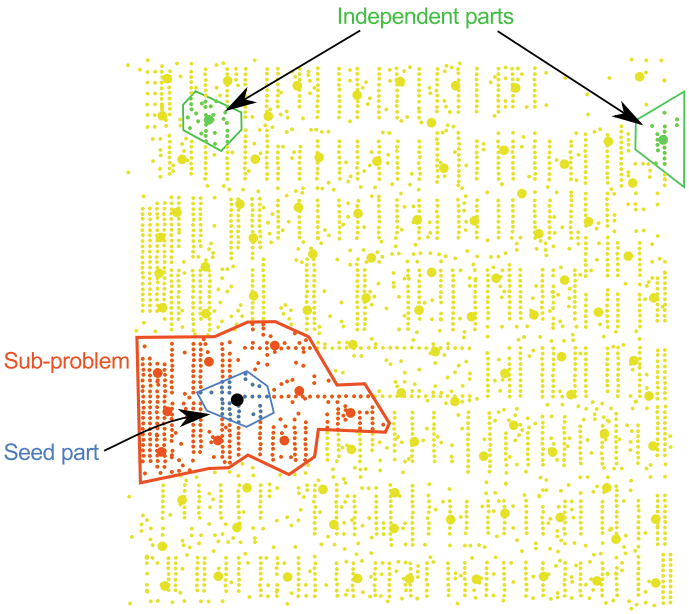

Fig. 4 Building a subproblem from a seed part in the case of a p-median problem. Clusters that are well separated can be considered as independent and should not be involved in the same subproblem

Application of POPMUSIC to Max Weight Stable Set Problems

The POPMUSIC template is also well adapted to the search of a stable set with maximum weight in a graph. Several practical problems can be modeled under this form. For instance, the map labeling problem can be formulated as a stable set with maximum weight. The problem is the following: Given objects on the Euclidean plane, one wants to place a label around them to identify them. For instance, when drawing a map, an object can be the top of a mountain and the label the name of the mountain. The label can be placed at several predefined positions. The problem consists of finding a position for each label in such a way that no label partially covers another one. If it is not possible to label all objects without superposition, it is searched to maximize the number of labels correctly placed. For typographic reasons, a different weight is associated to each label position, reflecting the positioning preferences or the importance of the object.

The problem can be formulated as the search of a stable set with maximum weight in a graph. The graph is built as follows: A node is associated with every label position, with a weight corresponding to the preference. An edge connects two nodes if the corresponding labels are incompatible: Either they are associated with the same object (every object must be labeled at most once) or they overlap. Figure 5 illustrates the construction of a graph for labeling three objects with four possible label positions for each of them.

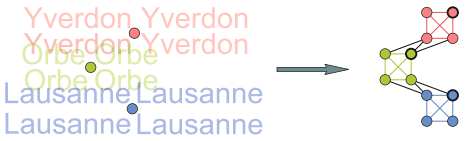

Fig. 5 Formulation of the problem of map labeling under a stable set

Applying the POPMUSIC template to this problem can be done as follows: A part is an object to label, so the set of all nodes representing the different possible label positions for this object. The distance between two objects (interpreted as parts) is the minimum number of edges needed to connect two nodes associated to labels of the objects they identify. A subproblem is constituted by r objects for which the label position can be modified. A subproblem must also consider other labels of the current solution that may overlap, but without searching to modify the position of these labels.

The optimization procedure is a re-implementation of a tabu search due to [35] for which the parameters were tuned for solving at best problem instances with few dozens of objects. Alvim and Taillard [2] have shown that excellent solutions can be obtained for problem instances with one thousand objects and that the method can still be used for instances with millions of objects.

This work was continued by Laurent et al. [21] for allowing the labeling of cartographic maps containing non-punctual objects like lines (streets, rivers) or polygons (states, countries). The subproblem optimization used in this reference is based on ejection chains. The algorithms developed by Laurent et al. [21] have been integrated in the QGIS open-source software (http://www.qgis.org/en/site/).

Various problems in the domain of transportation can be formulated as a map labeling (or a maximum weight stable set). The assignment of cruising levels of commercial aircraft is one of them. Knowing the departure hour and horizontal trajectory of every aircraft at a continent level, it is required to assign each of them a cruising level in order to avoid the collision between aircraft. The label shape is determined in this case by the possible position of the aircraft for a given time interval. The exact position of the aircraft cannot be determined, since the departure hour may fluctuate (traffic delay in the airport) and the weather conditions may affect the speed and position of the aircraft (wind, clouds, storm, ...). For a time interval, it is required to find a level for each label in such a way that no label covers another one.

Application of POPMUSIC to Berth Allocation Problems

The berth allocation problem (BAP) is a well-known optimization problem within maritime shipping. It aims at assigning and scheduling incoming vessels to berthing positions along the quay of a container terminal. Lalla-Ruiz and Voß[17] propose two POPMUSIC approaches that incorporate an existing mathematical program-

ming formulation based on modeling the problem as a set partitioning problem. The computational experiments reveal state-of-the-art results outperforming all previous approaches regarding solution quality.

To be specific, [17] study the application of POPMUSIC for solving the discrete dynamic berth allocation problem (DBAP). In the DBAP, one is given a set of incoming container vessels, N, and a set of berths, M. Each container vessel, $i \in N$, must be assigned to an empty berth, $k \in M$, within its time window, $[t_i, t_i']$, and the assigned berth time window, $[s_k, e_k]$. A simplified assumption is that each berth can handle at most one vessel at a time. For each container vessel, $i \in N$, its handling time, ρ_{ik}, depends on the berth $k \in M$ where it is assigned to. That is, the service time of a given vessel differs from one berth to another. Moreover, some vessels may have forbidden berths in order to model water-depth or maintenance constraints. Finally, each vessel $i \in N$ has a given service priority, denoted as v_i, according to its contractual agreement with the terminal.

A natural way to define parts is by means of the berths themselves. If a restricted number of berths (and assigned vessels) can be handled with an exact approach, this allows for efficient subproblem solving. Moreover, it is also easy to define the proximity between berths, taking real distances.

An interesting observation deduced from solving the DBAP and extensions by means of POPMUSIC also reveals some general lessons learned regarding the definition of parts. Let us assume a problem extension as the berth allocation problem under time-dependent limitations (BAP-TL) [20]. In this problem, in order to assign a vessel to a berth, terminal managers might have to take into account not only the berthing place and vessel draft, but also the arrival and berthing time of an incoming vessel while observing changing environments due to tidal changes. Note that in the DBAP the decisions about to which berth the vessel should be assigned to is relevant since there are different handling times depending on the berth. This is relaxed in the BAP-TL, i.e., all the berths provide the same handling time, having also an important implication on the proper definition of parts. Note also that in the BAP-TL the berthing time is important due to the tidal constraints. Thus, it makes sense to define the parts not necessarily following the berths delimitation, but defining the parts as intervals of time. Numerical results are given in [20].

To end this subsection, we should point to an interesting analogy which may be drawn between the pure (and possibly simplified) berth allocation problem and the map labeling problem. In this case, the width of a label corresponds to the time interval during which the vessel must be at the berth for being loaded/unloaded. The height of the label is the vessel length. A label can be placed at different positions along the berth. Figure 6 provides an example of the transformation of a small problem with four vessels arriving at different times and that can be placed at few different positions along a berth (considering vessel length and time windows, TW).

The POPMUSIC template was used in [17, 20] for the dynamic berth allocation problem without and with the consideration of tidal constraints. In these references, the optimization procedure is an exact method.

The use of the POPMUSIC framework in multi-objective optimization for an integrated berth allocation and quay crane assignment problem is described in [36].

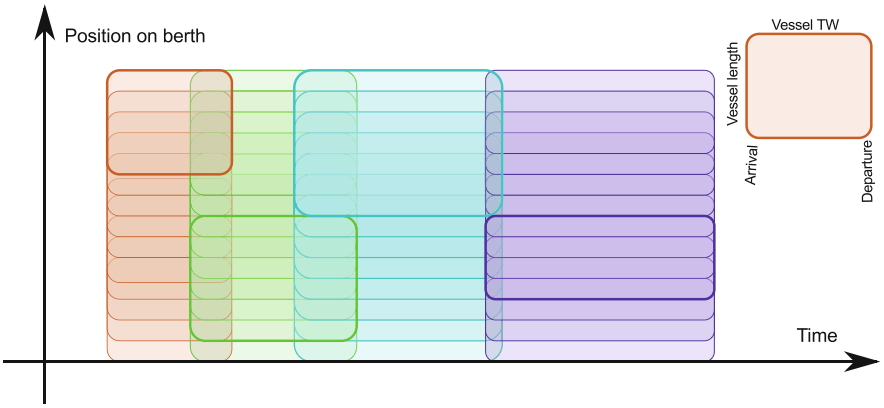

Fig. 6 Transformation of berth allocation problem to a map labeling

An integrative algorithm framework is developed, composed of POPMUSIC, the Strength Pareto Evolutionary Algorithm 2, and k-means clustering. An extension, again applying the POPMUSIC framework in multi-objective optimization, toward the adoption of different green technologies is described in [37].

Related Approaches

For large optimization problems, it is often possible to interpret a solution as composed of parts or chunks [34] as can also be found under the term vocabulary building. Suppose that a solution can be represented as a set of parts as seen above, some parts are more in relation with some other parts so that a corresponding heuristic measure can be defined between two parts.

The *corridor method* (CM) has been presented by Sniedovich and Voß [28] as a hybrid metaheuristic, linking mathematical programming techniques with heuristic schemes. The basic idea of the CM relies on the use of an exact method over restricted portions of the solution space of a given problem. Given an optimization problem, the basic ingredients of the method are a very large feasible space, and an exact method that could easily solve the problem if the feasible space were not large.

The basic concept of a *corridor* is introduced to delimit a portion of the solution space around the incumbent solution. The optimization method will then be applied within the neighborhood defined by the corridor with the aim of finding an improved solution. Consequently, the CM defines method-based neighborhoods, in which a neighborhood is built taking into account the method used to explore it.

As mentioned before, POPMUSIC may be seen as a soft fixing approach as does the CM. Food for thought might be considered putting POPMUSIC into perspective regarding other methods like large neighborhood search, adaptive randomized decomposition, kernel search, etc. An older research which may serve as motivation

relates to solving the job shop problem by means of the shifting bottleneck heuristic [1]. The idea of developing heuristics identifying a small/moderate size subset of variables in order to intensify the search in a promising region of the solution space has been used in other contexts. In the knapsack problem family, for instance, [7] propose the idea of selecting a small subset of items (called the core) and solving exactly a restricted problem on that subset. The use of an expanding method to modify the size of the core during the algorithm execution is proposed by Pisinger [25]. A heuristic framework called kernel search has been proposed for the solution of mixed-integer linear problems in [5, 6]. The kernel search framework is based on the idea of exhaustively exploring promising portions of the solution space. Kernel search is similar to POPMUSIC since "buckets," analogous to parts, are defined at the beginning of the search. During the execution, the algorithm revises the definition of the core problem, called "kernel," by adding/removing buckets to/from the current problem. Once the current kernel is defined, an exact method is applied to the restricted problem.

Local branching [10] is another soft fixing technique, in which the introduction of linear constraints is used to cut solutions from the feasible space. The feasible space of the constrained problem includes only solutions that are not too far away from the incumbent. When presented, local branching was used within a branch and bound framework. A generalized local branching concept has been proposed by Hill and Voß [16].

Variable neighborhood decomposition search is in line with the strategy employed by POPMUSIC. Neighborhoods around an incumbent are defined using a distance metric and explored via any method. If a local optimum better than the incumbent is found in the current neighborhood, the neighborhood is re-centered around the new incumbent, and the mechanism moves on to the exploration of the new neighborhood. If no improvement occurs, the search moves to the next neighborhood defined around the same incumbent. An interesting modification of variable neighborhood decomposition is provided in [13], where variable neighborhood search is coupled with local branching. Neighborhoods are defined imposing linear constraints on a mixed-integer linear programming model, as done in local branching, and then explored using a general-purpose solver as black box.

Fischetti et al. [11] propose a similar method called diversification, refining, and tight refining (DRT). It is aimed at solving problems with two-level variables, in which fixing the value of the first-level variables leads to an easier to solve, but still hard, subproblem. Finally, another way to see POPMUSIC is to exploit the proximate optimality principle (POP, see, e.g., [12]). In tabu search, the POP notion is exploited by performing a number of iterations at a given level before restoring the best solution found to initiate the search at the next level. In that context, a level corresponds to the optimization of a subproblem in the POPMUSIC terminology.

POPMUSIC is also applied toward various combinatorial optimization problems as part of an integrated approach combining various metaheuristics. As an example, we mention [23] for a matheuristic approach hybridizing particle swarm optimization, simulated annealing, and mathematical programming based on the POPMUSIC concept.

Conclusion and Future Works

The main strength of POPMUSIC is its simplicity, the fact that it has a unique parameter and its ability to solve large problem instances. So, the main effort when implementing a POPMUSIC-based procedure is not devoted to parameter tuning as it can be the case for other metaheuristics. But there is no free lunch. The weakness of POPMUSIC is that an initial solution with a structure adapted to the template must be available as well as an optimization procedure for the subproblems. These points make POPMUSIC less general and more problem-specific than other metaheuristics. Adapting POPMUSIC to various hard problems which are not easy to decompose is a first research avenue.

Up to now, very few works have been devoted to study the influence of POPMUSIC options, such as the way the seed part is chosen or the procedure used for optimizing subproblems. These are other promising research topics for the future. It can also be interesting to revisit existing methods that are somewhat based on decomposition principles under the form of the POPMUSIC template. This could lead to simplifications and/or efficiency improvements.

The POPMUSIC template can be adapted to parallel implementations. Our first works on the vehicle-routing problem were primarily devoted to parallel implementations of metaheuristics. A relatively easy issue is to use the few cores of CPU in parallel. However, implementing a POPMUSIC with a number of processors dependent on problem size is less trivial. Another research avenue is to see how to exploit the large number of processors of graphic process units in the context of POPMUSIC.

Abstract

A random-key genetic algorithm is an evolutionary metaheuristic for discrete and global optimization. Each solution is encoded as a vector of n random keys, where a random key is a real number randomly generated in the continuous

interval [0, 1). A decoder maps each vector of random keys to a solution of the optimization problem being solved and computes its cost. The benefit of this approach is that all genetic operators and transformations can be maintained within the unitary hypercube, regardless of the problem being addressed. This enhances the productivity and maintainability of the core framework. The algorithm starts with a population of p vectors of random keys. At each iteration, the vectors are partitioned into two sets: a smaller set of high-valued elite solutions and the remaining non-elite solutions. All elite elements are copied, without change, to the next population. A small number of random-key vectors (the mutants) are added to the population of the next iteration. The remaining elements of the population of the next iteration are generated by combining, with the parametrized uniform crossover of Spears and DeJong (On the virtues of parameterized uniform crossover. In: Proceedings of the Fourth International Conference on Genetic Algorithms, pp 230–236, 1991), pairs of solutions. This chapter reviews random-key genetic algorithms and describes an effective variant called biased random-key genetic algorithms.

Introduction

Genetic algorithms (GAs) are inspired by Darwin's theory of evolution. Holland [39] introduces this approach, which considers that a possible solution to a combinatorial optimization problem is an individual inside a population of potential solutions. In this population, evolutionary operators are applied at each iteration/generation to obtain new populations and solutions.

A class of GAs is described by Bean [9], whose solutions are represented by a vector of random keys, called a chromosome. A *random key* is a real number belonging to the interval [0, 1). This makes the evolutionary process of the *random-key genetic algorithms* (RKGAs) problem-independent, as the evolutionary operators can be specified for the chromosomes, which allows for a generalization of the framework. The quality of a solution is calculated by the *decoder* procedure, which maps a chromosome to a fitness value. In [9], the decoding procedure simply orders the elements of the vector of random keys, which produces a permutation of the indices of the sorted elements.

In the RKGA evolutionary process, the algorithm starts with an initial population $\mathcal{P}$ of vectors of n random keys. In each generation, the vectors are partitioned into a set of the best solutions $\mathcal{P}^e < |\mathcal{P}|/2$, called the elite set, and a set with the remainder of non-elite solutions of the population. All elite solutions are copied, unchanged, into the population of the next generation. This elitism characterizes the Darwinian

principle in the RKGA. Next, a set $\mathcal{P}^m$ of randomly created vectors is introduced into the next population. This set comprises *mutants*, which play the same role as the mutation operators of classical GAs, i.e., they help increase population diversity and avoid convergence to non-global local optimum. To complete the elements of the next population, $|\mathcal{P}| - |\mathcal{P}^e| - |\mathcal{P}^m|$ are generated by combining solutions from the entire population using a parametrized uniform crossover [107, 108]. In this crossover, consider a and b to be the vectors chosen for mating, and let c be the offspring produced. Random key $c[i]$, the i-th component of the offspring vector, receives the i-th key of one of its parents. It receives the key $a[i]$ with probability ρ_a and $b[i]$ with probability $\rho_b = 1 - \rho_a$.

Biased Random-Key Genetic Algorithms

A *biased random-key genetic algorithm* (BRKGA), meanwhile, also uses an elitist strategy in the mating procedure, not only regarding the reproduction of the elite set.

In BRKGA, one parent is always chosen from the elite set. When performing the coin toss to choose whose parent passes the gene to the offspring, the gene of the elite parent has a probability of being inherited $\rho > 0.5$. This means that the offspring has a higher chance of inheriting the keys of the elite parent and of retaining substructures of a good solution while still allowing the insertion of substructures of a not-so-good solution. This difference between the two algorithms tends to result in BRKGA outperforming Bean's algorithm [38]. As a result, most of the literature published after the introduction of BRKGA tends to use the biased variant. A flowchart detailing the BRKGA framework can be seen in Fig. 1. In it, the problem-independent structure of classical BRKGA is highlighted. The decoding procedure in black is problem-dependent, as it makes the correlation between a random-key vector and a feasible problem solution.

The double elitism of BRKGA leads to rapid convergence to high-quality solutions. Alongside its problem-agnostic approach, it has led to a significant increase in use, with over 250 papers published until 2025 [56, 57]. The BRKGA was formally introduced in Gonçalves and Resende [36], but some of its characteristics can be seen in the early 2000s [15, 27, 35]. Since then, several applications, hybridizations, and features have been described in the literature. Among the problems in which BRKGA was applied since 2020, the following are considered:

- *Scheduling*: Abreu et al. [1], Abreu et al. [2], Bolsi et al. [11], Fontes and Homayouni [31], Fontes et al. [32], Huang et al. [42], Ibarra-Rojas et al. [44], Kong et al. [48], Kong et al. - *Clustering*: Brito et al. [13], Fadel et al. [28], Martarelli and Nagano [64], and Xu et al. [117]
- *Graph problems*: Lima et al. [51], Londe et al. [54], Londe et al. [55], Melo et al. [66], Pinto et al. [86], Silva et al. [102], and Silva et al. [101]
- *Automatic tuning of parameters in heuristics*: Cicek and Ozturk [22], Falls et al. [29], Japa et al. [45], and Sun and Zhou [109]
- *Other applications*: Morgan et al. [69], Ochoa et al. [70], Pan et al. [79], Pastore et al. [81], Pinacho-Davidson and Blum [84], Ramos et al. [88], Reixach et al. [90], and Silva et al. [100]

A Model for the Implementation of a BRKGA

Algorithm 1 shows a pseudo-code of a BRKGA for the minimization of $f(x)$, where $x \in X$ and X is a discrete set of solutions and $f : X \to \mathbb{R}$. This implementation is a multi-start variant of a BRKGA where several populations are evolved in sequence,

Algorithm 1: Model for biased random-key genetic algorithm with restart

```
1  BRKGA(|P|, |P_e|, |P_m|, n, ρ_a)
2  Initialize value of the best solution found: f* ← ∞;
3  while stopping criterion not satisfied do
4      Generate a population P with |P| vectors of n random keys;
5      while restart criterion not satisfied do
6          Evaluate the cost of each new solution in P;
7          Partition P into two sets: P_e and P_ē;
8          Initialize population of next generation: P+ ← P_e;
9          Generate set P_m of mutants, each mutant with n random keys;
10         Add P_m to population of next generation: P+ ← P+ ∪ P_m;
11         foreach i ← 1 to |P| − |P_e| − |P_m| do
12             Select parent a at random from P_e;
13             Select parent b at random from P_ē;
14             foreach j ← 1 to n do
15                 Throw a biased coin with probability ρ > 0.5 of resulting heads;
16                 if heads then c[j] ← a[j];
17                 else c[j] ← b[j];
18             end
19             Add offspring c to population of next generation: P+ ← P+ ∪ {c};
20         end
21         Update population: P ← P+;
22         Find best solution χ+ in P: χ+ ← argmin{f(χ) | χ ∈ P};
23         if f(χ+) < f* then
24             χ* ← χ+;
25             f* ← f(χ+);
26         end
27     end
28 end
29 return χ*
```

and the best solution among all in the population is returned as the output of the algorithm.

In line 2, the value f^* of the best solution found is initialized to a large value, i.e., not smaller than $f(x^0)$, where $x^0 \in X$ is some feasible solution to the problem. Evolution of each population is done in lines 3–28. The algorithm halts when a stopping criterion in line 3 is satisfied. This criterion can be, for example, the number of evolved populations, the total time, or the quality of the best solution found.

In line 4, the population being evolved is initialized with $|\mathcal{P}|$ vectors of random keys. Evolution of population $\mathcal{P}$ takes place in lines 5–27. This evolution ends when a restart criterion is satisfied in line 5. This criterion can be, for example, a maximum number of generations without improvement in the value of the best solution in $\mathcal{P}$. At each generation, or iteration, the following operations are carried out: In line 6, all new solutions (offspring and mutants) are decoded and their costs evaluated. Note that each decoding and evaluation in this step can be computed simultaneously, i.e., in parallel. In line 7, population $\mathcal{P}$ is partitioned into two subpopulations $\mathcal{P}_e$

(elite) and $\mathcal{P}_{\bar{e}}$ (non-elite), where $\mathcal{P}_e$ is such that $|\mathcal{P}_e| < |\mathcal{P}|/2$ and contains $|\mathcal{P}_e|$ of the best solutions in $\mathcal{P}$ and $\mathcal{P}_{\bar{e}}$ consists of the remaining solutions in $\mathcal{P}$, that is, $\mathcal{P}_{\bar{e}} = \mathcal{P} \setminus \mathcal{P}_e$. $\mathcal{P}^+$ is the population of the next generation. It is initialized in line 8 with the elite solutions of the current generation. In line 9, the mutant subpopulation $\mathcal{P}_m$ is generated. Each mutant is a vector of n random keys. The number of generated mutants in general is such that $|\mathcal{P}_m| < |\mathcal{P}|/2$. This subpopulation is added to the population $\mathcal{P}^+$ of the next generation in line 10.

With $|\mathcal{P}_e| + |\mathcal{P}_m|$ vectors inserted in population $\mathcal{P}^+$, it is necessary to generate $|\mathcal{P}| - |\mathcal{P}_2| - |\mathcal{P}_m|$ new offspring to complete the $|\mathcal{P}|$ vectors that form population $\mathcal{P}^+$. This is done in lines 11–20. In lines 12 and 13 parents a and b are chosen, respectively, at random from subpopulations $\mathcal{P}_e$ and $\mathcal{P}_{\bar{e}}$. The generation of offspring c from parents a and b occurs in lines 14–18. A biased coin (with probability $\rho > 0.5$ of flipping to heads) is thrown n times. If the i-th toss is a head, the offspring inherits the i-th key of parent a. Otherwise, it inherits the i-th key of parent b. After the offspring is generated, c is added to population $\mathcal{P}^+$ in line 19.

The generation of $\mathcal{P}^+$ ends when it consists of $|\mathcal{P}|$ elements. In line 21, $\mathcal{P}^+$ is copied to $\mathcal{P}$ to start a new generation. The best solution in the current population in evolution is computed in line 22, and if its value is better than all solutions examined so far, the solution and its cost are saved in lines 24 and 25 as χ^* and f^*, respectively. χ^*, the best solution found across all populations, is returned by the algorithm in line 29.

Optional Procedures of the Framework

There are several ways to modify the BRKGA algorithm in order to increase solution quality, convergence, diversity, and other criteria. One of these is the use of the restart. In BRKGA, the restart or reset of the population is the elimination of all current individuals and the recreation of the entire population with random chromosomes. This is done, generally, after I_r number of iterations without improvement in the best overall solution $\chi*$, similar to the restart strategy for GRASP with path-relinking [91], has been shown to increase individual diversity and prevent premature convergence [80, 110].

A partial restart is also possible. The shaking method [6] is akin to a perturbation of the Iterated Local Search (ILS) algorithm [59] and acts by modifying a part of the genes of the elite solutions, while the non-elite chromosomes are completely restarted. That means some of the structures gained in the evolutionary process are preserved in the elite set, while the complete population has guaranteed diversity. The shake operator is usually applied after I_s iterations without improvement in the best overall solution $\chi*$ and, like the ILS perturbation, has strength parameters SK_l, indicating the lower bound, and SK_u, corresponding to the upper bound.

Another common feature is the island model [115]. Inspired by divergent evolution, the island model is the simultaneous evolution of p parallel populations.

The idea is that parallel evolution will lead to different characteristics in the solutions, thereby enabling a more extensive exploration of the solution space. Every g generations, i elite individuals are exchanged among populations, which increases diversity and helps spread novel and interesting structures among the solutions.

Many authors also attempt to introduce interesting structures into the initial population by injecting warm start solutions. This addition is shown to increase the performance and convergence of the method. In general, one or more good solutions are created with other heuristics [1, 4, 18, 54, 64, 100, 116] or mathematical models [17, 98] and then inserted into the initial population. In some cases, the entire initial population can be created using alternative methods, as is done in [120], where the solutions have specific characteristics that are not easily obtained in randomly generated individuals.

One more recent addition to the BRKGA framework is the use of multi-parent crossover [7]. In it, several parents are considered in the mating process, and the choice of inheritance is done using a ranking function. Consider the following example: there are three total parents, denoted as a, b, and c. Of those, both a and b belong to the elite set, while c belongs to the non-elite set. For multi-parent crossover, those parents would be ranked according to their fitness values, so that the first in order would have better fitness than the following ones, and so forth. In this case, considering a minimization problem, observe that $f(a) < f(b) < f(c)$. The ranking of solutions would, thus, be $r(a) = 1$, $r(b) = 2$, and $r(c) = 3$. With these values, the procedure uses a bias function $\Phi(r)$ [12] to calculate the probabilities of each parent being chosen in the mating. The bias function is nonincreasing, so parents with better fitness have a higher chance of being chosen and can belong to several classes, such as exponential, linear, logarithmic, and others.

One last optional procedure is Implicit Path-Relinking [7]. The classical path-linking is an intensification strategy that explores the neighborhood in the path between two distinct solutions [34, 92]. Typically, path-relinking is problem-dependent, due to the exploration of the intermediate solutions. However, the implicit variant leverages the random-key structure of BRKGA to perform the procedure within the random-key solution space, with differences depending on the type typ of the decoding process. This procedure works by first selecting two solutions from different populations using method sel, which can be the best or randomly chosen among the elite individuals. The selected individuals must have a minimum distance of md, which is calculated by either the Hamming (direct IPR) or Kendall Tau (permutation IPR) distances. A percentage $cp\%$ of the total pairs of elite chromosomes are tested as candidates from IPR, and if no pairs have the minimum distance, then the IPR procedure is not executed. This limitation of candidate pair testing is done to decrease the computational burden of the algorithm. Two other parameters are used in IPR. Parameter $ps\%$ is the size of the path between the two candidates that is evaluated at each IPR iteration, given as a percentage of the chromosome size. In each test, a block of genes of size bs is modified in the base solution to become similar to the one in the guide solution, thus obtaining intermediate solutions that are then explored.

Hybridizing a Random-Key Genetic Algorithm

To increase performance and/or adapt the algorithm to problems with specific characteristics, the authors often incorporate additional methods or frameworks to work in conjunction with BRKGA. This practice is very common for BRKGA, especially when the addition is a local search.

The use of local search (LS) in a genetic framework is viewed as an application of Lamarck's theory of evolution, in which individuals pass on the characteristics they acquire during their lifetime to their descendants [23]. It is particularly common for BRKGA, as it has been shown to significantly increase solution quality and convergence [56]. The use of local search can be within [54, 61] or outside the decoding process, with the latter case applied to all chromosomes in every iteration [14,100], only the best incumbent solution after evolution is complete [18,65], or to special chromosomes in some generations [2, 16, 45, 53]. Established methods can also be used as LS, such as Variable Neighborhood Search [21, 60, 96, 104, 105], Clustering Search [19], ILS [99], IGA [1], and INLS [117].

When not performed as a local search, hybridization is typically used to adapt the framework to specific problem characteristics. Some examples are:

- *Multi-objective optimization*: Bierbüße et al. [10], Bolsi et al. [11], Chagas et al. [18], Damm et al. [25], Fontes and Homayouni [31], Fontes et al. [32], Ibarra-Rojas et al. [44], Liu et al. [52], Marques Jr et al. [63], Mikulski and Tomczewski [68], Ramos et al. [88], Raposo et al. [89], Santiyuda et al. [95], and Silva-Soto and Ibarra-Rojas [103]
- *Matheuristics*: Lima et al. [51], Pinacho-Davidson and Blum [84], Pinto et al. [86], and Sun and Zhou [109]
- *Machine learning*: Amaro Júnior et al. [4], Damm et al. [25], Pan et al. [79], Schenekemberg et al. [96], Schenekemberg et al. [97], Xie et al. [116], Xu et al. [117], and Yang et al. [118]
- *Stochastic optimization and scenario generation*: Huang et al. [42], Londe et al. [53], Oliveira et al. [73], Oliveira et al. [74], and Oliveira et al. [75]

Customizing a RKGA

To customize an RKGA, one needs to define how a solution is represented, or encoded, and how the corresponding decoding procedure is done. Also, it is necessary to choose and customize any hybrid methods, if applicable. After this, the algorithm's parameters must be tuned.

Since each solution is represented as a vector of n random keys, it is necessary only to specify a value for n for the encoding. It may represent the number of vertices in a graph, or the total number of jobs and pauses in parallel machines, or the possible locations for facility installation, or the number of parameters to be analyzed, for example.

The decoder is a deterministic procedure that takes as input the chromosome of n random keys and produces as output the solution of the problem alongside the corresponding fitness value. Three types of decoding procedures can be defined as follows: indicator, permutation, and a mix of both. In a permutation decoder, the solution is obtained by sorting the random keys and constructing a feasible solution with the permutation of the indices. Examples of problems that often have permutation-based decoders are Location [53, 65], Cutting and Packing [3, 71], Vehicle Routing [43, 96], Traveling Salesman Problem [4, 18], and Graph Problems [51, 101].

An indicator decoder, in contrast, obtains meaning directly from the values of the random keys. For example, consider that one wishes to assign each point, represented by one random key, to one of the four classes. In this case, the algorithm may consider that the interval [0, 1) is divided into four equal intervals of size 0.25, with the first class being indicated by values in the interval [0, 0.25), the second class by the interval [0.25, 0.50), and so forth. For solution c, if the i-th gene has value $0.25 \leq c[i] < 0.50$, then the corresponding i-th element belongs to the second class. The use of indicator decoders is common in Network Configuration [7, 8, 82, 89], Clustering [64, 72], and Parameter Optimization [22, 29, 45].

Sometimes, a problem has characteristics that make a pure indicator- or permutation-based representation inadequate. When this happens, the authors tend to mix those two, generally by partitioning the chromosome into two or more parts. One example of this practice is done in [113] to locate mobile labs, in which the first genes are sorted to obtain the order of service points, while the last genes indicate an increase of the area of service radius. Another example is [33] for a two-level hub location problem, where the random-key interval is divided by the number of desired hubs. For the genes in each interval, the values are sorted, with the order of the directed graph being indicated by the ordered genes and the first gene corresponding to the hub. In [5], a complex problem related to wireless network design is addressed using a five-part chromosome. The first two sections consist of random keys that indicate the pertaining and parameterization of the solution. The next two sections are used to establish the evaluation order of the deployed equipment and its relation. Lastly, the final section serves as indicators to determine the depths of the network trees.

Tuning an RKGA

Table 1 presents all the parameters that were commented on in the traditional BRKGA and the optional procedures, together with their recommended values from the current literature. One can note that if all procedures are desired, then almost 20 parameters need to be specified to run a BRKGA.

Due to the number of parameters and how much they affect performance, the authors have used many strategies for parameter configuration, either before or during the execution of experiments. When done before, this is called *offline tuning* and is widely used for metaheuristics [26].

Table 1 BRKGA parameters and recommended ranges

Parameter	Recommended value
$\|\mathcal{P}\|$: size of population	$\min\{[100, 500], \lfloor 10 \times n \rfloor\}$
$\mathcal{P}_e\%$: percentage of elite partition of population	[0.1, 0.5]
$\mathcal{P}_m\%$: percentage of mutant partition of population	[0.1, 0.5]
ρ: probability of inheriting key from elite parent	[0.5, 1]
p: number of parallel populations	$\{1, \ldots, 3\}$
g: frequency for population interchange	[50, 500]
i: number of elite migrants between parallel populations	{1, 2}
I_r: iterations without improvement for restart	[200, 500]
I_s: iterations without improvement for shaking	[20, 100]
SK_l: lower bound for shake intensity	[0.1, 0.5]
SK_u: upper bound for shake intensity	[0.5, 0.9]
π_t: total number of parents in multi-parent crossover	[3, 10]
π_e: total number of elite parents in multi-parent crossover	$[1, 7], \pi_e < \pi_t$
$\Phi(r)$: type of bias function for multi-parent crossover	$\{1/\log(r+1), r^{-1}, r^{-2}, r^{-3}, e^{-r}, 1/\pi_t\}$
sel: individual selection method for path-relinking	[*BESTSOLUTION*, *RANDOMELITE*]
$cp\%$: percentage of chromosome pairs to be tested for path-relinking	[50, 500]
md: minimum distance between chromosome pairs for path-relinking	[0.0, 0.30]
bs: block size for path-relinking	1.00
$ps\%$: path size for path-relinking	[0.01, 1]
I_{ipr}: frequency of path-relinking	[50, 500]

For BRKGA, the authors have used several offline strategies. One of the simplest methods is a grid search, also known as the full factorial design of experiments. Grid search evaluates all possible combinations of given discrete parameters. However, the complexity of the method increases with each parameter and each candidate range, making it costly to perform if there are many parameters with their own interactions and codependence [30]. Some studies that used grid search are [16, 24, 83, 93].

Other authors utilize parameters suggested by similar groups of problem instances in the literature. However, the performance of a particular algorithm with a specific configuration on some instances is of limited utility, and the generalization of configurations should be done cautiously [47]. The use of literature suggestions is done in [22, 74, 123].

Lastly, one may use an automated method of parameterization. For BRKGA, the authors seem to prefer Iterated F-Race [58], used recently in papers such as [5–8, 53–55, 65].

The parameters may also be tuned during the execution of the algorithm. This process, known as *online parameter control*, falls within the class of machine learning techniques and has been applied to BRKGA in two distinct approaches. In both cases, the parameters are updated at each algorithm generation, aiming to balance intensification and exploitation during evolution. In [4, 20, 99, 117], the authors use the Adaptive BRKGA (A-BRKGA), which updates parameters for population size, elite proportion, mutant proportion, crossover probability, and maximum number of generations at each iteration. It also utilizes two self-adaptive parameters, denoted as α and β, where α indicates the number of members from the elite restricted list that evolve, and β represents the probability of perturbing individuals that are too similar. At each generation, the values of population size, mutant proportion, and α decrease, while elite proportion increases. β and crossover probability are incorporated as genes into the chromosomes and are thus always modified randomly.

The other online approach is called BRKGA-QL [21, 96]. It uses a Q-Learning algorithm [114] to control the same parameters of A-BRKGA in an environment of actions, states, and rewards. Simply put, each possible parameter modification is mapped to a possible reward, and the algorithm chooses one of the actions, with an η probability of selecting the action with the highest reward in terms of intensification. The value of η decays during evolution, so that in later generations, actions that increase diversification tend to be chosen. BRKGA-QL was extended to work with multi-objective problems [25] and had a new reward scheme and diversity methods introduced in [97].

In [112], the author also studies online approaches for BRKGA. It is demonstrated that a random parameter strategy can yield better results compared to more elaborate schemes. This strategy defines upper and lower bounds for parameters $\mathcal{P}$, $\mathcal{P}^e$, $\mathcal{P}^m$, and ρ. Then, in each generation, the parameter values are randomly sampled inside uniform probability distributions between the specified bounds. This approach outperformed the common F-Race-tuned BRKGA in problems with simple decoding strategies.

APIs for BRKGA

To simplify the implementation of BRKGAs, Toso and Resende [110] proposed an *Application Programming Interface (API)* in C++ for BRKGA. The API is efficient and user-friendly. The library is portable and automatically handles several aspects of the BRKGA, including population management and evolutionary dynamics. The API is implemented in C++ and uses an object-oriented architecture. In systems with available *OpenMP* [78], the API enables parallel decoding of random key vectors. The user only needs to implement the decoder and specify the stopping criteria, restart and population exchange mechanisms, as well as the parameters of

the algorithm. The API is open source and can be downloaded from http://github.com/rfrancotoso/brkgaAPI.

Andrade et al. [7] modernized Toso and Resende [110] leveraging the BRKGA with multi-parent crossover and implicit path-relinking, alongside a multi-population strategy, warm start solution injection, restart, and partial restart features. This framework is also easy to use, as it automatically handles all of those features during the evolutionary process, with the user needing to define only the parameters, decoder, and instance class. The C++ version is available at https://github.com/ceandrade/brkga_mp_ipr_cpp, the Python version at https://github.com/ceandrade/brkga_mp_ipr_python, and the Julia package at https://github.com/ceandrade/BrkgaMpIpr.jl.

One last API, called BRKGACuda 2.0, is presented by Oliveira et al. [76]. This novel application is optimized to work with parallelism and GPUs, significantly accelerating the algorithm. The API provides all of the classical BRKGA evolutionary operators, with the user only needing to specify the decoder. This C++ algorithm can be found at https://github.com/discovery-unicamp/brkga-cuda.

Conclusion

This chapter reviewed random-key genetic algorithms, covering both the unbiased and biased variants. After introducing Bean's algorithm [9], this chapter highlights the minor differences between the RKGA and the BRKGA that contribute to the improved performance of the biased variant. A model for implementing the BRKGA is described, followed by a discussion of optional procedures within the framework. The use of hybrid methods, as well as the customization of the algorithm regarding decoding processes and tuning methodologies, is also detailed. Finally, this chapter concludes by presenting three APIs for BRKGA that allow for easy implementation of the algorithm.

Abstract

Tabu search (TS) is a solution methodology within the area of metaheuristics. While the methodology applies to optimization problems in general, most TS applications have been and continue to be in discrete optimization. A key and distinguishing feature of tabu search is the use of special strategies based on adaptive memory. The underlying philosophy is that an effective search for optimal solutions should involve a flexible process that responds to the objective function landscape in a manner that allows it to learn appropriate directions to

exploit specific areas of the solution space and useful departures to explore new terrain. The adaptive memory structures of tabu search enable the implementation of procedures that are capable of searching effectively and produce solutions of suitable quality within reasonable computational effort.

Keywords

Heuristic search · Metaheuristics · Optimization

Introduction

Tabu search (TS) has its origins in Fred Glover's seminal 1977 paper *Heuristics for Integer Programming Using Surrogate Constraints*. This article introduced three key concepts: (1) scatter search, (2) oscillating assignment, and (3) strongly determined and consistent variables. Scatter search was later developed into a full-blown metaheuristic that is now well-established in the literature. Once tabu search was fully developed, oscillating assignment became the TS mechanism known as strategic oscillation. The concept of strongly determined and consistent variables became part of the tabu search long-term memory strategies, as described below. Without using the term tabu, the knapsack heuristic in [1] illustrates the use of short-term memory. The tabu search name was coined in [2], where the method was introduced as a "metaheuristic superimposed on another heuristic." It was also the first time that "metaheuristic" was used in the literature.

A tabu search starts from an initial solution and explores the solution space by making transformations to move from one solution to the next. That is, TS belongs to the family of metaheuristic methodologies that are based on single-solution searches. This family includes methodologies such as simulated annealing and variable neighborhood search. In contrast, genetic algorithms and scatter search belong to population-based metaheuristics, which create, maintain, and evolve a population of solutions as a means to explore the solution space. TS is based on the premise that problem-solving, in order to qualify as intelligent, must incorporate adaptive memory and responsive exploration.

The choices to determine how to transform a solution are guided by information collected during the search through adaptive memory structures that minimize the reliance in the sampling techniques that are typically employed by memoryless designs. Adaptive memory contrasts with rigid memory designs characteristic of branch and bound strategies. Responsive exploration integrates the basic principles of intelligent search, i.e., exploiting good solution features while exploring new promising regions. Tabu search is concerned with finding new and more effective ways of taking advantage of the mechanisms associated with both adaptive memory and responsive exploration.

Short-Term Memory

Tabu search can be applied directly to verbal or symbolic statements of many kinds of decision problems, without the need to transform them into mathematical formulations. Nevertheless, it is useful to introduce mathematical notation to express a broad class of these problems, as a basis for describing certain features of tabu search. We characterize this class of problems as that of optimizing (minimizing or maximizing) a function $f(x)$ subject to $x \in X$, where the set X summarizes constraints on the vector of decision variables x, including those that compel all or some components of x to receive discrete values. The problem of interest may not have an easy mathematical representation, but the verbal stipulations could be coded as rules.

Tabu search begins in the same way as ordinary local or neighborhood search, proceeding iteratively from one point (solution) to another until a chosen termination criterion is satisfied. Each solution $x \in X$ has an associated neighborhood $N(x) \subset X$, and each solution $x' \in N(x)$ is reached from x by an operation called a *move*. Hence, x' is said to be a neighbor of x.

In a minimization problem, best improving refers to the strategy of identifying $x^* \in N(x)$ such that $f(x^*) < f(x')$ for all $x' \in N(x)$. The move value is the change in the objective function value from the current solution to the solution after the move, i.e., $v = f(x^*) - f(x)$. Therefore, $v < 0$ for improving moves and $v \geqslant 0$ for nonimproving moves. In steepest descent, the procedure only makes improving moves, and it stops when no improving move is available in the neighborhood of the current solution. That is, the best neighbor of a solution becomes the new current solution as long as the move reduces the objective function value. In contrast, the best-improving strategy in TS chooses the best neighbor of x^* of x even when $v \geqslant 0$. In spite of its attractiveness, in certain settings the best-improving strategy is sometimes impractical because it may be computationally too expensive, as when $N(x)$ is large or each element is costly to retrieve or evaluate.

The relevance of choosing good solutions from current neighborhoods is magnified when the guidance mechanisms of tabu search are introduced to go beyond the locally optimal termination point of a descent method. Thus, an important first-level consideration for tabu search is to determine an appropriate *candidate list strategy* for narrowing the examination of elements of $N(x)$ in order to achieve an effective trade-off between the quality of x_* and the effort expended to find it. A popular candidate list strategy is known as the first-improving strategy. This strategy is such that neighbors are scanned in a predetermined order and the search moves to the first $x' \in N(x)$ for which $f(x') < f(x)$. If no such a move exists, then the search moves to the best-nonimproving move in the neighborhood.

Short-term memory functions give the search the opportunity to continue beyond local optima, by allowing the execution of nonimproving moves coupled with the modification of the neighborhood structure of subsequent solutions. The modified neighborhood, denoted by $N^*(x)$, is the result of maintaining a selective history of the states encountered during the search.

The tabu classification serves to identify elements of $N(x)$ that are excluded from $N^*(x)$. Characterized in this way, TS may be viewed as a dynamic neighborhood method. This means that the neighborhood of x is not a static set, but rather a set that can change according to the history of the search. A TS process based on short-term strategies may allow a solution x to be visited more than once, but it is likely that the corresponding reduced neighborhood $N^*(x)$ will be different each time. From a practical standpoint, the method will characteristically identify an optimal or near-optimal solution long before a substantial portion of X is examined.

The approach of storing complete solutions (*explicit* memory) generally consumes a massive amount of space and time when applied to each solution generated. Therefore, instead of recording full solutions, TS memory structures are based on recording attributes (*attributive* memory). In addition, short-term memory is based on the most recent history of the search trajectory (*recency-based* memory). In recency-based attributive memory, selected attributes that occur in solutions recently visited are labeled *tabu-active* and moves that contain tabu-active elements, or particular combinations of these attributes, are those that are classified tabu. This prevents certain solutions from the recent past from belonging to $N^*(x)$ and hence from being revisited. Other solutions that share such tabu-active attributes are also similarly prevented from being visited.

The number of iterations (i.e., executed moves) that an attribute remains tabu-active is known as the tabu tenure. Tabu tenure can be static, i.e., fixed throughout the search, or dynamic, i.e., vary either systematically or probabilistically. Aspiration criteria are introduced in tabu search to determine when tabu activation rules can be overridden, thus removing a tabu classification otherwise applied to a move. The most common aspiration criterion consists of removing a tabu classification from a trial move when the move yields a solution better than the best obtained so far.

Example 1

The short-term memory structure of tabu search will be illustrated with the following instance of the classical 0-1 knapsack problem:

Maximize $67x_1 + 500x_2 + 98x_3 + 200x_4 + 120x_5 + 312x_6 + 100x_7 + 200x_8 + 180x_9 + 100x_{10}$

$$\text{Subject to } 5x_1 + 45x_2 + 9x_3 + 19x_4 + 12x_5 + 32x_6 + 11x_7 + 23x_8 + 21x_9 +$$

$$14x_{10} \leqslant 100$$

$$x \in \{0, 1\}$$

The initial solution is found using a greedy heuristic that consists of selecting items (i.e., setting variable values to 1), one by one, in decreasing order of their bang-for-buck ratio. The process ends when adding one more item exceeds the capacity of the knapsack. The bang for buck is the ratio of profit to weight,

where profits are the objective function coefficients and weights are the constraint coefficients. For simplicity, the variables in the example are indexed by their bang-for-buck ratio. That is, x_1 is the variable with the highest ratio and x_{10} is the variable with the lowest ratio. The construction of the initial solution is summarized in Table 1.

The move mechanism is defined as changing the value of a single variable from either zero to one or one to zero; this is also known as a "flip" move. The best-improving strategy is used, meaning that all moves are considered and the one that results in the neighbor with the best objective function value is chosen. The neighborhood of the current solution is then given in Table 2.

Since in this example the search is not allowed to visit infeasible solutions, there is no improving move in the neighborhood of the current solution. Under this restriction, the best move is the first in the table and consists of changing the value of x_1 from one to zero. The Neighbor column shows the indexes of the variables that are set to one as a result of the corresponding move. The short-term memory structure may be designed as follows:

Attribute: Index of the variable that was chosen to change values
Tabu classification: A move that includes a tabu-active variable is classified tabu
Tabu tenure: Three iterations

Table 1 Construction of initial solution for Example 1

Item	Profit	Weight	Ratio	Chosen?	Profit	Weight
1	67	5	13.40	1	67	5

				Total	985	90

Table 2 Neighborhood of the current solution in Example 1

No.	Move	Neighbor	Profit	Weight
1	$x_1 = 0$	(2, 3, 4, 5)	918	85
2	$x_2 = 0$	(1, 3, 4, 5)	485	45
3	$x_3 = 0$	(1, 2, 4, 5)	887	81
4	$x_4 = 0$	(1, 2, 3, 5)	785	71
5	$x_5 = 0$	(1, 2, 3, 4)	865	78
6	$x_6 = 1$	(1, 2, 3, 4, 5, 6)	1297	122
7	$x_7 = 1$	(1, 2, 3, 4, 5, 7)	1085	101
8	$x_8 = 1$	(1, 2, 3, 4, 5, 8)	1185	113
9	$x_9 = 1$	(1, 2, 3, 4, 5, 9)	1165	111
10	$x_{10} = 1$	(1, 2, 3, 4, 5, 10)	1085	104

Table 3 Ten iterations of the short-term memory procedure

Iteration	Tabu-active	Move	Solution	Profit	Weight
0			(1, 2, 3, 4, 5)	985	90
1		1	(2, 3, 4, 5)	918	85
2	1	7	(2, 3, 4, 5, 7)	1018	96
3	7 1	3	(2, 4, 5, 7)	920	87
4	3 7 1	5	(2, 4, 7)	800	75
5	5 3 7	8	(2, 4, 7, 8)	1000	98
6	8 5 3	7	(2, 4, 8)	900	87
7	7 8 5	3	(2, 3, 4, 8)	998	96
8	3 7 8	4	(2, 3, 8)	798	77
9	4 3 7	9	(2, 3, 8, 9)	978	98
10	9 4 3	8	(2, 3, 9)	778	75

Using this structure, attribute 1 is declared tabu-active and therefore a move that attempts to change the current value of x_1 is classified tabu for three iterations. Table 3 shows ten iterations of the procedure using the short-term memory structure defined above.

The tabu-active column shows the indexes of the variables that are tabu-active. Each index appears for three iterations. It starts in the first position, and it moves one position in each iteration until it is removed from the list. The Move column indicates the variable that has been chosen to "flip" its value. The Solution column shows the solution after the move has been executed with the resulting profit and weight shown in the last two columns, respectively. The best solution is found in the second iteration and has a profit of 1018.

This example is based on very simple "flip" moves. The neighborhood defined by the move mechanism is a design choice of critical importance for the performance of the method. Often, the neighborhood is defined by several move types that may vary in complexity. The attributes to be used for the tabu classification of moves depend on those choices, and they also influence the performance of the search. For instance, in this example, a slightly more complex move would consist of flipping the values of two variables. Instead of 10 neighbors, this move mechanism would generate 45 neighbors, corresponding to all combinations of variables taken two at a time. A potential short-term memory structure for this neighborhood is as follows:

Attributes: Indexes of the variables that were chosen to change values.

Tabu classification: A move that includes at least one tabu-active variable is classified tabu.

Tabu tenure: Three iterations for a variable flipping from 1 to 0 and two iterations for a variable flipping from 0 to 1.

The tabu tenure recognizes that in a typical knapsack problem there will be more variables outside the knapsack (i.e., with their values set to zero) than those inside the knapsack (i.e., with their values set to one). Therefore, if an item is taken from

the knapsack (i.e., its corresponding variable value is switched from one to zero), the tabu tenure keeps this item outside longer than when an item enters the knapsack. This illustrates that the flexibility of the TS methodology allows the analyst to be creative and take full advantage of context information.

Example 2

Given a matrix of weights, the linear ordering problem (LOP) consists of finding a permutation p of the columns (and rows) in order to maximize the sum of the weights in the upper triangle. Consider the LOP instance in Table 4.

The objective function value associated with the solution $p = (1, 2, 3, 4, 5, 6, 7)$ is $f(p) = 78$, corresponding to the sum of the 21 values in the upper triangle. The elements in the permutation correspond to columns (and rows) of the matrix. Suppose that a tabu search explores the solution space by moving an element $p(i)$ from its current position i to a position j, between elements $p(j-1)$ and $p(j)$. In permutation problems, these are commonly referred to as *insert* moves. For instance, inserting $p(6) = 6$ in position 2 results in $p' = (1, 6, 2, 3, 4, 5, 7)$ with $f(p') = 86$.

Since TS determines where to move via neighborhood search, it is important to be able to calculate move values with the fewest possible number of operations. One naïve way of calculating a move value consists of executing the proposed move and calculating, from scratch, the objective function of the resulting neighbor solution. Then, the value of the move is obtained as the difference between the objective function value of the current solution and the objective function value that results after executing the move. In many settings, this process is inefficient and unnecessary. Clever move value calculations can significantly improve the efficiency of the neighborhood exploration. In the case of the LOP, the move value involves only a portion of the entries in the column (and corresponding row) associated with the element that is changing positions. For instance, for the insertion of $p(6) = 6$ in position 2 to transforms p into p', only the entries in the bold rectangles in Table 5 are needed to calculate the move value v.

The move value in this case is $v = 1 - 4 + 6 - 0 + 2 - 6 + 13 - 4 = 8$. The objective function value is $f(p^{'}) = f(p) + v = 78 + 8 = 86$. A short-term memory structure for this problem may be defined as follows:

Table 4 Instance of the linear ordering problem

p	1	2	3	4	5	6	7
1	0	12	5	3	1	8	3
2	6	0	3	6	4	4	2
3	8	5	0	5	7	0	3
4	−2	7	2	0	−3	6	0
5	8	0	3	−1	0	4	1
6	9	1	6	2	13	0	4
7	2	9	4	−5	8	1	0

Table 5 Data for the move value calculation (bold-outlined rectangles)

p	1	2	3	4	5	6	7
1	0	12	5	3	1	8	3
2	6	0	3	6	4	4	2
3	8	5	0	5	7	0	3
4	−2	7	2	0	−3	6	0
5	8	0	3	−1	0	4	1
6	9	1	6	2	13	0	4
7	2	9	4	−5	8	1	0

Attribute: Index of the element that was inserted in a new position
Tabu classification: An insertion of a tabu-active element is classified tabu
Tabu tenure: Five iterations

Note that due to the nature of the moves and the tabu classification, elements during their tabu-active period may change positions. To illustrate this point, consider the insertion of $p(6) = 6$ in position 2 that results in $p' = (1, 6, 2, 3, 4, 5, 7)$. Element 6 becomes tabu-active, and therefore it is not allowed to participate in insertions for the next five iterations. However, other non-tabu-active elements may be inserted in either position 2 or position 1, causing element 6 to shift to position 3.

Long-Term Memory

In many applications, the short-term TS memory components are sufficient to produce very high-quality solutions. However, in general, TS becomes significantly stronger by including longer-term memory and its associated strategies. Long-term memory plays an important role in creating the right balance between intensification and diversification of a tabu search. Intensification strategies are based on modifying choice rules to encourage move combinations and solution features historically found good. They may also initiate a return to attractive regions to search them more thoroughly. Diversification on the other hand encourages the search process to examine unvisited regions and to generate solutions that differ in various significant ways from those seen before.

Long-term memory is often implemented using a frequency-based approach. Frequency-based memory provides a type of information that complements the information provided by recency-based memory, broadening the foundation for selecting preferred moves. Like recency, frequency often is weighted or decomposed into subclasses by considering solution quality.

Frequencies consist of ratios, whose numerators represent either *transition* counts or *residence* counts. A transition count is the number of iterations where an attribute changes (enters or leaves) the solutions visited. A residence count

is the number of iterations where an attribute belongs to solutions visited. The denominators generally represent one of three types of quantities: (1) the total number of occurrences of all events represented by the numerators (such as the total number of iterations), (2) the sum (or average) of the numerators, and (3) the maximum numerator value.

The use of longer-term memory does not require long solution runs before its benefits become visible. Often its improvements begin to be manifest in a relatively modest length of time and can allow solution efforts to be terminated somewhat earlier than otherwise possible, due to finding very high-quality solutions within an economical time span. The chance of finding still better solutions as time grows—in the case where an optimal solution has not already been found—is enhanced by using longer-term TS memory in addition to short-term memory.

Residence frequencies and transition frequencies sometimes convey related information but in general carry different implications. For example, residence measures, by contrast to transition measures, are not concerned with whether an attribute changes in moving from somewhat inferior solutions to better solutions. A high residence frequency may indicate that an attribute is highly attractive if the domain consists of high-quality solutions or may indicate the opposite, if the domain consists of low-quality solutions.

Frequency-based memory is used to define penalty and incentive values to modify the evaluation of moves and therefore determine which moves are selected. In a minimization problem, the modified move value function has the following mathematical form:

$$v' = v \times (1 + pq)$$

Here, v is the original move value, p is the penalty factor, q is the frequency ratio, and v' is the modified move value. When $p = 0$, the original move value is not modified. A value of $p > 0$ penalizes the move and v' makes it less attractive. A value of $p < 0$ provides an incentive, and v' makes the move more attractive.

Long-term memory is linked to the notion of *strongly determined* and *consistent* variables. A strongly determined variable is one that cannot change its value in a given high-quality solution without seriously degrading quality or feasibility, while a consistent variable is one that frequently takes on a specific value (or a highly restricted range of values) in good solutions. The development of useful measures of "strength" and "consistency" is critical to exploiting these notions, particularly by accounting for trade-offs determined by context. However, straightforward uses of frequency-based memory for keeping track of consistency, sometimes weighted by elements of quality and influence, have produced methods with very good performance outcomes.

For instance, a penalty/incentive function based on frequency ratios may be used in a restarting procedure to generate initial solutions based on penalty/incentive functions. The function may be designed to asses a penalty on consistent variables in order to induce diversification.

Table 6 Reordering of the variables with the modified bang-for-buck ratios

Variable	q	r	r'	Order by r'
1	0.28	13.40	9.65	6
2	1.00	11.11	0.00	1
3	0.38	10.89	6.75	3
4	0.39	10.53	6.42	4
5	0.47	10.00	5.30	10
6	0.00	9.75	9.75	7
7	0.39	9.09	5.55	5
8	0.50	8.70	4.35	9
9	0.41	8.57	5.06	8
10	0.16	7.14	6.00	2

Example 3

Suppose that a residency memory is added to the short-term memory TS for the knapsack problem described above. The memory accumulates the number of times each item is included in the knapsack. That is, the memory is a count of the number of times that a variable takes on the value of one. To create a frequency ratio, the numerator is defined as the number of iterations. The search is going to be restarted from a new initial solution. Restarting means that the short-term memory will be erased and the long-term memory will be used during the construction of the new solution. The construction is guided by the following modified bang-for-buck ratio:

$$r' = r \times (1 - q)$$

The original bang-for-buck ratio is r and q is the frequency ratio. In this penalty function, the implicit value of p is -1. The function penalizes items with high-frequency ratios (i.e., the consistent variables). In this example, long-term memory is being used to induce diversification by attempting to construct a solution that has not been visited so far. Table 6 shows the calculation of the modified bang-for-buck ratios for a given set of q values.

The last column in the table above shows the order in which the items will be considered to be included in the knapsack according to the modified ratio. This results in a solution with variables 6, 1, 3, 4, 10, and 7 set to 1. The total profit is 877 and the weight is 90. This solution, which has not been visited so far, becomes the restarting point for the search.

Strategic Oscillation

Strategic oscillation is closely linked to the origins of tabu search and provides a means to achieve an effective interplay between intensification and diversification

over the intermediate to long term. Strategic oscillation operates by orienting moves in relation to the feasibility boundary, which represents a point where a search would normally stop. Instead of stopping when this boundary is reached, however, the rules for selecting moves are modified, to permit the region defined by the feasibility boundary to be crossed. The approach then proceeds for a specified depth beyond the oscillation boundary and turns around. The oscillation boundary again is approached and crossed, this time from the opposite direction, and the method proceeds to a new turning point.

The process of repeatedly approaching and crossing the feasibility boundary from different directions creates an oscillatory behavior, which gives the method its name. Control over this behavior is established by generating modified evaluations and rules of movement, depending on the region navigated and the direction of search.

The implementation of strategic oscillation entails the selection of a proximity measure and the amplitude of the oscillation. The proximity measure assigns a numerical value to moving toward or away from the feasibility boundary. This measure serves as guidance to create the oscillation pattern. The amplitude determines the point at which the search is directed to turn around once it has crossed the feasibility boundary in either direction.

Proximity measures are defined in reference to the problem constraints. For instance, for a combinatorial optimization problem consisting of selecting k out of a given number elements, a proximity measure t may be the difference between the number of elements that have been selected and k. Feasible solutions are those for which $t = 0$. Solutions with $t > 0$ have too many elements and solutions with $t < 0$ have too few. Moves can be designed to keep the search at $t = 0$ or to create an oscillation pattern around $t = 0$.

The oscillation amplitude is controlled by a number of moves m. If a move is made that causes the search to cross the feasibility boundary, then $m - 1$ is the number of additional moves that the search is allowed to make in the same direction (i.e., moving away from the feasibility boundary) before turning around.

In combinatorial optimization problems that require the selection of k elements, the rule to delete elements from the solution will typically be different in character from the one used for adding elements. In other words, one rule is not simply the inverse of the other. Rule differences are features of strategic oscillation that provide an enhanced heuristic vitality. The application of different rules may be accompanied by crossing a boundary to different depths on different sides. An option is to approach and retreat from the boundary while remaining on a single side, without crossing (i.e., electing a crossing of "zero depth").

In both one-sided and two-sided oscillation approaches, it is frequently important to spend additional search time in regions close to the feasibility boundary and, especially, to spend time at the boundary itself. In problems for which feasibility is determined by a set of constraints, vector-valued functions can be used to control the oscillation. In this case, controlling the search by bounding this function can be viewed as manipulating a parameterization of the constraint set.

Example 4

The feasibility boundary in the knapsack example is defined by the capacity of the knapsack, which in the example introduced above is a total weight of 100. To create a simple oscillation around the feasible boundary, the search is allowed to cross to the infeasible region and m is set to 1. The proximity measure t is defined as the difference between the total weight of the items in the knapsack and the knapsack capacity. Therefore, $t > 0$ indicates an infeasible solution and $t \leqslant 0$ corresponds to feasible solutions. The procedure operates with the following rules:

- When approaching the feasibility boundary from the feasible region, select the best non-tabu feasible move. If no feasible move is available, then select the non-tabu move that improves profit the most
- When approaching the feasibility boundary from the infeasible region, select the non-tabu move that removes the variable with the smallest bang-for-buck ratio.

The short-term memory structure is the same as the one defined in the "Short-Term Memory" section. Therefore, the move selections have to be done by considering the tabu classifications. Table 7 shows ten iterations of TS with strategic oscillation. The initial solution is given by the bang-for-buck heuristic.

The oscillation can be observed in the Weight column. Every time that the weight exceeds 100, the search turns around and moves are made to decrease the weight. The same occurs when the weight falls below 100. It is noteworthy to discuss the move made in the last iteration. The move is selected even though the move is classified tabu (note that 3 appears in the tabu-active list). At iteration 10, the initial solution is the best feasible solution found so far, and it has an objective function value of 985. Therefore, an aspiration criterion that overrides the tabu status of a move can be invoked (as discussed in the "Short-Term Memory" section). The

Table 7 Iterations of TS with strategic oscillation

Iteration	Tabu-active	Move	Solution	Profit	Weight
0			(1, 2, 3, 4, 5)	985	90
1		6	(1, 2, 3, 4, 5, 6)	1297	122
2	6	5	(1, 2, 3, 4, 6)	1177	110
3	5 6	4	(1, 2, 3, 6)	977	91

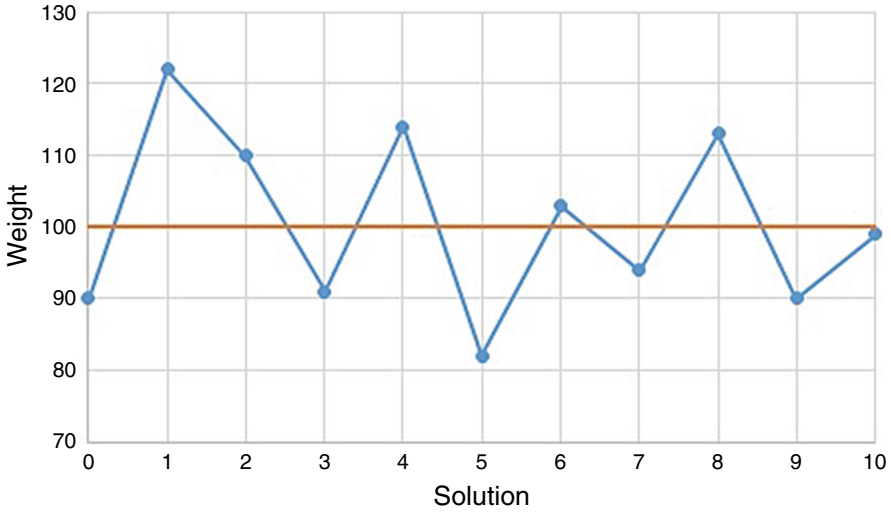

Fig. 1 Strategic oscillation around the knapsack capacity of 100

criterion states that the tabu classification can be overridden if the move leads to a solution that is better than the best solution found so far. Figure 1 shows a graphical representation of the oscillation pattern.

Example 5

The problem of maximizing diversity deals with selecting a subset of k elements from a given set of n elements in such a way that the diversity among the chosen elements is maximized. The best-known problem in this class deals with maximizing the sum of the diversity of the chosen elements. That is, if d_{ij} is the diversity measure between elements i and j, then the problem consists of maximizing $\sum_{i,j \in K} d_{ij}$, where K is the subset of chosen elements. The proximity measure t may be defined as the difference between the number of elements that have been selected and k, for an amplitude of m, t ranges between $-m$ and m, with $t = 0$ representing a feasible solution.

A swap move is defined as the exchange of an element currently in K with an element that is not currently in K. In this context, a swap neighborhood maintains feasibility as long as the starting solution is feasible (i.e., the solution includes k elements). In contrast, an add/delete neighborhood will not. A strategic oscillation may be defined as follows.

1. Construct a feasible solution K
2. Add elements $j \notin K$ that increases diversity the most. Elements are added one at a time until m is reached.

3. Delete elements $j \in K$ that decrease the diversity the least. Elements are deleted one at a time until m is reached.
4. Repeat 2 and 3 until a termination criterion is satisfied.

Short-term memory tabu structures may be embedded in this simple design in order to avoid cycling. For instance, elements that have been added may be declared tabu-active and are not allowed to be deleted during the next deletion cycle, and vice versa. Consider the diversity values in Table 8 for a problem with $k = 5$ and $n = 10$.

Let's assume that the starting solution is given by (1, 2, 3, 4, 5) with an objective function value of 45 and let $m = 2$. Table 9 shows 16 iterations of the strategic oscillation process, where a solution is defined by a set of 10 binary variables x_j:

Table 8 Instance of the maximum diversity problem

	1	2	3	4	5	6	7	8	9	10
1		4	5	0	3	2	0	2	4	2

5						4	8	6	2	1
6							6	5	4	5
7								0	6	8
8									6	1
9										3
10										

Table 9 Sixteen iterations of the strategic oscillation process

Iter	x_1	x_2	x_3	x_4	x_5	x_6	x_7	x_8	x_9	x_{10}	Move	t	MaxSum
0	1	1	1	1	1	0	0	0	0	0	+8	0	45
1	1	1	1	1	1	0	0	1	0	0	+9	1	73
2	1	1	1	1	1	0	0	1	1	0	−1	2	99
3	0	1	1	1	1	0	0	1	1	0	−5	1	81
4	0	1	1	1	0	0	0	1	1	0	−9	0	59
5	0	1	1	1	0	0	0	1	0	0	−3	−1	39
6	0	1	0	1	0	0	0	1	0	0	+6	−2	22
7	0	1	0	1	0	1	0	1	0	0	+5	−1	40
8	**0**	**1**	**0**	**1**	**1**	**1**	**0**	**1**	**0**	**0**	**+7**	**0**	**60**
9	0	1	0	1	1	1	1	1	0	0	+3	1	83
10	0	1	1	1	1	1	1	1	0	0	−6	2	112
11	0	1	1	1	1	0	1	1	0	0	−8	1	84
12	0	1	1	1	1	0	1	0	0	0	−2	0	58
13	0	0	1	1	1	0	1	0	0	0	−4	−1	36
14	0	0	1	0	1	0	1	0	0	0	+9	−2	20
15	0	0	1	0	1	0	1	0	1	0	+10	−1	34
16	0	0	1	0	1	0	1	0	1	1		0	50

The first column (Iter) shows the iteration number, where 0 is the initial solution. The next 10 columns show the values of the binary variables, where a value of 1 indicates that the element has been chosen. The Move column indicates the index of the element that enters (plus sign) or leaves (minus sign) the solution. The proximity measure is given in the column labeled t. The objective function value is shown in the last column. The solution at iteration 8 is the best feasible solution, with a MaxSum value of 60 and $t = 0$. Note that an aspiration criterion is being used to override the tabu status. In particular, the tabu status of a move is overridden if it leads to a solution with an objective function value that is the best visited so far for the corresponding t value. For instance, element 3 is added at iteration 9 even though this element is tabu (since it was deleted in the last deletion cycle). However, the addition of 3 results in the solution at iteration 10 that has the best objective function value of all those solutions with $t = 2$ that have been visited so far. The same logic is applied to allow the deletion of element 6 at iteration 10.

Path Relinking

A useful integration of intensification and diversification strategies occurs in the approach called *path relinking*. This approach generates new solutions by exploring trajectories that connect reference solutions—by starting from one of these solutions, called an *initiating solution*, and generating a path in the neighborhood space that leads toward the other solutions, called *guiding solutions*. This is accomplished by selecting moves that introduce attributes contained in the guiding solutions.

Path relinking is a strategy that seeks to incorporate attributes of high-quality solutions, by creating inducements to favor these attributes in the moves selected. However, instead of using an inducement that merely encourages the inclusion of such attributes, the path relinking approach subordinates all other considerations to the goal of choosing moves that introduce the attributes of the guiding solution, in order to create a "good attribute composition" in the current solution.

The procedure, at each step, chooses the best move, according to the change in the objective function value, from the restricted set of moves that incorporate a maximum number of the attributes of the guiding solutions. As in other applications of TS, aspiration criteria can override this restriction to allow other moves of particularly high quality to be considered.

Membership in the reference set is determined by setting a threshold which is connected to the objective function value of the best solution found during the search. For example, reference solutions might be those whose objective function value is within 10% of the best objective function value known so far.

Path relinking can be used to generate intensification strategies by choosing reference solutions that lie in a common region or that share common features. Similarly, diversification strategies based on path relinking characteristically select reference solutions that come from different regions or that exhibit contrasting features. The initiating solution can be used to give a beginning partial construction, by specifying particular attributes as a basis for remaining constructive steps.

Constructive neighborhoods can be viewed as a feasibility-restoring mechanism since a null or partially constructed solution does not satisfy all conditions to qualify as feasible. Similarly, path relinking can make use of destructive neighborhoods, where an initial solution is "overloaded" with attributes donated by the guiding solutions, and such attributes are progressively stripped away or modified until reaching a set with an appropriate composition. Destructive neighborhoods represent an instance of a feasibility-restoring function, as where an excess of elements may violate explicit problem constraints.

Path relinking consists of the following steps:

(a) Identify the neighborhood structure and associated solution attributes for path relinking (possibly different from those of other TS strategies applied to the problem).
(b) Select a collection of two or more reference solutions, and identify which members will serve as the initiating solution and the guiding solution(s). (Reference solutions can be infeasible, such as "incomplete" or "overloaded" solution components treated by constructive or destructive neighborhoods.)
(c) Move from the initiating solution toward the guiding solution(s), generating one or more intermediate solutions.

Example 6

Consider the two reference solutions in Table 10.

These solutions were found with a TS that used simple moves consisting of flipping one variable at a time. Both of these solutions are feasible. Suppose that solution 2 is chosen as the initiating solution and that solution 1 is the guiding solution. The relinking process starts by identifying the values that are common to both solutions. These correspond to variables 2, 3, and 5. Swap moves are used during the path relinking process in order to keep the intermediate solutions close to the feasibility boundary. A swap in this context corresponds to adding one item to the knapsack while taking another item out of the knapsack. This means that a variable that is set to 1 in the initiating solution and to 0 in the guiding solution must be paired with a variable that is set to 0 in the initiating solution and to 1 in the guiding solution. The pairs in our example are (1, 7), (1, 9), (4, 7), and (4, 9). Table 11 shows the intermediate solutions that result from these swaps:

Table 10 Two reference solutions

Solution	x_1	x_2	x_3	x_4	x_5	x_6	x_7	x_8	x_9	x_{10}	Profit	Weight
1	0	1	1	0	1	0	1	0	1	0	998	98
2	1	1	1	1	1	0	0	0	0	0	985	90

Table 11 Swaps in the path relinking process of Example 6

Swap	x_1	x_2	x_3	x_4	x_5	x_6	x_7	x_8	x_9	x_{10}	Profit	Weight
(1, 7)	0	1	1	1	1	0	1	0	0	0	1018	96
(1, 9)	0	1	1	1	1	0	0	0	1	0	1098	106
(4, 7)	1	1	1	0	1	0	1	0	0	0	885	82
(4, 9)	1	1	1	0	1	0	0	0	1	0	965	92

The best feasible swap is (1, 7), and the search moves to the intermediate solution with profit of 1018 and weight of 96. After the move, there is only one swap left to reach the guiding solution, namely, (4, 9). In this case, the process produced only one intermediate solution; however, in general, path relinking visits more solutions during the transformation of the initiating solution into the guiding solution.

Conclusions

This chapter presented the essential elements of tabu search, namely, short-term memory, long-term memory, strategic oscillation, and path relinking. Attention was given to these core components of the tabu search framework for the following reasons:

- Such a focus may help to uncover a better form for the strategies associated with these core components.
- Weaknesses and strengths of these core components, when studied in isolation from other ideas, may stand out more clearly, thus yielding insights into the features that a complete approach may require to produce better methods.
- For methods which are susceptible to highly modular implementations, as typically occurs for tabu search, simpler designs can readily be made a part of more complex designs.

While TS implementations using a combinations of these elements are likely to produce decent outcomes, readers are encouraged to pursue more complete approaches by examining strategies outlined in the publications referenced below, in particular those in the Tabu Search book [4].

A great deal remains to be learned about tabu search. Evidently, very little is known about how human beings use memory in problem-solving. It is not inconceivable that discoveries about effective uses of memory within search methods will provide clues about strategies that humans skillfully employ. The potential links between the areas of heuristic search and psychology have barely been examined. The numerous successes of tabu search implementations provide encouragement that such relationships might be profitable to investigate more fully.

Abstract

Variable neighborhood search (VNS) is a metaheuristic for solving combinatorial and global optimization problems. Its basic idea is systematic change of neighborhood both within a descent phase to find a local optimum and in a perturbation phase to get out of the corresponding valley. In this chapter we present the basic schemes of variable neighborhood search and some of its extensions. We next present four families of applications of VNS in which it has proved to be very successful: (i) finding feasible solutions to large mixed-integer linear programs, by hybridization of VNS and local branching, (ii) finding good feasible solutions

Introduction

Optimization tools have greatly improved during the last two decades. This is due to several factors: (i) progress in mathematical programming theory and algorithmic design, (ii) rapid improvement in computer performances, and (iii) better communication of new ideas and integration of them in largely used complex softwares. Consequently, many problems long viewed as out of reach are currently solved, sometimes in very moderate computing times. This success, however, has led to address much larger instances and more difficult classes of problems. Many of these may again only be solved heuristically. Therefore thousands of papers describing, evaluating, and comparing new heuristics appear each year. Keeping abreast of such a large literature is a challenge. Metaheuristics or general frameworks for building heuristics are therefore needed in order to organize the study of heuristics. As evidenced by this handbook, there are many of them. Some desirable properties of metaheuristics [24, 27, 29] are listed in the concluding section of this chapter.

Variable neighborhood search (VNS) is a metaheuristic proposed by some of the present authors a dozen years ago [40]. Earlier work that motivated this approach is given in [8, 13, 18, 38]. It is based upon the idea of systematic change of neighborhood both in a descent phase to find a local optimum and in a perturbation phase to get out of the corresponding valley. Originally designed for approximate solution of combinatorial optimization problems, it was extended to address, nonlinear programs, and recently mixed-integer nonlinear programs. In addition VNS has been used as a tool for automated or computer-assisted graph theory. This led to the discovery of over 1500 conjectures in that field, the automated proof of more than half of them as well as the unassisted proof of about 400 of them by many mathematicians. Moreover, VNS methodology is recently applied in artificial intelligence as automatic programming technique.

Applications are rapidly increasing in number and pertain to many fields: location theory, cluster analysis, scheduling, vehicle routing, network design, lot sizing, artificial intelligence, engineering, pooling problems, biology, phylogeny, reliability, geometry, telecommunication design, etc. References are too numerous to be listed here, but many of them can be found in [25, 28, 29] and in the following special issues devoted to VNS: *IMA Journal of Management Mathematics* [37], *European*

Journal of Operational Research [29], *Journal of heuristics* [47], *Computers and Operations Research* [45] and *Journal of Global Optimization* [11].

This chapter is organized as follows. In the next section we present the basic schemes of VNS, i.e., variable neighborhood descent (VND), reduced VNS (RVNS), basic VNS (BVNS), and general VNS (GVNS). In addition, to the list of basic schemes, we add skewed VNS (SVNS) and variable neighborhood decomposition search (VNDS). Three important extensions are presented in section "Some Extensions": primal-dual VNS (PD-VNS), formulation space search (FSS), and recently developed variable formulation search (VFS). The remainder of the paper describes applications of VNS to several classes of large-scale and complex optimization problems for which it has proven to be particularly successful. Finding feasible solutions to large mixed-integer linear programs with VNS is discussed in section "VNS for Mixed-Integer Linear Programming." Section "VNS for Continuous Global Optimization" addresses ways to apply VNS in continuous global optimization. Recent application of VNS in *automatic programming* field is discussed in section "Variable Neighborhood Programming." Applying VNS to graph theory per se (and not just to particular optimization problems defined on graphs) is discussed in section "Discovery Science." Conclusions are drawn in section "Conclusions." There the desirable properties of any metaheuristic are listed as well.

Basic Schemes

A deterministic optimization problem may be formulated as

$$\min \{f(x) | x \in X, X \subseteq \mathcal{S}\}, \tag{1}$$

where $\mathcal{S}$, X, x, and f, respectively, denote the *solution space* and *feasible set*, a *feasible solution*, and a real-valued *objective function*. If $\mathcal{S}$ is a finite but large set, a *combinatorial optimization* problem is defined. If $\mathcal{S} = \mathbb{R}^n$, we refer to *continuous optimization*. A solution $x^* \in X$ is *optimal* if

$$f\left(x^*\right) \leq f(x), \quad \forall x \in X.$$

An *exact algorithm* for problem (1), if one exists, finds an optimal solution x^*, together with the proof of its optimality, or shows that there is no feasible solution, i.e., $X = \varnothing$, or the solution is unbounded. Moreover, in practice, the time needed to do so should be finite (and not too long). For continuous optimization, it is reasonable to allow for some degree of tolerance, i.e., to stop when sufficient convergence is detected.

Let us denote with $\mathcal{N}_k$, $(k = 1, \ldots, k_{\max})$, a finite set of preselected neighborhood structures, and with $\mathcal{N}_k(x)$ the set of solutions in the kth neighborhood of x. Most local search heuristics use only one neighborhood structure, i.e., $k_{\max} = 1$. Neighborhoods $\mathcal{N}_k$ may be induced from one or more metric (or quasi-metric)

functions introduced into a solution space S. An *optimal solution* x_{opt} (or global minimum) is a feasible solution where a minimum is reached. We call $x' \in X$ a *local minimum* of (1) with respect to $\mathcal{N}_k$ (w.r.t. $\mathcal{N}_k$ for short), if there is no solution $x \in \mathcal{N}_k(x') \subseteq X$ such that $f(x) < f(x')$. Metaheuristics (based on local search procedures) try to continue the search by other means after finding the first local minimum. VNS is based on three simple facts:

Fact 1

A local minimum w.r.t. one neighborhood structure is not necessarily so for another;

Fact 2

A global minimum is a local minimum w.r.t. all possible neighborhood structures;

Fact 3

Local minima w.r.t. one or several $\mathcal{N}_k$ are relatively close to each other, for many problems.

This last observation, which is empirical, implies that a local optimum often provides some information about the global one. This may for instance be several variables with the same value in both. However, it is usually not known which ones are such. An organized study of the neighborhoods of this local optimum is therefore in order, until a better solution is found.

In order to solve (1) by using several neighborhoods, facts 1–3 can be used in three different ways: (i) deterministic, (ii) stochastic, and (iii) both deterministic and stochastic. We first give in Algorithm 1 the steps of the neighborhood change function that will be used later.

Algorithm 1: Neighborhood change

Function `NeighborhoodChange` (x, x', k);
1 **if** $f(x') < f(x)$ **then**
2 $\quad x \leftarrow x'$; $k \leftarrow 1$ // Make a move
else
3 $\quad k \leftarrow k + 1$ // Next neighborhood

Function `NeighborhoodChange()` compares the new value $f(x')$ with the incumbent value $f(x)$ obtained from the kth neighborhood (line 1). If an improvement is obtained, k is returned to its initial value and the new incumbent updated (line 2). Otherwise, the next neighborhood is considered (line 3).

(i) The *variable neighborhood descent* (VND) method is obtained if a change of neighborhoods is performed in a deterministic way. Its steps are presented in Algorithm 2, where neighborhoods are denoted as N_ℓ, $\ell = 1, \ell_{\max}$.

Algorithm 2: Steps of the basic VND

Function VND $(x, \ell_{\max})$
1 $\ell \leftarrow 1$
2 **repeat**
3 $\quad x' \leftarrow \arg\min_{y \in N_\ell(x)} f(x)$ // Find the best neighbor in $N_\ell(x)$
4 $\quad$ NeighborhoodChange (x, x', ℓ) // Change neighborhood
until $\ell = \ell_{\max}$

Most local search heuristics use in their descents a single or sometimes two neighborhoods ($\ell_{\max} \leq 2$). Note that the final solution should be a local minimum w.r.t. all $\ell_{\max}$ neighborhoods, and thus chances to reach a global one are larger than by using a single structure. Besides this *sequential* order of neighborhood structures in VND above, one can develop a *nested* strategy. Assume, e.g., that $\ell_{\max} = 3$; then a possible nested strategy is: perform VND from Algorithm 2 for the first two neighborhoods from each point x' that belongs to the third ($x' \in N_3(x)$). Such an approach is successfully applied in [5, 7, 25].

(ii) The *reduced VNS* (RVNS) method is obtained if random points are selected from $\mathcal{N}_k(x)$ and no descent is made. Rather, the values of these new points are compared with that of the incumbent, and updating takes place in case of improvement. We assume that a stopping condition has been chosen, among various possibilities, e.g., the maximum CPU time allowed $t_{\max}$, or the maximum number of iterations between two improvements. To simplify the description of the algorithms, we always use $t_{\max}$ below. Therefore, RVNS uses two parameters: $t_{\max}$ and $k_{\max}$. Its steps are presented in Algorithm 3.

Algorithm 3: Steps of the reduced VNS

Function RVNS$(x, k_{\max}, t_{\max})$
1 **repeat**
2 $\quad k \leftarrow 1$
3 $\quad$ **repeat**
4 $\quad\quad x' \leftarrow$ Shake(x, k)
5 $\quad\quad$ NeighborhoodChange (x, x', k)
$\quad$ **until** $k = k_{\max}$
6 $\quad t \leftarrow$ CpuTime ()
until $t > t_{\max}$

With the function Shake represented in line 4, we generate a point x' at random from the kth neighborhood of x, i.e., $x' \in \mathcal{N}_k(x)$. Its steps are given in Algorithm 4,

where it is assumed that points from $\mathcal{N}_k(x)$ are $\{x^1, \ldots, x^{|\mathcal{N}_k(x)|}\}$. RVNS is useful for very large instances for which local search is costly. It can be used as well for finding initial solutions for large problems before decomposition. It has been observed that the best value for the parameter $k_{\max}$ is often 2 or 3. In addition, a maximum number of iterations between two improvements is usually used as the stopping condition. RVNS is akin to a Monte Carlo method, but is more systematic (see, e.g., [42] where results obtained by RVNS were 30% better than those of the Monte Carlo method in solving a continuous min-max problem). When applied to the p-median problem, RVNS gave equally good solutions as the *fast interchange* heuristic of [56] while being 20–40 times faster [30].

Algorithm 4: Steps of the shaking function

Function `Shake`(x, x', k)
1 $w \leftarrow [1+\texttt{Rand}(0, 1) \times |\mathcal{N}_k(x)|]$
2 $x' \leftarrow x^w$

(iii) The *basic VNS* (VNS) method [40] combines deterministic and stochastic changes of neighborhood. The deterministic part is represented by a local search heuristic. It consists in (a) choosing an initial solution x, (b) finding a direction of descent from x (within a neighborhood $N(x)$), and (c) moving to the minimum of $f(x)$ within $N(x)$ along that direction. If there is no direction of descent, the heuristic stops, and otherwise it is iterated. Usually the steepest descent direction, also referred to as *best improvement*, is used (`BestImprovement`). This set of rules is summarized in Algorithm 5, where we assume that an initial solution x is given. The output consists of a local minimum, also denoted by x, and its value.

Algorithm 5: Best improvement (steepest descent) heuristic

Function `BestImprovement`(x)
1 **repeat**
2 $\quad x' \leftarrow x$
3 $\quad x \leftarrow \arg\min_{y \in N(x)} f(y)$
until $(f(x) \geq f(x'))$

As *steepest descent* heuristic may be time-consuming, an alternative is to use the *first descent* heuristic. Vectors $x_i \in N(x)$ are then enumerated systematically and a move is made as soon as a direction for the descent is found. This is summarized in Algorithm 6.

Algorithm 6: First improvement (first descent) heuristic

```
Function FirstImprovement(x)
1  repeat
2  |  x' ← x; i ← 0
3  |  repeat
4  |  |  i ← i + 1
5  |  |  x ← arg min{f(x), f(x_i)}, x_i ∈ N(x)
   |  until (f(x) < f(x_i) or i = |N(x)|)
   until (f(x) ≥ f(x'))
```

The stochastic phase is represented by random selection of one point from the k-th neighborhood. The steps of the BVNS are given on Algorithm 7.

Algorithm 7: Steps of the basic VNS

```
Function BVNS(x, k_max, t_max)
1  t ← 0
2  while t < t_max do
3  |  k ← 1
4  |  repeat
5  |  |  x' ← Shake(x, k)                  // Shaking
6  |  |  x'' ← BestImprovement(x')          // Local search
7  |  |  NeighborhoodChange(x, x'', k)     //Change neighborhood
   |  until k = k_max
8  |  t ← CpuTime()
```

Often successive neighborhoods $\mathcal{N}_k$ are nested. Note that point x' is generated at random in Step 4 in order to avoid cycling, which might occur if a deterministic rule were applied. Basic VNS is also illustrated in Fig. 1.

Example. We illustrate the basic step on a minimum k-cardinality tree instance taken from [34] (see Fig. 2). The minimum k-cardinality tree problem on graph G (k-card for short) consists in finding a sub-tree of G with exactly k edges whose sum of weights is minimum.

The steps of BVNS for solving the 4-card problem are illustrated in Fig. 3. In Step 0 the objective function value, i.e., the sum of edge weights, is equal to 40; it is indicated in the right bottom corner of the figure. That first solution is a local minimum with respect to the edge-exchange neighborhood structure (one edge in, one out). After shaking, the objective function is 60, and after another local search, we are back to the same solution. Then, in Step 3, we take out 2 edges and add another 2 at random, and after a local search, an improved solution is obtained with

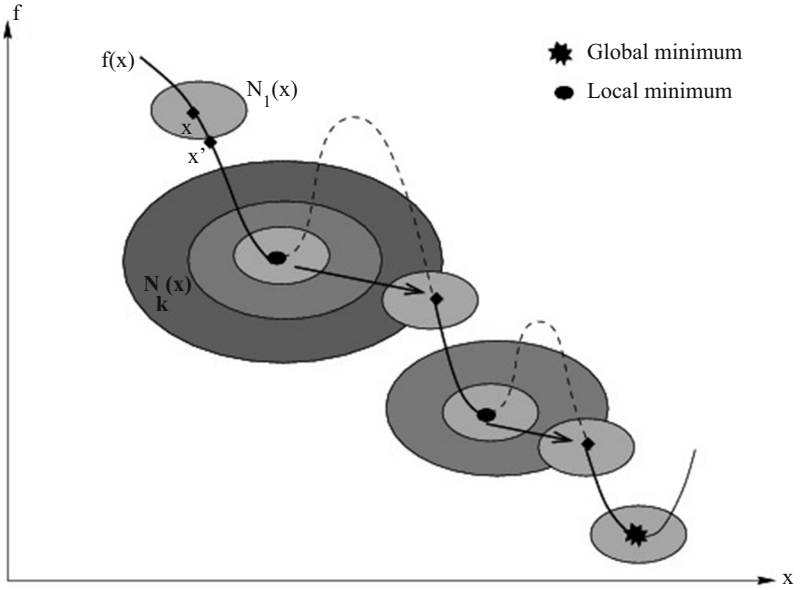

Fig. 1 Basic VNS

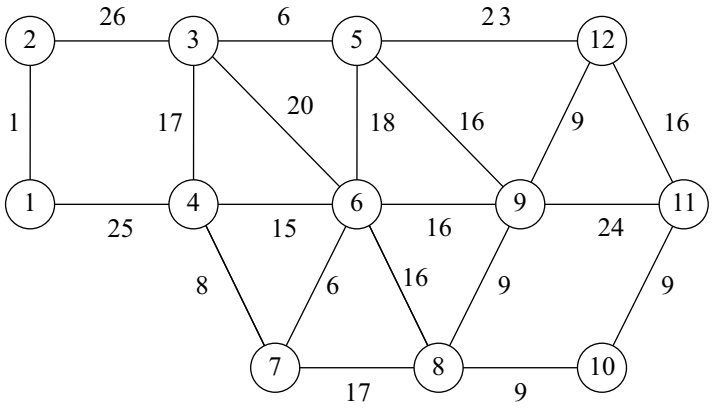

Fig. 2 4-cardinality tree problem

a value of 39. Continuing in that fashion, we obtain in Step 8 the optimal solution with an objective function value equal to 36.

(iv) *General VNS.* Note that the local search Step 5 may also be replaced by VND (Algorithm 2). Using this general VNS (VNS/VND) approach led to some of the most successful applications reported (see, e.g., [1, 7, 9, 10, 25, 31, 52, 53]). The steps of general VNS (GVNS) are given in Algorithm 8 below.

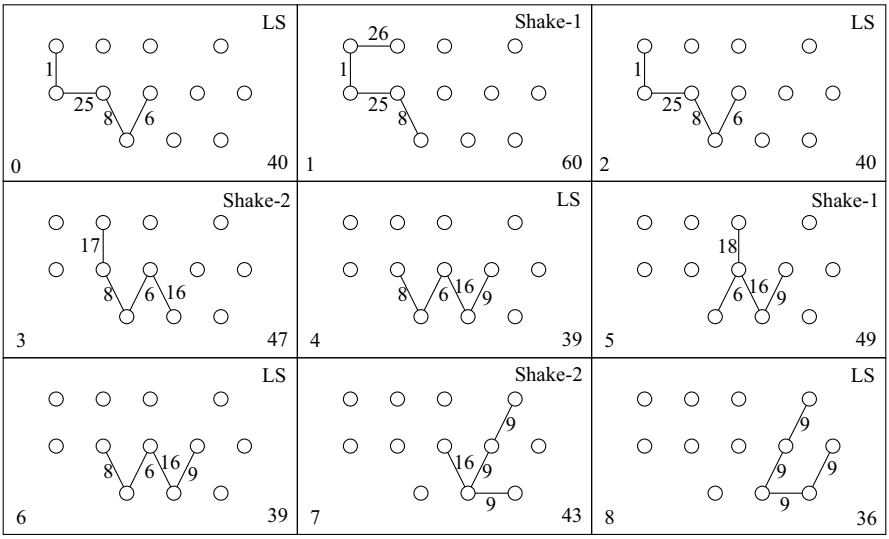

Fig. 3 Steps of the basicVNS for solving 4-card tree problem

Algorithm 8: Steps of the general VNS

Function GVNS $(x, \ell_{\max}, k_{\max}, t_{\max})$
repeat
  $k \leftarrow 1$
  repeat
    $x' \leftarrow$ Shake(x, k)
    $x'' \leftarrow$ VND$(x', \ell_{\max})$
    NeighborhoodChange(x, x'', k)
  until $k = k_{\max}$
  $t \leftarrow$ CpuTime()
until $t > t_{\max}$

(v) The *skewed VNS* (SVNS) method [23] addresses the problem of exploring valleys far from the incumbent solution. Indeed, once the best solution in a large region has been found, it is necessary to go quite far to obtain an improved one. Solutions drawn at random in faraway neighborhoods may differ substantially from the incumbent, and VNS may then degenerate, to some extent, into the multistart heuristic (in which descents are made iteratively from solutions generated at random, and that is known not to be very efficient). So some compensation for distance from the incumbent must be made, and a scheme called skewed VNS is proposed for that purpose. Its steps are presented in

Algorithms 9, 10, and 11. The KeepBest(x, x') function in Algorithm 10 simply keeps the better one of solutions x and x'.

Algorithm 9: Steps of neighborhood change for the skewed VNS

Function NeighborhoodChangeS(x, x'', k, α)
if $f(x'') - \alpha\rho(x, x'') < f(x)$ **then**
  $x \leftarrow x''$; $k \leftarrow 1$
else
  $k \leftarrow k + 1$

Algorithm 10: Steps of the skewed VNS

Function SVNS ($x, k_{\max}, t_{\max}, \alpha$)
repeat
  $k \leftarrow 1$; $x_{\text{best}} \leftarrow x$
  repeat
    $x' \leftarrow$ Shake(x, k)
    $x'' \leftarrow$ FirstImprovement(x')
    KeepBest (x_{best}, x)
    NeighborhoodChangeS(x, x'', k, α)
  until $k = k_{\max}$
  $x \leftarrow x_{\text{best}}$
  $t \leftarrow$ CpuTime()
until $t > t_{\max}$

Algorithm 11: Keep the better solution

Function KeepBest(x, x');
if $f(x') < f(x)$ **then**
  $x \leftarrow x'$

SVNS makes use of a function $\rho(x, x'')$ to measure distance between the incumbent solution x and the local optimum found x''. The distance function used to define $\mathcal{N}_k$, as in the above examples, could be used also for this purpose. The parameter α must be chosen in such a way to accept movement to valleys faraway from x when $f(x'')$ is larger than $f(x)$ but not too much larger (otherwise one will always leave x). A good value for α is to be found experimentally in each case. Moreover, in order to avoid frequent moves from x to a close solution, one may take a smaller value for α when $\rho(x, x'')$ is small. More sophisticated choices for a function of $\alpha\rho(x, x'')$ could be made through some learning process.

(vi) *Variable neighborhood decomposition search* (VNDS). The VNDS method [30] extends the basic VNS into a two-level VNS scheme based upon decomposition of the problem. Its steps are presented in Algorithm 12, where t_d is an additional parameter and represents the running time given for solving decomposed (smaller sized) problems by VNS.

Algorithm 12: Steps of VNDS

Function VNDS $(x, k_{\max}, t_{\max}, t_d)$
1 **repeat**
2 $\quad k \leftarrow 1$
3 $\quad$ **repeat**
4 $\quad\quad x' \leftarrow$ Shake (x, k); $y \leftarrow x' \setminus x$
5 $\quad\quad y' \leftarrow$ VNS(y, k, t_d); $x'' = (x' \setminus y) \cup y'$
6 $\quad\quad x''' \leftarrow$ FirstImprovement(x'')
7 $\quad\quad$ NeighborhoodChange(x, x''', k)
$\quad$ **until** $k = k_{\max}$
until $t > t_{\max}$

For ease of presentation, but without loss of generality, we assume that the solution x represents the set of some elements. In Step 4 we denote with y a set of k solution attributes present in x' but not in x ($y = x' \setminus x$). In Step 5 we find the local optimum y' in the space of y; then we denote with x'' the corresponding solution in the whole space S ($x'' = (x' \setminus y) \cup y'$). We notice that exploiting some *boundary effects* in a new solution can significantly improve the solution quality. That is why, in Step 6, we find the local optimum x''' in the whole space S using x'' as an initial solution. If this is time-consuming, then at least a few local search iterations should be performed.

VNDS can be viewed as embedding the classical successive approximation scheme (which has been used in combinatorial optimizationat least since the 1960s; see, e.g., [21]) in the VNS framework.

Some Extensions

(i) *Primal-dual VNS*. For most modern heuristics, the difference in value between the optimal solution and the obtained one is completely unknown. Guaranteed performance of the primal heuristic may be determined if a lower bound on the objective function value is known. To that end, the standard approach is to relax the integrality condition on the primal variables, based on a mathematical programming formulation of the problem. However, when the dimension of the problem is large, even the relaxed problem may be impossible to solve exactly by standard commercial solvers. Therefore, it seems a good idea to solve dual relaxed problems heuristically as well. In this way we get guaranteed bounds

on the primal heuristic's performance. The next problem arises if we want to get an exact solution within a branch-and-bound framework since having the approximate value of the relaxed dual does not allow us to branch in an easy way, e.g., exploiting complementary slackness conditions. Thus, the exact value of the dual is necessary.

In primal-dual VNS (PD-VNS) [22] one possible general way to get both the guaranteed bounds and the exact solution is proposed. Its steps are given in Algorithm 13. In the first stage a heuristic procedure based on VNS is used to obtain a near-optimal solution. In [22] it is shown that VNS with decomposition is a very powerful technique for large-scale simple plant location problems (SPLP) with up to 15,000 facilities and 15,000 users. In the second phase the objective is to find an exact solution of the relaxed dual problem. Solving the relaxed dual is accomplished in three stages: (i) find an initial dual solution (generally infeasible) using the primal heuristic solution and complementary slackness conditions, (ii) find a feasible solution by applying VNS to the unconstrained nonlinear form of the dual, and (iii) solve the dual exactly starting with initial feasible solution using a customized "sliding simplex" algorithm that applies "windows" on the dual variables substantially reducing the size of the problem. In all problems tested, including instances much larger than previously reported in the literature, the procedure was able to find the exact dual solution in reasonable computing time. In the third and final phase armed with tight upper and lower bounds, obtained respectively, from the heuristic primal solution in phase one and the exact dual solution in phase two, we apply a standard branch-and-bound algorithm to find an optimal solution of the original problem. The lower bounds are updated with the dual sliding simplex method and the upper bounds whenever new integer solutions are obtained at the nodes of the branching tree. In this way it was possible to solve exactly problem instances of sizes up to 7000 × 7000 for uniform fixed costs and 15,000 × 15,000 otherwise.

Algorithm 13: Steps of the basic PD-VNS

Function `PD-VNS` $(x, \ell_{\max}, k_{\max}, t_{\max})$
1 `BVNS` $(x, \ell_{\max}, k_{\max}, t_{\max})$ // Solve primal by VNS
2 `DualFeasible`(x, y) // Find (infeasible) dual such that $f_P = f_D$
3 `DualVNS`(y) // Use VNS do decrease infeasibility
4 `DualExact`(y) // Find exact (relaxed) dual
5 `BandB`(x, y) // Apply branch-and-bound method

(ii) *Variable neighborhood formulation space search*. Traditional ways to tackle an optimizationproblem consider a given formulation and search in some way through its feasible set X. The fact that a same problem may often be formulated in different ways allows to extend search paradigms to include jumps from one

formulation to another. Each formulation should lend itself to some traditional search method, its "local search" that works totally within this formulation, and yields a final solution when started from some initial solution. Any solution found in one formulation should easily be translatable to its equivalent solution in any other formulation. We may then move from one formulation to another using the solution resulting from the former's local search as initial solution for the latter's local search. Such a strategy will of course only be useful when local searches in different formulations behave differently.

This idea was recently investigated in [43] using an approach that systematically changes formulations for solving circle packing problems (CPP). It is shown there that a stationary point of a nonlinear programming formulation of CPP in Cartesian coordinates is not necessarily also a stationary point in a polar coordinate system. A method called *reformulation descent* (RD) that alternates between these two formulations until the final solution is stationary with respect to both is suggested. Results obtained were comparable with the best known values, but they were achieved some 150 times faster than by an alternative single formulation approach. In the same paper the idea suggested above of *formulation space search* (FSS) is also introduced, using more than two formulations. Some research in that direction has been reported in [32, 43, 44, 50]. One methodology that uses variable neighborhood idea in searching through the formulation space is given in Algorithms 14 and 15. Here ϕ (ϕ') denotes a formulation from given space $\mathcal{F}$, x (x') denotes a solution in the feasible set defined with that formulation, and $\ell \leq \ell_{\max}$ is the formulation neighborhood index. Note that Algorithm 15 uses a reduced VNS strategy in $\mathcal{F}$.

Algorithm 14: Formulation change function

Function `FormulationChange`$(x, x', \phi, \phi', \ell)$;
if $f(\phi', x') < f(\phi, x)$ **then**
  $\phi \leftarrow \phi'$; $x \leftarrow x'$; $\ell \leftarrow \ell_{\min}$
else
  $\ell \leftarrow \ell + \ell_{\text{step}}$

Algorithm 15: Reduced variable neighborhood FSS

Function `VNFSS`$(x, \phi, \ell_{\max})$
repeat
  $\ell \leftarrow 1$ // Initialize formulation in $\mathcal{F}$
  while $\ell \leq \ell_{\max}$ **do**
    `ShakeFormulation`(x,x',ϕ,ϕ',ℓ) // $(\phi',x') \in (N_\ell(\phi),\mathcal{N}(x))$ at random
    `FormulationChange`(x,x',ϕ,ϕ',ℓ) // Change formulation
until *some stopping condition is met*

(iii) *Variable formulation search*. Many optimization problems in the literature, like min-max type of problems, present a flat landscape. This means that, given a formulation of the problem, there are many neighboring solutions with the same value of the objective function. When this happens, it is difficult to determine which neighborhood solution is more promising to continue the search. To address this drawback, the use of alternative formulations of the problem within VNS is proposed in [41, 46, 49]. In [49] it is named variable formulation search (VFS). It combines the change of neighborhood within the VNS framework, with the use of alternative formulations. In particular, the alternative formulations will be used to compare different solutions with the same value of the objective function, when considering the original formulation.

Let us assume that, besides the original formulation and the corresponding objective function $f_0(x)$, there are p other formulations denoted as $f_1(x), \ldots, f_p(x)$, $x \in X$. Note that two formulations are equivalent if the optimal solution of one is the optimal solution of the other and vice versa. Without loss of clarity, we will denote different formulations as different objectives $f_i(x)$, $i = 1, \ldots, p$. The idea of VFS is to add the procedure `Accept`(x, x', p), given in Algorithm 16 in all three basic steps of BVNS: `Shaking`, `LocalSearch`, and `NeighbourhoodChange`. Clearly, if a better solution is not obtained by any formulation among the p preselected, the move is rejected. The next iteration in the loop of Algorithm 16 will take place only if the objective function values according to all previous formulations are equal.

Algorithm 16: Accept procedure with p secondary formulations

```
1: logical function Accept (x, x', p)
2: for i = 0 to p do
3:    condition1 = f_i(x') < f_i(x)
4:    condition2 = f_i(x') > f_i(x)
5:    if (condition1) then
6:       Accept← True; return
7:    else if (condition2) then
8:       Accept ← False return
9:    end if
10: end for
```

If `Accept` (x, x', p) is included into `LocalSearch` subroutine of BVNS, then it will not stop the first time a non-improved solution is found. In order to stop `LocalSearch` and thus claim that x' is local minimum, x' should not be improved by any among the p different formulations. Thus, for any particular problem, one needs to design different formulations of the problem considered and decide the order they will be used in the `Accept` subroutine. Answers to those two questions

are problem specific and sometimes not easy. The `Accept` (x, x', p) subroutine can obviously be added to `NeighbourhoodChange` and `Shaking` steps of BVNS from Algorithm 7 as well.

In [46], three evaluation functions, or acceptance criteria, within `Neighborhood Change` step are used in solving **bandwith minimization problem**. This min-max problem consists in finding permutations of rows and columns of a given square matrix such that the maximal distance of nonzero element from the main diagonal in the corresponding row is minimum. Solution x may be presented as a labeling of a graph and the move from x to x' as $x \leftarrow x'$. Three criteria used are (1) the simplest one is based on the objective function value $f_0(x)$ (bandwidth lenth), (2) the total number of critical vertices $f_1(x)$ ($f_1(x') < f_1(x)|$), and (3) $f_3(x, x') = \rho(x, x') - \alpha$, if ($f_0(x') = f_0(x)$ and $f_1(x') = f_1(x)$), but x and x' are relatively far one from another $\rho(x, x') > \alpha$, where α is an additional parameter. The idea for a move to even worse solution if it is very far is used within skewed VNS. However, move to the solution with the same value only if its Hamming distance from the incumbent is greater than α that is performed in [46].

In [41] different mathematical programming formulation of the original problem is used as a secondary objective within `Neighborhood Change` function of VNS. There, two combinatorial optimization problems on the graph are considered: **metric dimension problem** and **minimal doubly resolving set problem**.

More general VFS approach is done in [49], where the **cutwidth graph minimization problem** (CWP) is considered. CWP also belongs to min-max problem family. For a given graph, one needs to make sequence of nodes such that the maximum cutwidth is minimum. The definition of the cutwidth of the graph is clear from Fig. 4, where at (a) graph G with six vertices and nine edges is given.

At Fig. 4b, ordering x of the vertices of the graph in (a) with the corresponding cutwidth CW values of each vertex is presented. It is clear that the CW represents

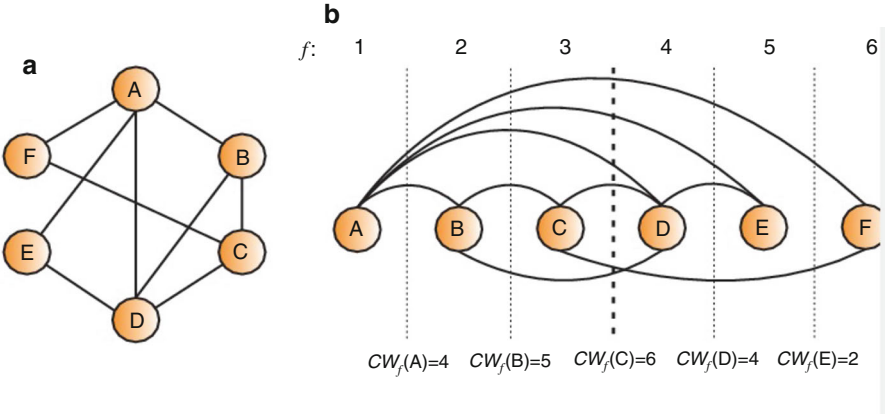

Fig. 4 Cutwidth minimization example as in [49]

Table 1 Impact of the use of alternative formulations in the search process, within 30 s

	BVNS	VFS_1	VFS_2	VFS_3
Avg.	137.31	93.56	91.56	90.75
Dev. (%)	192.44	60.40	49.23	48.22

Table 2 Comparison with the state-of-the-art algorithms over the grid and HB data sets

	81 'grid' test instances				86 HB instances			
	GPR [2]	SA [12]	SS [48]	VFS [49]	GPR [2]	SA [12]	SS [48]	VFS [49]
Avg.	38.44	16.14	13.00	12.23	364.83	346.21	315.22	314.39
Dev. (%)	201.81	25.42	7.76	3.25	95.13	53.30	3.40	1.77
#Opt.	2	37	44	59	2	8	47	61
CPU t (s)	235.16	216.14	210.07	90.34	557.49	435.40	430.57	128.12

the number of cut edges between two consecutive nodes in the solution x. The cutwidth value $f_0(x) = CW(x)$ of the ordering $x = (A, B, C, D, E, F)$ is equal to $f_0(x) = \max\{4, 5, 6, 4, 2\} = 6$ (see Fig. 4). One needs to find order x that minimizes the maximum cutwidth value of each vertex.

Two additional formulations are used in [49] and implemented within VND local search. In Table 1 the results obtained with four different VFS variants, when executing them for 30 s over each instance of the *test* data set, are presented. The column BVNS represents a heuristic based on the BVNS which make use only of the original formulation of the CMP. VFS_1 denotes BVNS heuristic that uses only one secondary criterion. VFS_2 is equivalent to the previous one with the difference that now only f_2 is considered (instead of f_1). Finally, the fourth column of the table, denoted as VFS_3, combines the original formulation of the CMP with the two alternative ones, in the way presented in Algorithm 16. All the algorithms were configured with $k_{\max} = 0.1n$ and they start from the same random solution. It appears that the significant improvements in the solution quality are obtained when at least one secondary formulation is used in case of ties (compare, e.g., 192.44% and 60.40% deviations from the best known solutions reported by BVNS and VFS_1, respectively). Additional improvement is obtained if all three formulations are used (in VFS_3).

Comparison of VFS_3 and state-of-the-art heuristics are given in Table 2. It appears that the best quality results are obtained by VFS in less computing time.

VNS for Mixed-Integer Linear Programming

The mixed-integer linear programming (MILP) problem consists of maximizing or minimizing a linear function, subject to equality or inequality constraints and integrality restrictions on some of the variables. The mixed integer programming problem (P) can be expressed as

$$(MILP) \quad \begin{bmatrix} \min & \sum_{j=1}^{n} c_j x_j & \\ \text{s.t.} & \sum_{j=1}^{n} a_{ij} x_j \geq b_i & \forall i \in M = \{1, 2, \ldots, m\} \\ & x_j \in \{0, 1\} & \forall j \in \mathcal{B} \neq \varnothing \\ & x_j \geq 0, \text{integer} & \forall j \in \mathcal{G} \\ & x_j \geq 0 & \forall j \in \mathcal{C} \end{bmatrix}$$

where the set of indices $N = \{1, 2, \ldots, n\}$ is partitioned into three subsets $\mathcal{B}$, $\mathcal{G}$, and $\mathcal{C}$, corresponding to binary, general integer, and continuous variables, respectively.

Numerous combinatorial optimization problems, including a wide range of practical problems in business, engineering, and science, can be modeled as MILP problems. Its several special cases, such as knapsack, set packing, cutting and packing, network design, protein alignment, traveling salesman, and other routing problems, are known to be NP-hard [19]. There are several commercial solvers such as CPLEX [33] for solving MILPs. Methods included in such software packages are usually of branch-and-bound (B&B) or of branch-and-cut (B&C) types. Basically, those methods enumerate all possible integer values in some order and perform some restrictions for the cases where such enumeration cannot improve the currently best solution.

The connection between local search type of heuristics and exact solvers may be established by introducing the so-called local branching constraint [17]. By adding just one constraint into the (MILP), the kth neighborhood of MILP is defined. This allows the use of all local search-based Metaheuristics, such as tabu search, simulating annealing, VNS, etc. More precisely, given two solutions x and y of the problem (MILP), we define the distance between x and y as

$$\delta(x, y) = \sum_{j \in \mathcal{B}} | x_j - y_j |.$$

Let X be the solution space of the problem (MILP) considered. The neighborhood structures $\{\mathcal{N}_k \mid k = 1, \ldots, k_{\max}\}$ can be defined, knowing the distance $\delta(x, y)$ between any two solutions $x, y \in X$. The set of all solutions in the kth neighborhood of $y \in X$ is denoted as $\mathcal{N}_k(y)$ where

$$\mathcal{N}_k(y) = \{x \in X \mid \delta(x, y) \leq k\}.$$

For the pure 0-1 MILP given above, ($\mathcal{G} = \varnothing$, $\delta(.,.)$ represents the Hamming distance, and $\mathcal{N}_k(y)$ may be expressed by the following so-called local branching constraint:

$$\delta(x, y) = \sum_{j \in S} (1 - x_j) + \sum_{j \in \mathcal{B} \setminus S} x_j \leq k, \tag{2}$$

where $S = \{j \in \mathcal{B} | \, y_j = 1\}$.

In [31] a general VNS procedure for solving 0-1 MILPs is developed (see Algorithm 17).

Algorithm 17: Steps of the VNS branching

```
Function VnsBra(total_time_limit, node_time_limit, k_step, x_opt);
 1  TL := total_time_limit; UB := ∞; first := true
 2  stat := MIPSOLVE(TL, UB, first, x_opt, f_opt)
 3  x_cur:=x_opt; f_cur:=f_opt
 4  while (elapsedtime < total_time_limit) do
 5      cont := true; rhs := 1; first := false
 6      while (cont or elapsedtime < total_time_limit) do
 7          TL = min(node_time_limit, total_time_limit-elapsedtime);
 8          add local br. constr. δ(x, x_cur) ≤ rhs; UB := f_cur
 9          stat := MIPSOLVE(TL, UB, first, x_next, f_next)
10          switch stat do
11              case "opt_sol_found":
12                  reverse last local br. const. into δ(x, x_cur) ≥ rhs + 1
13                  x_cur := x_next; f_cur := f_next; rhs := 1
14              case "feasible_sol_found":
15                  reverse last local br. constr. into δ(x, x_cur) ≥ 1
16                  x_cur := x_next; f_cur := f_next; rhs := 1
17              case "proven_infeasible":
18                  remove last local br. constr.; rhs := rhs+1
19              case "no_feasible_sol_found":
20                  cont := false
21      if f_cur < f_opt then
22          x_opt := x_cur; f_opt := f_cur; k_cur := k_step
        else
23          k_cur := k_cur+k_step
24      remove all added constraints; cont := true
25      while cont and (elapsedtime < total_time_limit) do
26          add constraints k_cur ≤ δ(x, x_opt) < k_cur + k_step
27          TL := total_time_limit-elapsedtime; UB := ∞; first := true
28          stat := MIPSOLVE(TL, UB, first, x_cur, f_cur)
29          remove last two added constraints; cont =false
30          if stat = "proven_infeasible" or "no_feasible" then
31              cont :=true; k_cur := k_cur+k_step
```

An exact MILP solver (CPLEX) is used as a black box for finding the best solution in the neighborhood, based on the given formulation (MILP) plus the added local branching constraints. Shaking is performed using the Hamming distance defined above. The detailed explanation of VNB method given in Algorithm 17 below and the meaning of all variables (*x_cur, x_opt, UB, first, f_opt, cont, rhs,* etc.) and constants (`total_time_limit, node_time_limit, k_step`) used may be found in [31].

VNS for Continuous Global Optimization

The continuous constrained nonlinear global optimization problem (GOP) in general form is given as follows:

$$\text{(GOP)} \quad \begin{bmatrix} \min & f(x) & \\ \text{s.t.} & g_i(x) \leq 0 & \forall i \in \{1, 2, \ldots, m\} \\ & h_i(x) = 0 & \forall i \in \{1, 2, \ldots, r\} \\ & a_j \leq x_j \leq b_j & \forall j \in \{1, 2, \ldots, n\} \end{bmatrix}$$

where $x \in R^n$, $f : R^n \rightarrow R$, $g_i : R^n \rightarrow R$, $i = 1, 2, \ldots, m$, and $h_i : R^n \rightarrow R$, $i = 1, 2, \ldots, r$ are possibly nonlinear continuous functions, and $a, b \in R^n$ are the variable bounds.

GOP naturally arises in many applications, e.g., in advanced engineering design, data analysis, financial planning, risk management, scientific modeling, etc. Most cases of practical interest are characterized by multiple local optima, and, therefore, in order to find the globally optimal solution, a global scope search effort is needed.

If the feasible set X is convex and objective function f is convex, then GOP is relatively easy to solve, i.e., the Karush-Kuhn-Tucker conditions may be applied. However, if X is not a convex set or f is not a convex function, we could have many local minima, and thus, the problem may not be solved by using classical techniques.

For solving GOP, VNS has been used in two different ways: (a) with neighborhoods induced by using an ℓ_p norm and (b) without using an ℓ_p norm.

(a) *VNS with ℓ_p norm neighborhoods* [3, 4, 15, 36, 39, 42]. A natural approach in applying VNS for solving GOP is to induce neighborhood structures $\mathcal{N}_k(x)$ from the ℓ_p metric:

$$\rho(x, y) = \left(\sum_{i=1}^{n} |x_i - y_i|^p \right)^{1/p} \quad (1 \leq p < \infty) \tag{3}$$

or

$$\rho(x, y) = \max_{1 \leq i \leq n} | x_i - y_i | \quad (p \rightarrow \infty). \tag{4}$$

The neighborhood $\mathcal{N}_k(x)$ denotes the set of solutions in the k-th neighborhood of x, and using the metric ρ, it is defined as

$$\mathcal{N}_k(x) = \{y \in X \mid \rho(x, y) \leq \rho_k\}, \tag{5}$$

or

$$\mathcal{N}_k(x) = \{y \in X \mid \rho_{k-1} \leq \rho(x, y) \leq \rho_k\}, \tag{6}$$

where ρ_k, known as the radius of $\mathcal{N}_k(x)$, is monotonically increasing with k.

For solving box constraint GOP, both [15, 36] use neighborhoods as defined in (6). The basic differences between the two are as follows: (1) in the procedure suggested in [36] the ℓ^∞ norm is used, while in [15] the choice of metric is either left to the analyst or changed automatically according to some predefined order; (2) as a local search procedure within VNS, the commercial solver SNOPT [20] is used in [36], while in [15] the analyst may choose one out of six different convex minimizers. A VNS-based heuristic for solving the generally constrained GOP is suggested in [39]. There, the problem is first transformed into a sequence of box-constrained problems within well-known exterior point method:

$$\min_{a \leq x \leq b} F_{\mu,q}(x) = f(x) + \frac{1}{\mu} \sum_{i=1}^{m} (\max\{0, q_i(x)\})^q + \sum_{i=1}^{r} |h_i(x)|^q, \tag{7}$$

where μ and $q \geq 1$ are a positive penalty parameter and penalty exponent, respectively. Algorithm 18 outlines the steps for solving the box constraint subproblem as proposed in [39]:

Algorithm 18: Steps of continuous VNS using ℓ_p norm

Function `Glob-VNS` $(x^*, k_{\max}, t_{\max})$
1 Select the set of neighborhood structures $\mathcal{N}_k$ $k = 1, \ldots, k_{\max}$
2 Select the array of random distributions types and an initial point $x* \in X$
3 $x \leftarrow x^*$, $f^* \leftarrow f(x)$, $t \leftarrow 0$
4 **while** $t < t_{\max}$ **do**
5 $\quad k \leftarrow 1$
6 $\quad$ **repeat**
7 $\quad\quad$ **for** *all distribution types* **do**
8 $\quad\quad\quad y \leftarrow$ `Shake`(x^*, k) // Get $y \in \mathcal{N}_k(x^*)$ at random
9 $\quad\quad\quad y' \leftarrow$ `BestImprovment`(y) // Apply LS to obtain a local minimum y'
10 $\quad\quad\quad$ **if** $f(y') < f^*$ **then**
11 $\quad\quad\quad\quad x^* \leftarrow y'$, $f^* \leftarrow f(y')$, `go to line 5`
12 $\quad\quad k \leftarrow k + 1$
$\quad$ **until** $k = k_{\max}$
13 $\quad t \leftarrow$ `CpuTime()`

The `Glob-VNS` procedure from Algorithm 18 contains the following parameters in addition to $k_{\max}$ and $t_{\max}$:

1. *Values of radii* ρ_k, $k = 1, \ldots, k_{\max}$. Those values may be defined by the user or calculated automatically in the minimizing process;

2. *Geometry* of neighborhood structures $\mathcal{N}_k$, defined by the choice of metric. Usual choices are the ℓ_1, ℓ_2, and $\ell\infty$ norms;
3. *Distribution* used for obtaining the random point y from $\mathcal{N}_k$ in the *shaking* step. Uniform distribution in $\mathcal{N}_k$ is the obvious choice, but other distributions may lead to much better performance on some problems.

Different choices of geometric neighborhood shapes and random point distributions lead to different VNS-based heuristics.

(b) *VNS without using ℓ_p norm*. Two different neighborhoods, $N_1(x)$ and $N_2(x)$, are used in VNS-based heuristic suggested in [55]. In $N_1(x)$, r (a parameter) random directions from the current point x are generated and one-dimensional searches along each performed. The best point (out of r) is selected as a new starting solution for the next iteration, if it is better than the current one. If not, as in VND, the search is continued within the next neighborhood $N_2(x)$. The new point in $N_2(x)$ is obtained as follows. The current solution is moved parallel to each x_j ($j = 1, \ldots, n$) by value Δ_j, taken at random from interval $(-\alpha, \alpha)$, i.e., $x_j^{(\text{new})} = x_j + \Delta_j$ or $x_j^{(\text{new})} = x_j - \Delta_j$. Points obtained by the plus or minus sign for each variable define neighborhood $N_2(x)$. If change of $x_j^{(\text{new})}$ by 1% to the right gives a better solution than in $x^{(\text{new})}$, the + sign is chosen; otherwise the–sign is chosen.

Neighborhoods N_1 and N_2 are used for designing two algorithms. The first, called VND, iterates these neighborhoods until there is no improvement in the solution value. In the second variant, a local search is performed in N_2 and $k_{\max}$ set to 2 for the shaking step. In other words, a point from neighborhood $k = 2$ is obtained by generating a random direction followed by line search along it (as prescribed for N_1) and then by changing each of the variables (as prescribed for N_2).

Variable Neighborhood Programming

Building an intelligent machine is an old dream that, thanks to computers, began to take shape. Automatic programming is an efficient technique that has contributed an important development in the field of artificial intelligence. Genetic programming (GP) [35], inspired by genetic algorithm (GA), is among the few evolutionary algorithms used to evolve population of programs. The main difference between GP and GA is the presentation of a solution. An individual in GA can be a string, while GPs individuals are programs. The usual way to present program within GP is by using a tree. For example, assume that the current solution of the problem is the following function:

$$f(x_1, \ldots, x_5) = \frac{x_1}{x_2 + x_3} + x_4 - x_5.$$

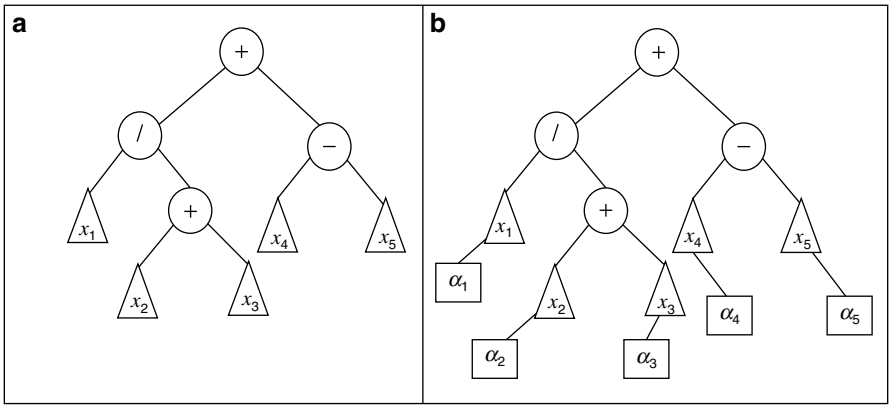

Fig. 5 Current solution representation in automatic programming problem: $\frac{x_1}{x_2+x_3} + x_4 - x_5$. (**a**) GP solution representation. (**b**) VNP solution representation

Then the code (tree) that calculates it using GP may be presented as in Fig. 5a.

Souhir et al. [16] recently adapted VNS rules in solving automatic programming problem. They first suggested an extended solution presentation by adding coefficients to variables. Each terminal node was attached to its own parameter value. These parameters gave a weight for each terminal node, with values from the interval [0, 1]. This form of presentation allowed VNP to examine parameter values and the remaining tree structures in the same iteration. Let $G = \{\alpha_1, \alpha_2, \ldots, \alpha_n\}$ denote a parameter set. In Fig. 5b an example of VNP's solution representation is illustrated.

Neighborhood structures. At such solution presentation as a tree T, nine different neighborhood structures are proposed in [16]. To save the space, we will just mention some of them:

- $N_1(T)$—**Changing a node value operator**. This neighborhood structure conserves the skeleton of the tree and changes only the values of a functional or a terminal node. Each node can obtain many values from its corresponding set. Let x_i be the current solution; its neighbor x_{i+1} differs from x_i by just a single node. A move within this neighborhood structure is shown in Fig. 6.
- $N_2(T)$—**Swap operator**. By this operator a first node from the current tree is taken at random, and a new sub-tree is generated as presented in Fig. 7a, b. Then the selected node is attached in the place of the sub-tree. In this move, the constraint related to the maximum tree size should be respected. More details can be seen in Fig. 7.
- $N_3(T)$—**Changing parameter values**. In the previous neighborhood structures, the tree form and its node values were considered. In $N_3(T)$ neighborhood, attention is paid on parameters. So, the position and value of nodes are kept in order to search the neighbors in the parametric space. Figure 8 illustrates details. The change from one value to another is at random.

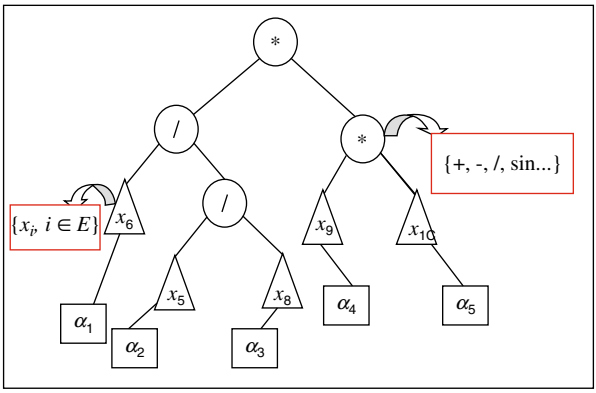

Fig. 6 Neighborhood structure N_1: changing a node value

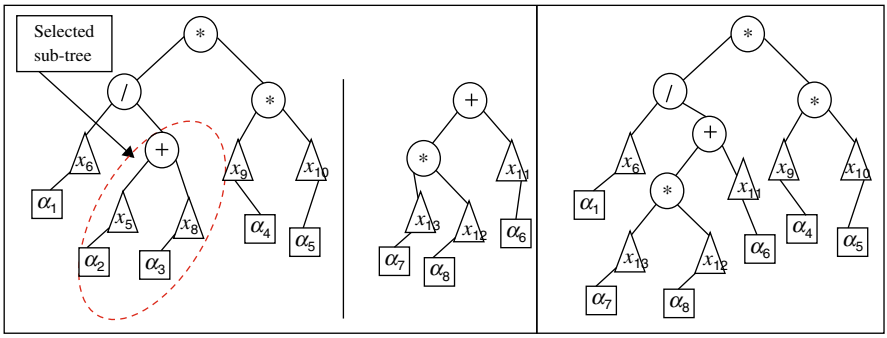

Fig. 7 Neighborhood structure N_2: swap operator

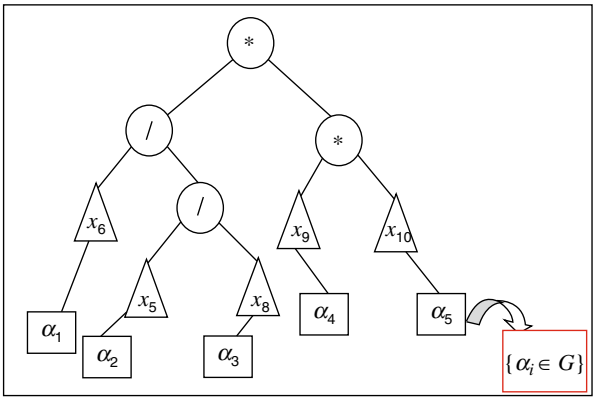

Fig. 8 Neighborhood structure N_3: change parameters

These neighborhood structures may be used in both local search step (N_ℓ, $\ell \in [1, \ell_{\max}]$) and in the shaking step ($\mathcal{N}_k$, $k \in [1, k_{\max}]$) of the VNS.

VNP shaking. The shaking step allows the diversification in the search space. Our proposed VNP algorithm does not use exactly the same neighborhood structures N_ℓ as for the local search. That is the reason why neighborhoods used in shaking are denoted differently: $\mathcal{N}_k(T), k = 1, k_{\max}$. $\mathcal{N}_k(T)$ may be constructed by repeating k times one or more moves from the set $\{N_\ell(T), |\ell = 1, \ldots, \ell_{\max}\}$, explained earlier. Nevertheless, in the shaking phase, we use a neighborhood structure that mainly affects the skeleton of a presented solution with its different forms for the perturbation. For more clear explanation, we take the swap operator $N_3(T)$ as an example. Let m denote the maximum size of a solution. We can get a solution from the kth neighborhood of T using the swap operator: k may represent the size of the new generated sub-tree. If n denotes the size of the original tree after deleting the old sub-tree, then $n + k_{\max} \leq m$. The objective of this phase is to provide a good starting point for the local search.

VNP objective function. The evaluation consists of defining a fitness or objective function assessing the proposed problem. This function is defined according to the problem considered. After running each solution (program) on training data set, fitness may be measured by counting how many training cases the current solution result is correct or near to the exact solution.

An example: time series forecasting (TSF) problem. Two widely used benchmark data sets of TSF problem are explored in [16] to examine VNP capabilities: Mackey-Glass series and Box-Jenkins set. The parameters for the VNP implementation are chosen after some preliminary testing are given in Table 3.

The root-mean-square error (RMSE) is used as fitness function, as it is usual in the literature:

$$f(T) = \sqrt{\frac{1}{n}\sum_{j=1}^{n}\left(y_t^j - y_{\text{out}}^j\right)^2}$$

where n represents the total number of samples and y_{out}^j and y_t^j are outputs of the sample number j obtained by the VNP model and the desired one, respectively. Here we will just illustrate comparison on Box-Jenkins instance.

Table 3 VNP parameters adjustment for the forecasting problem

Parameters	Values
The functional set	$F = \{+, *, pow\}$;
The terminal sets	$\{(x_i, c), i \in [1, \ldots, m], m =$ number of inputs, $c \in R\}$;
Neighborhood structures	$\{N_1, N_2, N_3\}$;
Minimum tree length	20 nodes;
Maximum tree length	200 nodes;
Maximum number of iterations	50,000

Table 4 Comparison of testing error on Box-Jenkins dataset

Method	Prediction error RMSE
ODE [54]	0.5132
HHMDDE [14]	0.3745
FBBFNT [6]	0.0047
VNP [16]	**0.0038**

The gas furnace data of Box and Jenkins were collected from a combustion process of a methane-air mixture [15]. This time series has found a widespread application as a benchmark example in many practical sciences for testing prediction algorithms. The data set contains 296 pairs of input-output values. The input $u(t)$ corresponds to the gas flow, and the output $y(t)$ presents the CO_2 concentration in outlet gas. The inputs are $u(t-4)$ and $y(t-1)$, and the output is $y(t)$. In this work, 200 samples are used in the training phase, and the remaining samples are used for the testing phase. The performance of the evolved model is evaluated by comparing it with the abovementioned approaches. The RMSE achieved by VNP output model is 0.0038, which appeared to be better than the RMSE obtained by other approaches. Table 4 shows that VNP approach proves effectiveness and generalization ability.

Discovery Science

In all the above applications, VNS is used as an optimization tool. It can also lead to results in "discovery science," i.e., help in the development of theories. This has been done for graph theory in a long series of papers with the common title "Variable neighborhood search for extremal graphs" and reporting on the development and applications of the system AutoGraphiX (AGX) [10]. This system addresses the following problems:

- Find a graph satisfying given constraints;
- Find optimal or near optimal graphs for an invariant subject to constraints;
- Refute a conjecture;
- Suggest a conjecture (or repair or sharpen one);
- Provide a proof (in simple cases) or suggest an idea of proof.

Then a basic idea is to consider all of these problems as parametric combinatorial optimization problems on the infinite set of all graphs (or in practice some smaller subset) with a generic heuristic. This is done by applying VNS to find extremal graphs, with a given number n of vertices (and possibly also a given number of edges). Then a VND with many neighborhoods is used. Those neighborhoods are defined by modifications of the graphs such as the removal or addition of an edge, rotation of an edge, and so forth. Recently all moves involving four vertices or less were considered jointly in learning optimization framework. Once a set of extremal or near-extremal graphs, parameterized by their order, is found, their properties are

explored with various data mining techniques, leading to conjectures, refutations, and simple proofs or ideas of proof.

All papers in this area are divided into the following groups in [28], where the extensive list of references for each class of problems can be found:

(i) *Principles of the approach* and its implementation;
(ii) *Applications to spectral graph theory*, e.g., finding bounds on the index or spectral radius of the adjacency matrix for various families of graphs and finding graphs maximizing or minimizing the index subject to some conditions;
(iii) *Studies of classical graph parameters*, e.g., independence, chromatic number, clique number, and average distance;
(iv) *Studies of little known or new parameters of graphs*, e.g., irregularity, proximity, and remoteness;
(v) *New families of graphs discovered by AGX*, e.g., bags, which are obtained from complete graphs by replacing an edge by a path, and bugs, which are obtained by cutting the paths of a bag;
(vi) *Applications to mathematical chemistry*, e.g., study of chemical graph energy and of the Randić index;
(vii) *Results of a systematic study of pairwise comparison of 20 graph invariants*, involving the four usual operators: plus, minus, ratio, and product, which led to almost 1500 new conjectures, more than half of which were automatically proved by AGX and over 300 by various mathematicians;
(viii) *Refutation or strengthening of conjectures from the literature*;
(ix) *Surveys and discussions about various discovery systems in graph theory*, assessment of the state-of-the-art and the forms of interesting conjectures together with proposals for the design of more powerful systems.

Conclusions

The general schemes of variable neighborhood search have been presented, discussed, and illustrated by examples. In order to evaluate the VNS research program, one needs a list of the desirable properties of Metaheuristics. The following eight of these are presented in Hansen and Mladenović [27]:

(i) *Simplicity:* the metaheuristic should be based on a simple and clear principle, which should be widely applicable;
(ii) *Precision:* the steps of the metaheuristic should be formulated in precise mathematical terms, independent of possible physical or biological analogies which may have been the initial source of inspiration;
(iii) *Coherence:* all steps of the heuristics for particular problems should follow naturally from the principle of the metaheuristic;

(iv) *Efficiency:* heuristics for particular problems should provide optimal or near-optimal solutions for all or at least most realistic instances. Preferably, they should find optimal solutions for most problems of benchmarks for which such solutions are known, when available;
(v) *Effectiveness:* heuristics for particular problems should take a moderate computing time to provide optimal or near-optimal solutions;
(vi) *Robustness:* the performance of heuristics should be consistent over a variety of instances, i.e., not merely fine-tuned to some training set and less good elsewhere;
(vii) *User-friendliness:* heuristics should be clearly expressed, easy to understand, and, most important, easy to use. This implies they should have as few parameters as possible, ideally none;
(viii) *Innovation:* preferably, the principle of the metaheuristic and/or the efficiency and effectiveness of the heuristics derived from it should lead to new types of application.
(ix) *Generality:* the metaheuristic should lead to good results for a wide variety of problems;
(x) *Interactivity:* the metaheuristic should allow the user to incorporate his knowledge to improve the resolution process;
(xi) *Multiplicity:* the metaheuristic should be able to present several near-optimal solutions from which the user can choose one.

As shown above, VNS possesses, to a great extent, all of the above properties. This has led to heuristics which are among the very best ones for many problems. Interest in VNS is clearly growing at speed. This is evidenced by the increasing number of papers published each year on this topic (15 years ago, only a few; 10 years ago, about a dozen; about 50 in 2007). According to Google Scholar, the first two papers on VNS were cited almost 4000 times!

Moreover, the 18th and 28th EURO Mini Conferences were entirely devoted to VNS. It led to special issues of *IMA Journal of Management Mathematics* in 2007 [37], *European Journal of Operational Research* [29], *Journal of heuristics* [47] in 2008, *Computers and Operations Research* in 2014 [45], and *Journal of Global Optimization* in 2016 [11]. The 3rd International VNS meeting took place in Tunisia, and three new special issues entirely devoted to VNS are in preparation (*Computers and Operations Research*, *Optimization Letters*, and *Yugoslav Journal of Operations Research*). In retrospect, it appears that the good shape of the VNS research program is due to the following decisions, strongly influenced by Karl Popper's philosophy of science [51]: (i) in devising heuristics favor insight over efficiency (which comes later) and (ii) learn from the heuristics mistakes.

Abstract

This chapter describes the history of metaheuristics in five distinct periods, starting long before the first use of the term and extending far into the future.

The field of metaheuristics has undergone several paradigm shifts—changes that have transformed the way researchers approach the development of heuristic

methods. Most notably, there has been a shift from the *method-centric* period, in which metaheuristics were thought of as algorithms, to the *framework-centric* period, in which researchers view metaheuristics as more general high-level frameworks, i.e., consistent collections of concepts and ideas that offer guidelines on how to solve an optimization problem heuristically.

Tremendous progress has been made in the development of heuristics over the years. Optimization problems that seemed intractable only a few decades ago can now be efficiently solved. Nevertheless, there is still much room for evolution in the research field—an evolution that will allow it to transition into the *scientific period*. In this period, we will see more structured knowledge generation that will benefit both researchers and practitioners.

Unfortunately, a significant fraction of the research community has deluded itself into thinking that scientific progress can be achieved by resorting to ever more outlandish metaphors as the basis for the so-called novel methods. Even though considerable damage to the research field will have been inflicted by the time these ideas are eradicated, there is no doubt that science will ultimately prevail.

Introduction

Optimization is the process of selecting or approximating the best solution from a set of alternatives by determining a configuration of inputs that maximizes or minimizes an output (objective function) while adhering to constraints. Over the course of history, several efficient algorithms have been developed to solve—i.e., to find the optimal solution for—specific optimization problems. A prime example is Dijkstra's [12] algorithm for the shortest path problem, which serves as the foundation for all navigation software and is heavily used in Internet-routing protocols. Problem-specific algorithms, however, have the disadvantage of only solving a single well-defined problem. Mathematical programming models (linear programming, (mixed) integer programming, etc.) have been crucial in generalizing these approaches, enabling the formulation of complex real-world problems into decision variables, objective functions, and constraints. When these models follow a very specific structure (e.g., all constraints and the objective function are linear functions of real-valued decision variables), standardized methods like Dantzig's simplex method [11] can be used to find the optimal solution.

Despite the success of the mathematical programming paradigm, however, it encounters limitations when addressing large-scale or complex problems, such as those involving nonlinear constraints or discrete variables in combinatorial optimization. As the problem size increases, solving for the optimal solution

generally becomes computationally impractical. This empirical fact is supported by *complexity theory*, which provides insight into why some combinatorial problems are likely to never be solvable in a reasonable time. The real world, however, requires solutions regardless of empirical or theoretical objections. As a result, researchers have turned to *heuristic* methods, which relax the goal of finding the optimal solution and instead aim for a feasible one in a practical amount of time. Heuristic optimization allows researchers to solve large-scale problems efficiently, though the solutions are not guaranteed to be optimal, and many heuristic algorithms (like the [6] algorithm for the vehicle-routing problem) have been developed.

Just like problem-specific exact methods, however, problem-specific heuristics are limited to solving a single problem, and, with researchers and practitioners wishing to solve different, more complicated problems, a need for more general, problem-agnostic algorithms arose. This need has been met by the development of a class of methods called *metaheuristics*, which provide *frameworks* or high-level strategies to guide the development of heuristic optimization algorithms. As linear and mixed-integer programming generalized *exact* algorithms for solving specific problems, metaheuristics similarly generalized problem-specific *heuristic* algorithms.

Even though people have used heuristics throughout history, and the human brain is equipped with a formidable heuristic engine to solve an enormous array of challenging optimization problems, the *scientific study* of heuristics (and, by extension, metaheuristics) is a relatively young endeavor. It is not an exaggeration to claim that the field of (meta)heuristics, especially compared to other fields of study like physics, chemistry, and mathematics, has yet to reach a mature state. Nevertheless, enormous progress has been made since the first metaheuristics concepts were established.

No history is ever neutral, and a history of metaheuristics—or any other topic—can be written in many different ways. A straightforward history of metaheuristics would consist of an annotated and chronological list of metaheuristic methods. Useful as such a list may be, it suffers from a lack of insight into the development of the field as a whole.

Taking a bird's eye view of the field of metaheuristics, one has to conclude that there has been a large amount of progressive insight over the years. Moreover, this progressive insight has not reached its endpoint: The way researchers and practitioners look at metaheuristics is still continually shifting. Even the answer to the question what a metaheuristic is has changed quite a lot since the word was first coined in the second half of the 1980s. The exploration of this shifting insight is the topic of this chapter. We believe it allows us to truly understand the historical advancements and learn many interesting lessons that could be useful for the future development of research in metaheuristics. We did not limit our discussion in this chapter to metaheuristics that have been formally written down and published. When studying the history of metaheuristics with an open mind, one has to conclude that people have been using heuristics and metaheuristics long before the term even existed.

We have therefore adopted a different approach to write "our" history of metaheuristics. Our approach starts well before the term "metaheuristic" was coined and is based on the premise that people have looked at metaheuristics through different sets of glasses over the years. The way in which people—not only researchers—have interpreted the different metaheuristic concepts has shaped the way in which the field has been developing. To understand the design choices that people have been making when developing metaheuristic optimization algorithms, it is paramount that these choices are understood in relationship to the trends and viewpoints of the time during which the development took place.

Our history divides time into five distinct periods. The crispness of the boundaries between each pair of consecutive periods, however, is a gross simplification of reality. The real (if one can use that word) time periods during which the paradigm shifts took place are usually spaced out over several years, but it is difficult, if not impossible, to trace the exact moments in time at which the paradigm shifts began and ended. More importantly, not every researcher necessarily makes the transition at the same time:

- The *pre-theoretical* period (until c. 1940), during which heuristics and even metaheuristics are used but not formally studied
- The *early* period (c. 1940–c. 1980), during which the first formal studies on heuristics appear
- The *method-centric* period (c. 1980–c. 2000), during which the field of metaheuristics truly takes off and many different methods are proposed
- The *framework-centric* period (c. 2000–now), during which the insight grows that metaheuristics are more usefully described as frameworks, and not as methods
- The *scientific* period (the future), during which the design of metaheuristics becomes a science instead of an art

Until recently, a clear definition of the word metaheuristic has been lacking, and it could be argued that it is still disputed. In this chapter, we adopt the definition of [51].

> A metaheuristic is a high-level problem-independent algorithmic framework that provides a set of guidelines or strategies to develop heuristic optimization algorithms. The term is also used to refer to a problem-specific implementation of a heuristic optimization algorithm according to the guidelines expressed in such a framework.

The term "metaheuristic" has been used (and is used) for two entirely different things. One is a high-level framework, a set of concepts and strategies that blend together and offer a perspective on the development of optimization algorithms. In this sense, variable neighborhood search [39] is nothing more (or less) than the idea to use different local search operators to work on a single solution, together with a perturbation operator once all neighborhoods have reached a local optimum. There is a compelling motivation, as well a large amount of empirical evidence, as to why multi-neighborhood search is indeed a very good idea. This motivation essentially

comes down to the fact that a local optimum for one local search operator (or one neighborhood structure) is usually not a local optimum for another local search operator. The idea to switch to a different local search operator once a local optimum has been found is therefore both sensible and in practice extremely powerful.

The second meaning of the term "metaheuristic" denotes a specific implementation of an algorithm based on such a framework (or on a combination of concepts from different frameworks) designed to find a solution to a specific optimization problem. The variable neighborhood search (-based) algorithm for the location-routing problem by [34] is an example of a metaheuristic in this sense.

In this chapter, we will use the term "metaheuristic framework" to refer to the first sense and "metaheuristic algorithm" to refer to the second sense of the word "metaheuristic."

As mentioned, a history of any topic is not neutral. We therefore do not attempt to hide the fact that certain ways in which the field has progressed seem to us less useful and, at times, even harmful to the overall development of the field. We also discuss this phenomenon, which has plagued—and continues to plague—the field of metaheuristics.

Period 0: The Pre-theoretical Period

Optimization problems are all around us. When we decide upon the road to take to work, when we put the groceries in the fridge, when we decide which investments to make so as to maximize our expected profit, we are essentially solving an optimization problem (a shortest path problem, a packing problem, and a knapsack problem, respectively). For human beings (and many animal species), solving an optimization problem does not require any formal training—something which is immediately clear from the examples given here. The difference between exact solutions and approximate solutions, the difference between easy and hard optimization problems, or between fast (polynomial) and slow (exponential) algorithms are all moot to the average problem solver.

Indeed, the human mind seems to be formidably equipped from early childhood to solve an incredible range of problems, many of which could be easily modeled as optimization problems. Most likely, the ability to solve optimization problems adequately and quickly is one of the most important determinants of the probability of survival in all sentient species and has therefore been favored by evolution throughout time. Clearly, the human (and animal) mind solves optimization problems *heuristically* and not exactly—i.e., the solutions produced by the brain are by no means guaranteed to be optimal. Given what we now know about exact solution procedures, this makes perfect sense. When selecting which berries to pick from a bush so as to maximize the nutritional content of the selection (under the hard constraint that a saber-toothed tiger will catch us in less than a minute), it is much more important that this selection be calculated quickly rather than optimally. Given our knowledge on exact solution methods, we can now say that the calculation of the exact solution of our berry-picking problem would almost certainly be found only

after the saber-toothed tiger has sunk its fangs into us. Moreover, it would almost certainly require too much computing power from the brain, quickly depleting the body's scarce energy resources.

Given the diversity of problems the human mind must solve, including problems with which it has no prior experience, there is very little doubt that the human mind has the capacity (whether evolved or learned) to use metaheuristic strategies. Just like the metaheuristics for optimization that form the subject of this book, such strategies are not heuristics in themselves but are used to derive heuristics from. For example, when confronted with a new problem to which a solution is not immediately obvious (e.g., determining the berries to pick), the human mind will automatically attempt to find similar problems it has solved in the past (e.g., determining which roots to dig up from the ground) and attempt to derive the rules it has learned by solving this problem. This strategy is called *learning by analogy* [4]. Another example is called means end analysis [47] and can be summarized as follows: Given a current state and a goal state, choose an action that will lead to a new state that is closer to the goal state than the current state. This rule is iteratively applied until the goal state has been reached or no other state can be found closer to the goal state than the current state. Obviously, this strategy is a more general counterpart of all formal optimization heuristics that can be categorized as local search, in which a solution is iteratively improved using small, incremental operations we have come to call *moves*. The technique of *path relinking* [20], in which an incumbent solution is transformed, one move at a time, into a guiding solution, is another example of a formalized means-end-analysis strategy.

Whereas heuristics (and even metaheuristics) are completely natural to us humans, exact methods seem to be a very recent invention—coinciding with the introduction of the field of Operations Research around WWII. On the other hand, even though heuristics have been applied since the first life on earth evolved, the *scientific study* of heuristics also had to wait until the twentieth century. It could be hypothesized that heuristics come so naturally to us that we had to wait for the development of a formal theory of optimization—particularly linear programming—before anyone considered them a topic worthy of study. Much like a fish does not notice the water it is swimming in, heuristics may have been too ingrained in our thinking to attract attention as a distinct field of research.

Period 1: The Early Period

In 1945, immediately after WWII, the Hungarian mathematician George Pólya, then working at Stanford University, published a small volume called "How to Solve it" [41]. In his book, he argued that problems can be solved by a limited set of generally applicable strategies, most of which serve to make the problem simpler to solve. The book's focus was not on optimization problems, but on the more general class of "mathematical" problems, i.e., problems that can be modeled and solved by mathematical techniques. Nevertheless, most of the solution strategies proposed book are equally applicable to develop optimization algorithms.

The "analogy" principle, e.g., tells the problem solver to look for another problem that closely resembles the problem at hand, and to which a solution method is known. By studying the similarities and differences between both problems, ideas can be garnered to solve the original problem. The principle of "induction" is to solve a problem by deriving a generalization from some examples. The "auxiliary problem" idea asks whether a subproblem exists that can help to solve the overall problem.

Even though it is a bit of stretch to call these principles "meta-heuristics," it is clear that the start of the field of OR also marks the age during which people start thinking about more general principles that are useful in the design of heuristic algorithms (or solution methods for other types of problems). A case can be made for the fact that many of Pólya's principles are still heavily used today by heuristic designers. Looking for similar problems in the literature or elsewhere, and modifying the best-known methods for them to suit the problem at hand (analogy), is an extremely common strategy to arrive at a good heuristic fast. Solving some simple examples by hand, and using the lessons learned from your own (or someone else's) perceived strategy to derive an intelligent solution strategy from (induction), is also a useful technique. Finally, decomposing a problem into smaller subproblems and developing specialized techniques for each of them (auxiliary problem) has proven to be a powerful heuristic design strategy on a large number of occasions.

What is important is that none of Pólya's strategies actually solves any problem, nor can they be called "algorithms" in themselves. Instead, they are high-level, meta-strategies that are useful to influence the way a heuristic designer thinks about a problem. In that sense at the very least, they are very like the more advanced and specialized metaheuristic frameworks that we have today.

Several very high-level algorithmic ideas also came about around this period. The fact that good solutions can be reached by a constructive procedure, for example, is one of them. A constructive algorithm is one that starts from an empty solution and iteratively adds one element at a time until a complete solution has been formed. Simple rules for selecting this element from the set of all potential elements have led to different types of algorithms. The *greedy* selection rule selects the best (value for each) element at each iteration. Kruskal's or Prim's algorithm for the minimum spanning tree problem, Dijkstra's algorithm for the shortest path problem, etc., are all examples of greedy heuristics [9]. *Regret* algorithms present a similar class of optimization procedures that select, at each iteration, the element for which *not* selecting its best value results in the highest penalty cost. Vogel's approximation method [46] for the transportation problem is a well-known example. Again, calling the greedy idea or the regret idea "metaheuristics" is a bit of a stretch, but they *are* high-level strategies, and they are *not* algorithms themselves.

Also during this period, [48] see heuristics specifically as fit to solve what they call "ill-structured" problems. Contrary to well-structured problems, such problems cannot be formulated explicitly or solved by known and feasible computational techniques. Their predictions in 1958 have turned out to be slightly optimistic, but it cannot be denied that heuristics have turned out to be more flexible problem-solving strategies than exact methods.

Even though the heuristics developed in the early period were very simple, the realization that high-level strategies existed that could be used as the basis for the development of heuristics for *any* optimization problem led to insights that paved the way for more complex meta-strategies. Together with the widespread availability of computers, these developments took the field of heuristics into the next period in this history, the method-centric period.

Period 2: The Method-Centric Period

Even though the frameworks and ideas developed during what we have called the early period lacked the comprehensiveness of the later developed metaheuristic frameworks like tabu search [19], it is not too far-fetched to call them early metaheuristics. Like later metaheuristic frameworks, these methods offered—in the form of some generally applicable strategies—inspiration for the development of optimization algorithms. Of course, these principles still needed to be instantiated for each different optimization problem, but at least the process of coming up with an optimization strategy did not have to start from scratch.

Much of the work done in the early period can be characterized under the umbrella term of *artificial intelligence* because it involves mimicking human problem-solving behavior and learning lessons from this behavior on a more abstract level. Starting in the 1960s however, an entirely different line of research into problem-solving methods came to life. These methods used an analogy with life's main problem-solving method: evolution.

Evolution by natural selection has been called "the best idea ever" [5]. No single idea explains as much as Darwin's realization that species evolve over time to adapt to their environment. The way in which this happens, by natural selection of inheritable characteristics, is both so clever and so simple it begs the question why the world needed to wait until the second half of the nineteenth century before someone thought of it. Nevertheless, it took another century and the advent of the computer before researchers would become interested in simulating the process of natural evolution.

Although researchers in the late 1950s and early 1960s had developed what we would now label as evolutionary algorithms, their main aim was not to solve optimization problems, but to study the phenomenon of natural evolution. The insight that the principles of natural evolution could be used to solve optimization problems in general came in the early 1960s, when researchers like Box, Friedman, and several others had independently developed algorithms inspired by evolution for function optimization and machine learning. One of the first methods to receive some share of recognition was the so-called evolution strategy [as later reported in 42]. Evolution strategy was still quite far from what we would call an evolutionary algorithm: It did not use a population or crossover. One solution (called the parent) was mutated, and the best of the two solutions became the parent for the next round of mutation.

Evolutionary programming, introduced a few years later [16], represented solutions as finite-state machines but also lacked the concepts of both a population and crossover. The true start of the field of evolutionary algorithms came with the seminal work of John Holland [30], who was the first to recognize the importance of both concepts. With his schemata theorem, which essentially states that high-quality schemata ("parts") of solutions will increase in frequency in successive iterations of the algorithm, Holland was also among the pioneers of theory building in metaheuristics. The schemata theory was criticized later for its limited use and lack of general applicability, but it demonstrated that the field of metaheuristics needed not forever be devoid of theoretical underpinning.

It was perhaps the book by [28] (a student of John Holland) that truly sparked the evolutionary revolution. Evolutionary methods became extremely popular, journals and conferences specifically devoted to this topic sprouted and an exponentially increasing number of papers appeared in the literature. A large number of variants were proposed, each with its own specific characteristics. Extraordinary claims were made, not necessarily grounded in empirical evidence. The quest for a generic heuristic optimization method that could solve any problem efficiently, without requiring problem-specific information, seemed finally to be on the right track.

In the 1980s, the first papers start to appear that introduced general problem-solving frameworks not based on natural evolution. One of the first used another metaphor: annealing, the controlled heating and cooling process used in metallurgy and glass production to remove stresses from the material [35]. Simulated annealing used random solution changes and "accepted" these if they improved the solution or, if they did not, with a probability inversely proportional to the solution quality decrease and proportional to an external parameter called the "temperature."

For a while, it might have seemed that the development of metaheuristics was all about finding a suitable process to imitate. The 1980s, however, also saw the development of several methods that reached back to the early period and used ideas derived from human problem solving. One of the most powerful ideas was that solutions could be gradually improved by iteratively making small changes, called *moves*, to them. To this end, an algorithm would investigate all or some of the solutions that could be reached from the *current* solution by executing a single move. Together, these solutions form the *neighborhood* of the current solution.

Perhaps the most influential of the AI-based methods was tabu search [19]. The basic premise of this framework is that a local search algorithm could be guided toward a good solution by using some of the information gathered during the search in the past. To this end, the tabu search framework defined a number of memory structures that captured aspects of the search. The most emblematic is without a doubt the *tabu list*, a list that records attributes of solutions and prohibits, for a certain number of iterations, any solutions that exhibit an attribute on the tabu list.

The tabu search framework, however, extended far beyond the introduction of the tabu list as a memory structure. Probabilistic Tabu Search, introduced by [23], proposed a novel concept: selecting moves probabilistically from a list of the best-performing candidates. This idea later gained significant traction in its constructive

form (replacing probabilistic choice with random choice) under the name GRASP (see below). Curiously, it has been largely overlooked in the context of local search metaheuristics.

While the foundational aspects of tabu search are widely recognized, its full potential is often left untapped. Tabu search, a cornerstone of modern metaheuristics, was developed with a philosophy rooted in deriving and exploiting principles of intelligent problem solving [24]. One of its foundational concepts is the use of *flexible memory*, a feature designed to both capture historical information and leverage it for better decision-making. This duality—acquiring and profiting from information—sets tabu search apart as a highly adaptive and strategic optimization method. However, as the 1997 Tabu Search book [21] elaborates, its deeper mechanisms and broader potential often remain underexplored.

The memory structures in tabu search are defined along four principal dimensions: *recency, frequency, quality, and influence*. These dimensions, when combined with the logical structure and connectivity of the solution space, form a powerful framework for problem solving. Yet, despite their significance, many implementations narrowly focus on short-term "tabu memory," neglecting the broader strategic potential. This oversight diminishes the effectiveness of tabu search implementations, as the principles governing *frequency-based memory*, *aspiration criteria*, and *complementary memory structures* often go unused.

Glover and Laguna [21] examine several aspects of tabu search, like *move values and updates* and *complementary tabu memory structures*, which highlight methods to optimize solution pathways through effective memory utilization. Additionally, the discussions on *aspiration criteria* and *frequency-based memory* offer insights into balancing intensification and diversification, a critical aspect for escaping local optima and exploring the solution space more broadly. Similarly, [21] draws connections between tabu search and other metaheuristics like simulated annealing, genetic algorithms, and neural networks, offering complementary insights that could inspire more robust hybrid approaches.

Another underappreciated feature is *path relinking*, which facilitates both intensification and diversification by constructing solution paths between elite solutions, and which can be seen as a deterministic variant of the crossover concept in evolutionary algorithms. This concept, which emphasizes connectivity and systematic exploration, has immense potential but is rarely implemented to its full capacity. Sörensen and Schittekat [50], e.g., develop a path relinking method that creates a chain of intermediate solutions between two given solutions for the vehicle-routing problem in such a way that two neighboring solutions in the chain are separated by exactly one move and the length of the chain is minimal.

The same paper that introduced tabu search also coined the word "metaheuristic" [19]. However, not everybody agreed with this term and a push was made to use the (more modest) term "modern heuristics" instead. Clearly, not everybody agreed that the limited set of metaheuristics proposed by the 1980s had a higher-level aspect to them. Many still viewed them essentially as (admittedly, more complicated than their simple counterparts) algorithms, i.e., unambiguous step-by-

step sets of operations to be performed. Indeed, it is very common in the late 1980s for a "new metaheuristic" to be described based on a flowchart or another typical algorithmic representation. The widespread realization that metaheuristics could and should be viewed as general frameworks rather than as algorithms would come during the next period, the framework-centric period.

Threshold accepting [14], a simple variant of simulated annealing, demonstrated that a metaphor was certainly not necessary to develop a powerful general-purpose optimization framework. The great deluge method and record-to-record travel [13] differed from threshold accepting only by the way in which they accepted new solutions. Still, each of these was seen as different methods.

Interestingly, neural networks [32] were among the limited set of metaheuristics proposed by the late 1980s. These methods, inspired by the functioning of the brain (including neurons and synapses), were initially introduced in the context of pattern recognition, a domain where they continue to be used.

In recent years, the link between metaheuristics and neural networks—now commonly referred to as deep learning models—has become a topic of intense exploration. The idea that neural networks could potentially replace traditional metaheuristics has been gaining attention in the research community. However, we are far from realizing this vision. While neural networks show promise in learning and guiding heuristic decisions, they often lack the interpretability, robustness, and general-purpose applicability that make metaheuristics so versatile. Current efforts are focused on integrating the strengths of both approaches rather than viewing them as competing methodologies.

By 1995, research in metaheuristics had grown to a level that could sustain its own conference series, and thus the MIC (Metaheuristics International Conference) series was established. This conference still exists and was organized in Lorient (F) in July 2024. In the same year, the first issue of the Journal of Heuristics (http://link.springer.com/journal/10732/1/1/page/1), the only journal dedicated to publishing research in metaheuristics, was published. Like MIC, the Journal of Heuristics continues to be published.

Several other frameworks that had been proposed around the early 1990s also gained increasing interest during the mid-1990s. The innovation proposed in the GRASP (greedy randomized adaptive search procedure) framework was to modify a greedy heuristic by selecting at each iteration not necessarily the best element, but one of the best elements randomly [15]. GRASP adopted a probabilistic move selection like probabilistic tabu search later, when it was coupled with path relinking. Similarly, Ant Colony Optimization [7] proposed not only to mix deterministic and stochastic information but also proposed a way for solutions to exchange information.

Evolutionary algorithms invariably introduce a large amount of randomness in the search process. Some authors argued that it might be beneficial to reduce the reliance on randomness, but rather create algorithms that perform a more systematic search of the solution space. Scatter search and path relinking, both introduced in [20], are the most notable examples in which the principles of evolutionary algorithms were used with the randomness removed from them [22].

By the second half of the 1990s, however, it gradually became clear that metaheuristics based on metaphors would not necessarily lead to good approaches. The promised black-box optimizers that would always "just work" and that had attracted so much attention, seemed elusive. Even the theoretical studies lost some of their shine. The convergence results obtained for simulated annealing [29], because they only worked when an infinite running time was available, were not as compelling for practical situations as initially thought. Similarly, the automatic detection of good building blocks by genetic algorithms only really worked if such building blocks actually existed, and if they were not continually being destroyed by the crossover and mutation operators operating on the solutions. Even though the early metaheuristic frameworks offered some compelling ideas, they did not remove the need for an experienced heuristic designer. The advent of metaheuristics had not changed the simple fact that a metaheuristic that extensively exploited the characteristics of the optimization problem at hand would almost always be superior to one that took a black-box approach, regardless of the metaheuristic framework used.

In general, researchers during the method-centric period proposed *algorithms*, i.e., formalized structures that were meant to be followed like a cook book recipe. More often than not, the "new metaheuristic" was given a name, even when the difference between the new method and an existing method was small.

Period 3: The Framework-Centric Period

The insight that metaheuristics could be more usefully described as high-level algorithmic *frameworks*, rather than as algorithms, was a natural thing to happen. The main indicator that this mindset change was taking place—a change that has given rise to a period that we have dubbed the *framework-centric* period—is the increasing popularity of the so-called hybrid metaheuristics during the early 2000s. Indeed, this period could by rights have been called the "hybrid metaheuristic period." Whereas earlier researchers used to restrain themselves to a single metaheuristic framework, more and more researchers around the turn of the century combined ideas from different frameworks into a single heuristic algorithm. Some combinations became more popular than others, like the use of a constructive heuristic to generate an initial solution for a local search algorithm, or the use of GRASP to generate solutions that are then combined using path relinking.

One type of hybrid metaheuristic even received a distinct name: The use of local search (or any "local learning" approach) to improve solutions that are obtained by an evolutionary algorithm was called a *memetic* algorithm [40]. In 2004, the term "hybrid metaheuristic" had become common, and a new conference series with the same name was started.

The hybridization of metaheuristics, however, did not restrict itself to a combination of a metaheuristic with another metaheuristic. Opening up the individual algorithmic frameworks allowed researchers to combine a metaheuristic with any auxiliary method available. Constraint programming, linear programming,

and mixed-integer programming were all used in combinations with ideas from metaheuristics. The combination of metaheuristics and exact methods was coined "matheuristics" [38] (though these methods too had many antecedents in the metaheuristics literature). In 2006, the first edition of the Matheuristics conference took place.

Soon after its introduction, the term "hybrid" metaheuristic would become obsolete, as researchers made a general transition from seeing metaheuristics as algorithms of which some components could be borrowed by other metaheuristics, to general sets of concepts ("frameworks"). The "metaheuristic framework" concept entailed that metaheuristics were nothing more (or less) than a more or less coherent set of ideas, which could of course be freely combined with other ideas. Today, many researchers develop metaheuristics using their experience and knowledge about which methods will work well for certain problems and which most likely will not.

Some general patterns started to appear in the literature on which methods work well for which problems, and the community gravitated toward approaches that always delivered. For almost any variant of the vehicle-routing problem, e.g., a large majority of approaches use some form of local search as their main engine, generally in a multi-neighborhood framework like variable neighborhood search [39]. The use of several different local search operators or the use of several different constructive procedures in general is now a well-regarded strategy and often used as the first choice by heuristic designers. Clearly, variable neighborhood search presented a framework within which the use of multiple neighborhoods could be captured, but many other ways of combining several local search operators in a single heuristic are possible. The use of several constructive heuristics (usually combined with several destructive operators) in a single heuristic became known under the name large neighborhood search [1, 44, 57].

Crucial in this period, which is still ongoing, is that researchers do not have to propose a "new algorithm" anymore to get their papers published. By combining the most efficient operators of existing metaheuristic frameworks, and carefully tuning the resulting heuristic, algorithms can be created that solve any real-life optimization problem efficiently. Researchers can now focus on studying a single, mundane aspect of a metaheuristic framework in detail like, e.g., its stopping rules [43].

Rather than developing ever more complicated methods, in the first decades of the 2000s, a focus can be observed on frameworks that present a much simpler approach that—in many cases—is not much less effective. Iterated local search [36], which proposes to use a single local search operator in alternation with a single perturbation operator, has a long history and dates back to at least the early 1980s [3], yet is still as popular as ever. Its constructive counterpart, often called iterated greedy [17, 45], has recently gained a large amount of traction, despite the fact that it can be seen as a restricted form of strategic oscillation (SO), a technique introduced in [18] often employed in the context of tabu search. SO offers a multitude of concepts and ideas to allow the search to move within and between regions demarcated by various boundaries within the search space, such as those defining feasibility or local optimality or thresholds for various functions

(such as objective functions or sums of variables). Reference to such boundaries enriches the search process by introducing different types of moves and evaluations depending on which side of the boundary the search lies on, and on whether the search is moving toward or away from the boundary. Moves leading toward or away from a boundary are joined by moves launched at the boundary and at selected distances from the boundary which involve more complex searches (for example, by employing exchange moves in place of constructive or destructive moves). Successful applications of strategic oscillation are reported in [8,21,33,37]. An apparent paradox is that the simplification of a metaheuristic to a few simple rules, which may restrict both its scope and its power, seems to increase its popularity. A possible explanation is that it renders the framework more accessible to nonexpert users, who—contrary to the scientific community—value robustness, ease of development, and flexibility over performance.

Traditionally, the metaheuristic community has put a heavy focus on *performance*. Research is only considered good if (and only if) it produces a heuristic algorithm that "performs" well with respect to some benchmark, such as another heuristic or a lower bound. This has been called the "up-the-wall game" (though it might also be called the "one-upmanship game"). All other contributions (e.g., heuristics that are many times simpler than the best-performing heuristic in the literature, studies on heuristics that should perform well but for some reason do not, ...) are much more difficult to publish. However, several researchers have pointed out the adverse effects of this paradigm (one of the earliest was probably [31]), and some recent contributions that go beyond the up-the-wall game demonstrate the framework-centric period is gradually transforming into the *scientific* period. In this period the study of metaheuristics will shift its focus from performance to understanding. Unfortunately, however, not all of the metaheuristics community makes the transition to the framework-centric period, and we are forced to report on a period which essentially runs in parallel with this period.

The Metaphor-Centric Period

Starting in the 1980s, a subfield emerged of research (we hesitate to put quote marks around the terms for reasons explained below) that focuses on developing new metaheuristic methods based on metaphors drawn from natural or man-made processes. In our historical narrative, this period has not been assigned a distinct number because it does not fit chronologically between other periods but instead represents a sidestep occurring in parallel with the framework-centric period.

While metaphors have historically served as a source of inspiration for the development of early metaheuristics, they have always been understood to have limitations. A metaphor is, by definition, a simplified analogy that eventually breaks down when scrutinized too closely. It can inspire innovation but does not inherently provide a robust justification for metaheuristic design choices or serve as a foundation for entirely new frameworks.

In recent years, however, a troubling trend has emerged in a subset of the metaheuristics community: a fixation on creating "novel" metaheuristics solely by introducing new metaphors. This metaphor-based subfield has produced an ever-growing list of processes used as inspiration, ranging from natural phenomena like ants, bees, termites, and bats, to man-made and abstract concepts such as league championships, cloud formation, black holes, and even the Lorentz transformation. The breadth of these inspirations appears limitless, with little regard for whether the underlying process genuinely involves optimization.

One would expect that, at a minimum, a process used as the basis for a metaheuristic should inherently involve some form of optimization. For example, annealing processes minimize energy levels, natural evolution minimizes the mismatch between a species and its environment, and ants minimize the distance between their nest and food sources. Yet, many of the proposed frameworks are based on processes that, by no stretch of the imagination, involve optimization—fireworks, mine blasts, and cloud formation are just a few examples.

The causes and consequences of this "metaphor fallacy" have been analyzed extensively in other publications [2, 49, 56], where the conclusion is clear: This approach is not scientific. This is not the place to revisit every argument against metaphor-based metaheuristics, but it suffices to say that such methods represent a deviation from the scientific rigor expected in the field. Nevertheless, metaphor-driven "novelty" has taken up a (dark) page in the history of metaheuristics—a page that the field would do well to turn quickly.

Period 4: The Scientific Period?

For a long time, the field of metaheuristics has had difficulties to be taken seriously. In 1977, one of the authors of this chapter wrote "[exact] algorithms are conceived in analytic purity in the high citadels of academic research, heuristics are midwifed by expediency in the dark corners of the practitioner's lair [...] and are accorded lower status." [18] Traditionally, the theoretical underpinning of heuristics and metaheuristics has not been on par with that of other areas in OR, more specifically exact methods. The development of heuristic optimization algorithms, whether using a metaheuristic framework or not, is guided by experience, not theory. Early attempts to firmly ground the development of metaheuristics in theory have not delivered upon their promises. Understanding the behavior of metaheuristics on a fundamental level has proven to be a difficult task, notwithstanding several noteworthy efforts [e.g., 54, 55].

Nevertheless, it is hard to argue with success. The obvious usefulness of metaheuristics in practical optimization problems has drawn researchers to improve the frameworks and methods developed. To solve a large majority of real-life optimization problems, heuristics are—and will remain—the only option, whether developed using a metaheuristic framework or not. Nevertheless, there are many things that can be improved about the way the metaheuristic community operates. To list just a few:

- The establishing of adequate *testing protocols* to ensure that algorithms perform as well as they are claimed to do. Here it seems the community still has a lot to learn. Unlike many fields of computational analysis, it is common in the field of metaheuristics to both develop and test an algorithm against the same set of benchmark instances, rather than separating these instances into a training set and a test set, as is standard practice in machine learning and other computational disciplines. This lack of separation introduces a risk of overfitting, where the algorithm is unintentionally fine-tuned to perform well on the benchmark set, rather than demonstrating robust performance across unseen instances.
- The introduction of *meta-analysis* (i.e., a review of a clearly formulated question that uses systematic methods to identify, select, and evaluate relevant research, as well as to collect and analyze data from relevant studies) to the field of metaheuristics ([53]; Hvattum, 2015, Personal communication). Again, there is still a lot of room for improvement, and the initial attempts to introduce this type of analysis into the metaheuristic research have not yet gained sufficient traction.
- The requirement to disclose *source code*, so that researchers can check and build on each other's work in a more efficient way, without reinventing the wheel. Like the previous point, journals that require source code to go along with the published paper are still few and far between.
- A point where considerable progress has been made over the past few years is in the development of powerful *general-purpose heuristic solvers* to decrease development time, like CPLEX or Gurobi, but then heuristically. Hexaly (https://www.hexaly.com) (formerly LocalSolver), for example, is now a robust product that is used heavily in several production environments (e.g., Amazon Web Services uses it to schedule server capacity). TimeFold is a commercially supported open-source general-purpose solver that focuses on solving planning and scheduling problems (https://timefold.ai/). InsideOpt solver (https://insideopt.com/) boasts the ability to handle uncertain data and multiple objectives.

  These existing solvers provide decision-makers with an alternative to hand-developing a heuristic optimization algorithm for their problem, since they are able to solve a model using a set of built-in heuristic operators (usually based on constructive or local search metaheuristics).
- Supporting these general-purpose solvers, the development of a powerful and generally accepted *modeling language* geared more toward the development of heuristics and less toward the MIP paradigm. While there definitely is no generally accepted modeling language, we do see that the examples mentioned above offer a far more expressive set of constructs that can be used to make the modeling of real-life problems much easier and more intuitive. Hexaly, e.g., offers a *list*-type variable that essentially encodes a permutation directly. This allows the modeling of all types of routing and scheduling problems in a far more natural way than MIP solvers (which require expressing routes and schedules using binary variables, combined with sub-tour elimination constraints, e.g.).

Importantly, the change from a performance-driven community to a community in which scientific understanding is more important will take place during the

scientific period. Without doubt, this will lead to the development of even better heuristics, even more efficient, but it will also lead to heuristics that are usable outside of the developer's lab environment.

To finish this section, we want to mention two topics that have garnered a lot of attention recently:

- The recent advances in *machine learning*, combined with the ubiquity of large language models, have sparked renewed interest in the combination of machine learning and metaheuristic approaches. This integration is being explored in both directions [52]. Machine learning algorithms often involve (or even constitute) optimization problems, and heuristics play an important role in solving these, especially given the size of typical machine learning problems. Conversely, machine learning tools have significant potential for modeling optimization problems and designing optimization algorithms [10]. The field that studies the integration of machine learning and metaheuristics is too vast to summarize in a single paragraph, but there is little doubt that these domains will converge in the coming years—which will lead to considerable advances in both.
- Metaheuristics are increasingly being explored in the context of *quantum computing*. Although still in the experimental stage, this integration holds potential for advancing optimization methods in problems where classical computing faces scalability limitations. An in-depth treatment of the current research in this area is out of the scope of this chapter, so we limit ourselves to mentioning the use of the QUBO (Quadratic Unconstrained Binary Optimization) model [25–27]. A significant reason for the QUBO model's usefulness lies in its mathematical equivalence to the Ising spin glass problem, a well-studied problem in physics. This equivalence allows QUBO problems to be directly mapped onto quantum annealers (like those from D-Wave Systems) or gate-based quantum computers (from companies like IBM and Google).

Conclusions

Outlining the history of the field of metaheuristics in a few pages is not an easy undertaking, and completeness is a goal that simply cannot be achieved. In this chapter, we have attempted to clarify the evolution of this field by not focusing exclusively on important events or publications, but by identifying the important paradigm shifts that the field has encountered. What is certain is that the use of metaheuristics is older—much older—than the term itself. As mentioned, our brain itself houses some powerful metaheuristics that have helped humans survive since the dawn of mankind. The scientific study of metaheuristics, however, had to wait until the second half of the previous century.

Scientific communities invariably develop a conceptual framework within which a few axioms are held to be true. This can also be said of the metaheuristics community. It is those shared truths that we have attempted to uncover in this chapter. Even though the field of metaheuristics is still young, it has already

undergone several paradigm shifts that have changed the way researchers approach the development of heuristic optimization methods.

The transition from the method-centric to the framework-centric period has been beneficial for the entire community, and there is no doubt that the transition toward the scientific period can take the field further in the right direction. Metaheuristics are a fascinating area of study with highly significant practical ramifications, and the field will certainly keep evolving in the foreseeable future. There is no doubt that a more scientific, less dogmatic, and broader point of view can help us all achieve our goals: the development of efficient methods to solve the most challenging and important real-life optimization problems.

Abstract

This chapter explores the importance of studying the entire set of optimal solutions in combinatorial optimization problems, rather than focusing solely on a single optimum. Understanding alternate optima is crucial for robust decision-making and comprehensive problem analysis. Using the Linear Ordering Problem (LOP) as a primary example, we illustrate how multiple optimal rankings can lead to significantly different interpretations of results, potentially

affecting real-world decisions. This chapter discusses various motivations for considering the optimal solution set, including improved insight into problem structure, enhanced stability analysis, and more accurate decision support. We examine how this approach can reveal hidden trade-offs, identify critical variables, and provide a more complete understanding of the solution space. By highlighting these motivations across various domains, we aim to encourage a shift in perspective within the field of combinatorial optimization, promoting more thorough and reliable analysis of complex problems. Although single optimum models can be extended to identify multiple optimal solutions, they have important limitations to target medium and large instances, as can be expected. We illustrate this typical performance on the LOP and how heuristics constitute a practical alternative.

Keywords

Multiple optimal solutions · Linear ordering problem · Variable neighborhood search metaheuristics

Introduction

In the field of combinatorial optimization, traditional focus has mainly relied on finding a single optimal solution. While this approach is valuable, it often overlooks a critical aspect: the existence and implications of multiple optimal solutions. As optimization techniques play an important role in decision-making across various domains, from logistics and finance to healthcare and environmental management, the importance of understanding and analyzing the entire set of optimal solutions becomes fundamental.

Studying alternate optima is not merely an academic exercise; it holds profound practical implications for decision-makers and analysts alike. The objective of this chapter is to give relevance to the study of the optimal solution set, emphasizing three key aspects: solution robustness, problem flexibility, and the challenges associated with drawing conclusions from one particular optimal solutions.

Firstly, the concept of solution robustness is intrinsically tied to the existence of alternate optima. In real-world applications, the parameters and constraints of optimization problems are often subject to uncertainties or fluctuations. By examining the set of all optimal solutions, we can assess the stability of our results and identify solutions that remain optimal or near optimal under various scenarios. This robustness analysis is crucial for implementing solutions that can withstand the test of time and changing conditions.

Secondly, the presence of multiple optimal solutions helps to address the needed flexibility of real-world optimization problems. For empirical problems, it is interesting to allow decision-makers to choose among equally optimal alternatives based on secondary criteria or qualitative factors not captured in the original objective function. If multiple optimal solutions are known, the implementation can be quickly switched to another solution without much interrupting the optimal

system performance. Understanding the full set of optimal solutions thus provides a richer context for decision-making, enabling more nuanced choices. If multiple optimal solutions are known, the implementation can be quickly switched to another solution without interrupting the optimal system performance. We may say that the study of alternate optimal solutions constitutes a bridge between single and multi-objective optimization and provides insights to disclose if a multi-objective model would suit better to the optimization problem that we are formulating due, for example, to the existence of different structures in the alternate optimal solutions.

Thirdly, and perhaps most critically, the existence of alternate optima poses significant challenges when attempting to draw conclusions from optimization results. In many fields, such as data analysis, policy-making, or scientific research, optimization techniques are used not just to find a solution, but to infer underlying structures or relationships. When multiple optimal solutions exist, conclusions drawn from a single optimum may be misleading or incomplete. This chapter will explore how considering the entire set of optimal solutions can lead to more reliable and comprehensive insights.

Throughout this chapter, we will use the Linear Ordering Problem (LOP) and some results from [11] as a primary example to illustrate these concepts. The LOP, with its applications in diverse areas such as economics, sociology, and bioinformatics, serves as an excellent case study for the implications of alternate optima. We will show how different optimal rankings in the LOP can lead to substantially different interpretations of the underlying data, highlighting the necessity of a more pragmatic approach to optimization analysis. By examining these aspects, this chapter aims to shift the paradigm in combinatorial optimization from a singular focus on finding "the" optimal solution to a more comprehensive understanding of the optimal solution space. This perspective not only enhances the theoretical foundations of optimization but also significantly improves its practical applications, leading to more robust solutions and insightful decision-making processes.

Related Work

The process of finding all the optimal solutions for a given optimization problem is not always practical for real-world situations. For instance, in well-known problems such as the Linear Ordering Problem, we may find instances with more than 500,000 optimal solution, making it unrealistic to compute the entire set of optimal solutions within reasonable computing time. So, depending on the problem, you may need to propose an alternative, such as computing only representative solutions or the ones that express better the characteristics of the optimal set of solutions. From a theoretical perspective, previous work focused on obtaining alternative optimal solutions for Mixed-Integer Linear Programs (MILPs). Implementations of these kinds of algorithms can be seen in the pool-based modes of popular solvers such as Gurobi and CPLEX. Additionally, due to the high computational cost of generating the complete set of optimal solutions—which can be substantial—there are studies [4] aimed at finding not just the optimal solution but also a set of diverse solutions that maximizes variation. However, because these studies have a general scope, they often lack efficiency and scalability for specific combinatorial problems.

In this section, we will review the previous work done regarding each one of the three key aspects mentioned above, solution robustness, problem flexibility, and the challenge of inferring conclusions from a combinatorial optimization problem. It is worth mentioning that in well-studied problems such as the Capacitated Vehicle Routing Problem (CVRP) [6] or job scheduling, the issues of robustness and flexibility are often addressed through more specific methodologies. These may include incorporating new constraints and variables into the models or utilizing multi-objective models that account for uncertainties or flexibility.

Solution Robustness

The concept of solution robustness in optimization problems was first formally introduced in [15]. While not specifically focused on alternate optima, it laid the groundwork for considering uncertainties and variations in optimization problems. Specifically, Mulvey et al.[15] proposed a framework for robust optimization that aimed to find solutions that perform well across a range of scenarios, rather than just in a single, deterministic case. When faced with an optimization problem, this framework modifies the mathematical model of the problem including probability distributions in order to maximize the stability of an optimal solution, instead of computing all the solutions and analyzing the stability.

Problem Flexibility

In practical optimization problems dealing with high-volatility scenarios, it is important to have multiple optimal solutions. This allows for quick adaptation to changing conditions without interrupting the performance of the system. It is unnecessary to calculate all the optimal solutions; instead, it is sufficient to identify a diverse set of solutions that try to cover all possible scenarios. This ensures that if one solution becomes unfeasible due to changes in the environment, there is always an alternative to rely on. In such cases, a general multimodal optimization algorithm may be sufficient. For instance, in wireless sensor networks (WSNs) [17], multiple optimal solutions for node placement may initially satisfy coverage and connectivity requirements. However, as the network operates, factors such as battery depletion, shifting traffic patterns, or node failures can necessitate adjustments. Having multiple preidentified optimal configurations allows the system to switch between solutions dynamically, ensuring continuous performance while balancing energy consumption or maintaining network integrity.

Inference from an Optimal Solution

As stated above, drawing a conclusion after a single optimal solution may be biased and premature. For example, in the field of evolutionary biology, the inference of phylogenetic trees is a critical task that aims to reconstruct the evolutionary relation-

ships among species or genes. When using the maximum-parsimony method, which seeks to minimize the number of evolutionary changes required to explain observed traits, multiple phylogenetic trees can equally well explain the observed genetic or morphological data. This phenomenon, known as phylogenetic uncertainty, underscores the importance of obtaining and analyzing multiple optimal solutions rather than settling for a single "best" tree. By considering alternate optimal trees, researchers can gain a more nuanced understanding of evolutionary relationships, assess the robustness of their conclusions, and avoid overconfidence in a single reconstruction that may be arbitrary among equally plausible alternatives. For instance, [16] demonstrated that different optimal trees might suggest conflicting evolutionary hypotheses, such as the timing of speciation events or the origin of specific traits. Moreover, as shown by [8], the consensus of multiple optimal trees often provides a more accurate representation of evolutionary relationships than any single tree. This approach also allows for the identification of stable clades across different reconstructions, providing a measure of confidence in specific evolutionary groupings. Furthermore, exploring the landscape of optimal and near-optimal trees can reveal important biological insights, such as rapid evolutionary radiations or instances of horizontal gene transfer, which might be masked when focusing on a single optimal solution. Therefore, in phylogenetic analysis, the pursuit and examination of multiple optimal solutions is not merely a statistical exercise, but a fundamental approach to gaining a comprehensive and reliable understanding of evolutionary history.

Linear Ordering Problem

In this section we will use the Linear Ordering Problem (LOP) as a vehicular example to show why and how to deal with multiple optimal solutions.

The Linear Ordering Problem (LOP) involves finding a permutation p of the columns and rows of an $n \times n$ weight matrix $C = (c_{ij})$ in order to maximize the sum of the weights in the triangular region above the main diagonal. This matrix is known in some applications as the dominance matrix, where the entry (i, j) indicates the degree to which element i dominates element j.

Linear ordering problems arise whenever there is a need to determine rankings for certain objects. For instance, given a set of n objects $O_1, O_2, \ldots, O_n$ rated by m individuals based on their individual preferences, the goal is to establish a ranking that globally reflects these individual rankings as closely as possible. This formulation is one of the oldest applications of the LOP, originally proposed in 1959 by [9]. In this problem, the entry (i, j) in the dominance matrix corresponds to the number of individuals who prefer object O_i over object O_j.

The most significant application of the Linear Ordering Problem (LOP) is likely the triangulation of input-output tables in economics. This was a central component of the study for which Leontiev[10] received the Nobel Prize in 1973. These tables illustrate the interdependencies among different branches of the economy, categorized into sectors, where the entries reflect the transactions between those sectors.

Triangulation is a method used to establish a hierarchy of all sectors in such a way that the flow of transactions that contradicts this hierarchy (specifically, transactions from sectors ranked lower to those ranked higher) is minimized. Establishing such rankings provides useful information of a country's industrial structure and allows for comparisons between different countries.

The LOP can be modeled using the following linear integer model, featuring binary variables x_{ij}, where $i, j = 1, \ldots, n$, indicating whether element i precedes element j.

$$\begin{aligned} \max f(x) &= \sum_{(i,j)\in A} c_{ij} x_{ij} \\ x_{ij} + x_{ji} &= 1, \text{ for } i, j = 1, \ldots, n, i < j, \\ x_{ij} + x_{jk} + x_{ki} &\leq 2, \text{ for } i, j, k = 1, \ldots, n, i < j, i < k, j \neq k, \\ x_{ij} &\in \{0, 1\}, \text{ for all } i, j = 1, \ldots, n. \end{aligned} \tag{1}$$

This 0/1-IP can be considered as the canonical IP formulation of the problem [13].

Considering only a single optimal ranking can result in premature conclusions, especially when there are multiple optimal rankings that differ significantly. In the case of the LOP, it is evident that having more than one optimal solution may be a critical issue that jeopardizes some of the interpretations of the solutions mentioned above.

The examination of various optimal solutions has significant implications; however, it has been largely ignored in the literature on Linear Ordering Problems (LOP) according to [13]. Anderson et al. [1] were the first to investigate the analysis of alternate optimal LOP solutions, revealing that certain elements maintain relative stability across different optimal solutions, while others may vary significantly in their rankings, thereby threatening the applicability of LOP. To exemplify this situation, the authors present the following 10 optimal solutions for the `N-pal13` instance (referred to as the *Paley graph*), sourced from the publicly available LOLIB—Linear Ordering LIBrary [12]:

1. ⟨8, 9, 3, 12, 7, 1, 10, 4, 13, 2, 11, 5, 6⟩
2. ⟨8, 9, 3, 12, 6, 1, 10, 4, 13, 7, 2, 11, 5⟩
3. ⟨8, 9, 3, 12, 1, 10, 4, 13, 7, 2, 11, 5, 6⟩
4. ⟨9, 12, 1, 10, 4, 13, 7, 8, 2, 11, 5, 3, 6⟩
5. ⟨9, 12, 7, 1, 10, 4, 13, 8, 2, 11, 5, 3, 6⟩
6. ⟨8, 11, 9, 3, 12, 6, 1, 10, 4, 13, 7, 2, 5⟩
7. ⟨8, 11, 9, 3, 12, 6, 7, 1, 10, 4, 13, 2, 5⟩
8. ⟨8, 9, 3, 12, 6, 7, 1, 10, 4, 13, 2, 11, 5⟩
9. ⟨9, 3, 12, 7, 1, 10, 4, 13, 8, 2, 11, 5, 6⟩
10. ⟨9, 3, 12, 1, 10, 4, 13, 7, 8, 2, 11, 5, 6⟩

These optimal solutions can be easily obtained with the *pool mode* of a commercial software for MILPs such as Gurobi or CPLEX. However, we have

empirically found that this pool mode has important limitations in practice, because in most of the cases a complete enumeration of all the optimal solutions is not possible due to its very large cardinality.

For example, in the LOLIB set of instances, we can find the Input-Output subset, in which the instances range from $n = 44$ to 56. In spite of the medium size of these instances, we have found that the size of the set of optimal solutions is very large (ranging in most of the cases from 1,000 to 500,000 solutions). This seems to indicate that in a way or another we have to simplify this information to be practical to the user.

It is clear in the optimal solutions of the example above that elements 8 and 9 consistently occupy the top positions. In contrast, other elements, such as 3 and 6, vary significantly in their rankings depending on the specific optimal solution considered. For instance, in Solution 1, element 3 is ranked third, while in Solution 4, it drops to twelfth place. Similarly, element 6 is ranked fifth in Solution 2 but often appears in the last place in many other optimal solutions. Given that most methods proposed for the Linear Ordering Problem (LOP) typically identify only one optimal solution—or a good one in the case of heuristics—it is important to moderate our conclusions when interpreting the individual rankings of elements. This is particularly true in applications where we seek to establish a ranking based on pairwise comparisons, such as in sports tournaments or lists of top universities. Ranking in sports is usually a controversial topic, as can be read in the sports section of well-reputed journals, such as the New York Times where only in this month we can read about it in the context of the Challenger Tour finished on the ATP circuit or the college football Playoff rankings. In these contexts, the standard LOP model alone may not be suitable, and additional factors should be considered to arrive at the most representative ranking.

Mathematical Models

When examining the representativeness of an optimal ordering from a Linear Order Problem (LOP) instance, it is important to analyze the distance between different optimal solutions. If we can identify two optimal solutions where their elements are positioned very differently from each other (indicating a large distance), then neither solution can be considered representative. Conversely, if all optimal solutions are quite similar (suggesting they are close to one another), any of these solutions can be seen as a good representative.

In this context, studies by [3] and [1] have proposed using the Kendall-Tau rank distance, developed by Maurice Kendall in 1938, to measure the number of discordant pairs between two rankings. The goal is to identify the two optimal solutions at the largest Kendall-Tau distance. The authors outlined a two-step method: First, they solve the canonical LOP to find the optimal value c^*; second, they solve a mathematical model aimed at maximizing the distance between all pairs of optimal LOP solutions, thus returning the two most distant optimal solutions. We found this approach very intuitive and informative. However, this method only gives information about the diameter of the optimal solution space, but not about its

geometry. In other words, these solutions may not be representative enough, as there may be alternative solutions that are quite different from the two already considered. Let us clarify this with the previously mentioned example.

We have examined 10 optimal solutions for the N-pal13 instance. The two solutions at the maximum distance according to the model in [3] are:

⟨9, 12, 1, 10, 4, 13, 7, 8, 2, 11, 5, 3, 6⟩
⟨8, 11, 9, 3, 12, 6, 7, 1, 10, 4, 13, 2, 5⟩

These two extreme solutions provide some insights into the ranking of elements across the optimal solutions. For example, element 7 is always ranked 7th, while element 8 is ranked 8th in the first solution and 1st in the second. We can represent the range of positions for each element as [min, max]. So for element 7, the range would be [7,7], and for element 8 the range would be [1,8]. However, this information from the two most distant solutions does not provide an accurate picture on the set of optimal solutions, and it may even be misleading. The following optimal solutions show that element 7 can actually be ranked 3rd, 7th, or 10th. So the ranges derived from the two extreme solutions do not accurately capture the full variation in element positions across all the optimal solutions. A more comprehensive analysis is needed to summarize how the elements are ranked across all the optimal solutions:

⟨8, 9, 3, 12, 6, 1, 10, 4, 13, 7, 2, 11, 5⟩
⟨8, 11, 9, 3, 12, 6, 7, 1, 10, 4, 13, 2, 5⟩
⟨9, 12, 7, 1, 10, 4, 13, 8, 2, 11, 5, 3, 6⟩

Using a similar approach, the following model from [11] generalizes the model to compute not just the two most distant solutions, but the m most distant solutions, to obtain a better representation of the entire set of optimal solutions.

$$
\begin{aligned}
\min \quad & \sum_{\substack{t,t'=1 \\ t<t'}}^{n} \sum_{\substack{i,j=1 \\ i\neq j}}^{n} z_{ij}^{(t,t')} \\
\text{s.t.} \quad & x_{ij}^t + x_{ji}^t = 1, && \forall i < j : i, j \in \{1,\dots,n\}, t \in \{1,\dots,m\} \\
& x_{ij}^t + x_{jk}^t + x_{ki}^t \leq 2, && \forall i < j, i < k, j \neq k : i, j, k \in \{1,\dots,n\}, t \in \{1,\dots,m\} \\
& \sum_{\substack{i,j=1 \\ i\neq j}}^{n} c_{ij} x_{ij}^t = c^* && t \in \{1,\dots,m\} \\
& x_{ij}^t + x_{ij}^{t'} - z_{ij}^{(t,t')} \leq 1, && \forall i \neq j : i, j \in \{1,\dots,n\} \forall t \neq t' : t < t', t, t' \in \{1,\dots,m\} \\
& x_{ij}^t, z_{ij}^{(t,t')} \in \{0,1\}, && \forall i \neq j : i, j \in \{1,\dots,n\}, \forall t \neq t' : t < t', t, t' \in \{1,\dots,m\}.
\end{aligned} \tag{2}
$$

We define an $n \times n$ dimensional binary variable x^t for each optimal solution, $t \in \{1,\dots,m\}$. As in the previous formulation, x_{ij}^t takes the value 1 if element

i precedes j in the t optimal solution. For each pair of optimal solutions x^t and $x^{t'}$, the variable $z_{ij}^{(t,t')}$ takes the value 1 if elements i and j are in the same relative positions in solutions x^t and $x^{t'}$. This is due to the constraint $x_{ij}^t + x_{ij}^{t'} - z_{ij}^{(t,t')} \leq 1$. To obtain the m-farthest optimal solutions, the objective function minimizes the sum of $z^{(t,t')}$-variables.

It is evident that the model described in equation (2) can have a very large number of variables. This is because, for every pair of optimal solutions we aim to identify, it introduces an $n \times n$ dimensional binary variable $z^{(t,t')}$. However, from a practical perspective, we will focus on relatively small values for the number of optimal distant solutions m.

Based on the results on the Maximum Diversity Problem (MDP)[13], instead of maximizing the overall sum of the distance among m optimal solutions, we can maximize the minimum distance among all the pairs of m solutions. According to previous work in the MDP, when the goal is to maximize the diversity among m selected points from a larger set, the model that focuses on maximizing the minimum distance between points, called MaxMin, generates solutions with a very different structure compared to the model that maximizes the sum of distances, MaxSum. Specifically, the MaxMin model produces equidistant points distributed throughout the space, and it does not avoid selecting points in central regions like the MaxSum model does. From [11] we propose a second model called m-farthest-min that aims to find the m most distant solutions by maximizing the minimum distance among the optimal solutions. We refer to the model in equation (2) as the m-farthest-sum model and that in equation (3) as the m-farthest-min model. It is worth noting that a potential downside of the sum of distances-based model (m-farthest-sum) is that it may generate the same optimal solution multiple times when maximizing the overall sum of distances. In contrast, the minimum distance-based model (m-farthest-min) does not have this issue, because repeating a solution would result in a minimum distance of 0, which is not desirable.

$$
\begin{aligned}
\min \quad & z \\
\text{s.t.} \quad & x_{ij}^t + x_{ji}^t = 1, && \forall i < j : i, j \in \{1, \ldots, n\}, t \in \{1, \ldots, m\} \\
& x_{ij}^t + x_{jk}^t + x_{ki}^t \leq 2, && \forall i < j, i < k, j \neq c : i, j, k \in \{1, \ldots, n\}, t \in \{1, \ldots, m\} \\
& \sum_{\substack{i,j=1 \\ i \neq j}}^{n} c_{ij} x_{ij}^t = c^* && t \in \{1, \ldots, m\} \\
& x_{ij}^t + x_{ij}^{t'} - z_{ij}^{(t,t')} \leq 1, && \forall i \neq j : i, j \in \{1, \ldots, n\} \forall t \neq t' : t < t', t, t' \in \{1, \ldots, m\}, \\
& z \geq \sum_{\substack{i,j=1 \\ i \neq j}}^{n} z_{ij}^{(t,t')} && \forall t \neq t' : t < t', t, t' \in \{1, \ldots, m\} \\
& x_{ij}^t, z_{ij}^{(t,t')} \in \{0, 1\}, && \forall i \neq j : i, j \in \{1, \ldots, n\}, \forall t \leq t' : t < t', t, t' \in \{1, \ldots, m\}.
\end{aligned} \tag{3}
$$

It is important to note that these models are designed to calculate the variable z_{ij}, which represents the count of pairs (i, j) that maintain the same relative order in different optimal solutions (for instance, t and t'). Consequently, to enhance the separation between solutions, they aim to reduce the total number of pairs of elements that are in the same relative order in these solutions. Specifically, the m-`farthest-sum` model focuses on minimizing the following expression within the objective function of (2):

$$\sum_{\substack{i,j=1 \\ i \neq j}}^{n} z_{ij}^{(t,t')}.$$

This expression counts the number of pairs (i, j) in the same relative position in solutions t and t'. The objective function adds this expression for all pairs of solutions, thus obtaining:

$$\sum_{t,t'=1 t<t'}^{n} \sum_{\substack{i,j=1 \\ i \neq j}}^{n} z_{ij}^{(t,t')}.$$

To minimize this expression is equivalent to maximize the Kendall-Tau distance between solutions.

The m-`farthest-min` model is shown in (3), where we can see that the right-hand side in the new constraint:

$$z \geq \sum_{\substack{i,j=1 \\ i \neq j}}^{n} z_{ij}^{(t,t')}$$

computes, as in (2), the number of pairs of elements in the same relative ordering in solutions t and t'. With the minimization of the z variable in the objective function, it takes in this constraint the value of the largest number of elements with the same ordering in a pair of solutions (t, t'). Note that this pair corresponds to the two solutions at minimum distance (since they are the two with more pairs in common).

Algorithmic Approach

The models described exhibit exponential growth, making them unsuitable for large instances (and even for medium-sized instances). Therefore, based on the same two-step methodology, we present a VNS heuristic from [11] to obtain approximate solutions in short computational times. This approach involves solving the Linear Ordering Problem (LOP) in the first step to achieve the best possible value. In the

second step, we identify the m-farthest solutions based on this objective function value. It is important to note that since the heuristic does not guarantee the optimality of the objective value in the first step, the second step may explore suboptimal regions of the solution space, and these suboptimal regions may not correlate with the optimal one.

We propose a two-step algorithm based on the Variable Neighborhood Search (VNS) methodology. In Algorithm 1, we show the pseudo-code of our complete approach. The algorithm takes five inputs: the number of m alternative solutions that we want to obtain, the largest neighborhood sizes k^1_{max} and k^2_{max}, the maximum number of iterations it_{max}, and the maximum CPU time τ_{max}. As in the mathematical models proposed above, the heuristic algorithm has basically two phases. In the first one, the algorithm finds the best solution (i.e., its approximation to the optimal LOP solution) with the BVNS method, numbered as step 2 in the pseudo-code. In the second phase (numbered as step 3), it finds the subset of the m-farthest solutions corresponding to the value identified in the first phase, which will ultimately determine the elements' ranking (computed in step 4). We denote as Δ^S the set of rankings of the elements in the m alternative solutions obtained.

As outlined in the mathematical models presented earlier, the heuristic algorithm consists of two main phases. In the first phase, the algorithm uses the BVNS method to identify the best solution, which serves as an approximation of the optimal LOP solution (this step is numbered as 2 in the pseudo-code). In the second phase (numbered as 3), the algorithm identifies the subset of m solutions that are farthest. This subset ultimately determines the ranking of the elements, as computed in step 4. Let us explain how this algorithm works.

Algorithm 1: `Two-step VNS`$(m, k^1_{max}, it_{max}, k^2_{max}, \tau_{max})$

1: $p \leftarrow random_solution()$
2: $p \leftarrow$`BVNS`(p, k^1_{max}, it_{max}) see Algorithm 2
3: $S \leftarrow$ `VNS`$(p, m, k^2_{max}, \tau_{max})$ see Algorithm 3
4: $\Delta^S \leftarrow elements_range(S)$
5: **return** Δ^S

Algorithm 2: `BVNS`(p, k^1_{max}, it_{max})

1: **while** $it < it_{max}$ **do**
2: $k \leftarrow 1$
3: **while** $k \leq k^1_{max}$ **do**
4: $p' \leftarrow Shake(p, k)$
5: $p'' \leftarrow LocalSearch(p')$
6: $k \leftarrow NeighborhoodChange(p, p'', k)$
7: **end while**
8: **end while**
9: **return** p

Algorithm 3: VNS $(p, m, k^2_{max}, \tau_{max})$

```
1: c ← f(p)
2: S ← {p}
3: while τ < τ_max do
4:     k ← 1
5:     q ← select_random(S)
6:     while k < k²_max do
7:         p' ← Shake(k, q)
8:         p'' ← LocalSearch(p')
9:         if f(p'') == c then
10:            S' ← Insert(S, p'', m)
11:            if K_d(S') > K_d(S) then
12:                S ← S'
13:                k ← 1
14:            else
15:                k ← k + 1
16:            end if
17:        end if
18:    end while
19: end while
20: return S
```

VNS was introduced in [14] and, since then, has gained significant relevance among metaheuristics. Several variants and extensions have been proposed, as detailed in [7]. Starting from an initial solution, the rationale behind VNS is to exploit the notion of changing neighborhoods, both in reaching the local optimum and in escaping from the valleys that contain them. This chapter considers the neighborhoods based on insertion moves proposed in [5] for the LOP. Given a solution (permutation) $p = (p_1, \ldots, p_n)$, where p_i represents the element in position i in the solution p, we define as $\texttt{insert}(p_j, i)$ dropping element p_j from solution p and adding it in position i. Then, the neighborhood $N_1(p)$ consists of the set of solutions obtained by the moves $\texttt{insert}(p_j, j-1)$ and $\texttt{insert}(p_j, j+1)$, which essentially represents the set of solutions obtained by switching one element either directly one position before or after their current position. The neighborhood $N_2(p)$ is defined as the solutions obtained by inserting any element p_j from p into a different position. In general, we define $N_k(p)$ as the set of solutions reached by applying N_2 recursively to solution $p, k-1$ times, which is equivalent to performing $k-1$ moves in p.

In the **first step** of the algorithm, we employ a Basic VNS (BVNS) method to solve the LOP, to obtain the objective function value of a high-quality solution that eventually can be the optimal solution. BVNS balances diversification and intensification by integrating deterministic and random changes within its neighborhood structures. Algorithm 2 shows the pseudo-code of the BVNS. The BVNS algorithm takes three inputs: a randomly generated initial solution, the largest neighborhood size k^1_{max}, and the maximum number of iterations it_{max}. At each iteration it, the algorithm first sets the parameter k to 1 (step 2). The main loop then iterates through

neighborhoods (steps 3–7). First, a solution p' is randomly generated from the kth neighborhood of solution p (step 4). A local search is applied to the obtained solution p' to find a local optimum p'' (step 5). Specifically, the local search iterates through each element (p'_j) in p', inserting it into the position that yields the best objective function value. If the improved solution p'' outperforms the current solution p, it becomes the new incumbent solution $p \leftarrow p''$, and the neighborhood exploration restarts at the smallest size $k \leftarrow 1$ (step 6). Otherwise, the algorithm explores a larger neighborhood ($k = k + 1$) until reaching the largest one.

As mentioned above, the **second step** of the algorithm aims to find the m-farthest alternative solutions according to the *Kendall-Tau distance*, which quantifies the dissimilarity between two permutations. Given two solutions (permutations) p and p' of length n, the Kendall-Tau distance, denoted as $K_d(p, p')$, is defined as the number of pairs (i, j) such that $1 \leq i < j \leq n$ and the orders of p and p' differ on these pairs. Formally,

$$K_d(p, p') = \left| \{(i, j) \mid 1 \leq i < j \leq n,\ (p_i < p_j \wedge p'_i > p'_j \text{ or } (p_i > p_j \wedge p'_i < p'_j \} \right|,$$

where p_i denotes the position of the element i in the permutation p. Intuitively, the Kendall-Tau distance counts the number of inversions needed to convert one permutation into another. An *inversion* is a pair of elements in the opposite order in the two permutations. Given a subset of m solutions $S = \{p^1, \ldots, p^m\}$, the Kendall-Tau distance of the set S, $K_d(S)$, is computed as the sum of the Kendall-Tau distances of each pair of solutions in S. In the VNS algorithm, a subset S' is better than a subset S if it has a larger Kendall-Tau distance, i.e., $K_d(S') > K_d(S)$.

Algorithm 3 outlines the pseudo-code for computing the m-farthest solutions. It takes the following inputs: the best solution found in the `BVNS`, p; the number m of desired farthest alternative solutions; the maximum size of the neighborhood k^2_{max}; and the maximum CPU time τ_{max}.

The algorithm first initializes the objective function value of the best solution found p (step 1) and the set S of alternative high-quality solutions (step 2). It then enters in a loop that continues until the time limit τ_{max} is reached. Inside the loop, a solution q is randomly selected from the set S (step 5). The main loop then iterates based on a basic variable neighborhood search scheme (steps 6–18). The shake procedure is applied to randomly select a solution p' in the neighborhood $N_k(q)$ (step 7). Then, a local search is performed on p' to find a local optimum within its N_2 neighborhood (step 8).

If the resulting solution of the local search p'' is a new high-quality solution (i.e., not already in S), the new set S' is constructed. If $|S| < m$, S' simply includes S and the new local optimum p'' (if it is a different solution). If $|S| = m$, S' is S by exchanging solution p'' with the solution that maximizes the Kendall-Tau distance gain (step 10). Finally, if the new set S' improves the overall Kendall distance compared to S, then S is updated with S', and the neighborhood size is reset to 1 (step 13). Otherwise, the neighborhood size is incremented by 1 (step 15).

Practical Cases with Multiple Optima

College Rankings and Fairness

When we use the Linear Ordering Problem to create a ranking, we take on a responsibility toward both the elements we are ranking and the users who will rely on our ranking. This is why it is important to incorporate the concept of fairness into the process. Biega et al. [2] present an example of fairness in the context of Airbnb room rankings. When an Airbnb user makes a search, an ordered list of rooms is displayed, and typically, the rooms ranked higher receive much more attention than those shown at the bottom of the list. Therefore, if we consistently show the same ranking of rooms for the same user query, we are being systematically unfair to those ranked last. The authors suggested considering a range of rankings and varying the displayed ranking over time to ensure that the attention given to rooms is fair in the aggregate. Biega et al. [2] define the unfairness of a set of m rankings of n elements as

$$unfairness(p^1, \ldots, p^m) = \sum_{i=0}^{n} \Big| \sum_{j=1}^{m} A_{ij} - \sum_{j=1}^{m} R_{ij} \Big|, \tag{4}$$

where $\sum_{j=1}^{m} A_{ij}$ is the total aggregated attention received by the element ith and $\sum_{j=1}^{m} R_{ij}$ is the relevance of the ith element.

We will use the US News and World Report college data used in [3] as a case study to examine how the models proposed above can help reduce unfairness when processing repeated queries for college rankings. Every year, U.S. News and World Report ranks colleges based on various quantitative factors, such as student-faculty ratio and acceptance rate. We can use these factors to create a dominance matrix and apply the Linear Ordering Problem (LOP) to rank the colleges. Although we are unsure of the exact algorithm used by U.S. News and World Report, LOP is a reliable option for this purpose. For simplicity, we will focus on a subset of 11 liberal arts colleges and construct a dominance matrix 11×11 where the entry (i, j) indicates in how many factors college i performs better than college j. Since one can choose which features to consider when creating the dominance matrix, the matrix we will use only reflects a possible query made by an individual.

Using the LOP mathematical model and the pool mode of the Gurobi solver, we obtain that our input dominance matrix has 72 optimal rankings. In our case, the true relevance of an element i will be the average position of element i across the optimal solution set, $\sum_{j=0}^{72} \frac{r_{ij}}{72}$, and the attention received by the element i will be the average position of the element i across the set of m solutions displayed. The situation is as follows: An individual requests a ranking of colleges based on attributes he considers important, and if the query is repeated by another individual, we must decide what information to present to them. It has become apparent that consistently showing the same ranking is unfair to colleges that may rank higher in other optimal rankings according to the same criteria. To address this issue, we propose four systems for responding to repeated queries:

- Cyclically return the two most distant solutions according to the m-farthest-sum model.
- Cyclically return the four most distant solutions according to the m-farthest-sum model.
- Cyclically return the four most distant solutions according to the m-farthest-min model.
- Cyclically return the four most distant solutions according to the m-farthest-sum model and the four most distant solutions according to the m-farthest-min model.

After all, unfairness measures how well a set of solutions represents the distributions of each element's positions across the optimal solution set. In our case, we can see in Fig. 1 that the best model by itself is the MaxMin model. However, the MaxSum produces solutions different to the MaxMin model, and that is why when we combine them, we get the most representative solutions.

In this case study, we have seen a method to reduce the unfairness in the aggregate toward the colleges when processing repeated queries, which we can extrapolate to every methodology that produces a ranking as an output for an individual request. It is worth noting that we are using a small instance, and the solvers are capable enough to compute the whole optimal set. However, larger instances may require a heuristic approach.

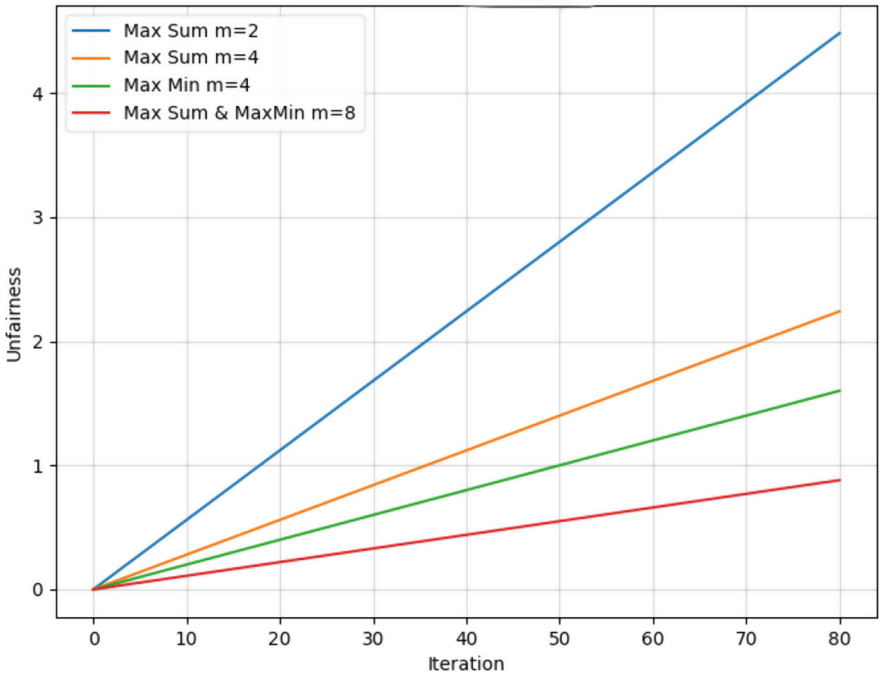

Fig. 1 Unfairness of different systems when used for repeated queries

In the next case study we will see how to sum up the information of the whole optimal solution set in a valuable way for the user.

Premier League

We are going to use the LOP to rank the teams of the Premier League on the 2017–2018 season. The standard method for ranking soccer teams based on league results is to award each team three points for a win and one point for a draw and then arrange them according to their total points. This approach has three main drawbacks. First, it fails to consider the margin of victory, which may indicate the team's strength. Second, it lacks nuance since it does not differentiate between victories over strong and weak teams; winning against a top team is valued the same as beating the last-place team. Third, a team that frequently draws may accumulate more points than a team with a combination of wins and losses, even if the latter has demonstrated the capability to defeat opponents. These factors justify the use of the LOP model to create a more accurate ranking of the teams.

First of all, we need a dominance matrix in order to classify the teams. Since 20 teams played that season, we create a 20×20 matrix where the entry (i, j) is set as the number of goals that team i scored against team j in the entire season. For example, if we associate Liverpool with the first row and column, and Manchester United with the second one, and they faced each other twice resulting in scores of 1–2 and 2–1, respectively, then the entry (1, 2) will be 3, and the entry (2, 1) will be 3 as well.

The traditional approach offers users a single optimal ranking. However, this can be problematic, as there may be multiple optimal solutions available, and presenting every optimal solution does not seem particularly useful. It is important to note that the difficulty of the multiple optima problem can vary based on how much the positions of each element differ within the optimal set. Therefore, it would be beneficial to provide users with the ranges of variation for each element. To accurately determine these ranges, we need to compute the entire optimal set, which can be challenging even for medium-sized instances. However, as noted in [11], we can approximate these ranges with high precision using the previous models or by employing the VNS algorithm to compute 3 or 4 distant solutions. It is worth mentioning that obtaining four or more solutions with the mathematical models can be challenging, even in cases with 30 or 40 elements, which makes it necessary to have an heuristic approach.

Figure 2 illustrates that the positions of most teams vary significantly, which supports the idea that analyzing a single optimal solution can be misleading. By comparing the ranges of optimal positions of each team with the official rankings, we can extract insightful information. For instance, Manchester City clearly emerged as the most dominant team. However, the official ranking method did not adequately represent the overall strengths of teams like Tottenham and Stoke City, which clearly demonstrate a better dominance than what the official ranking

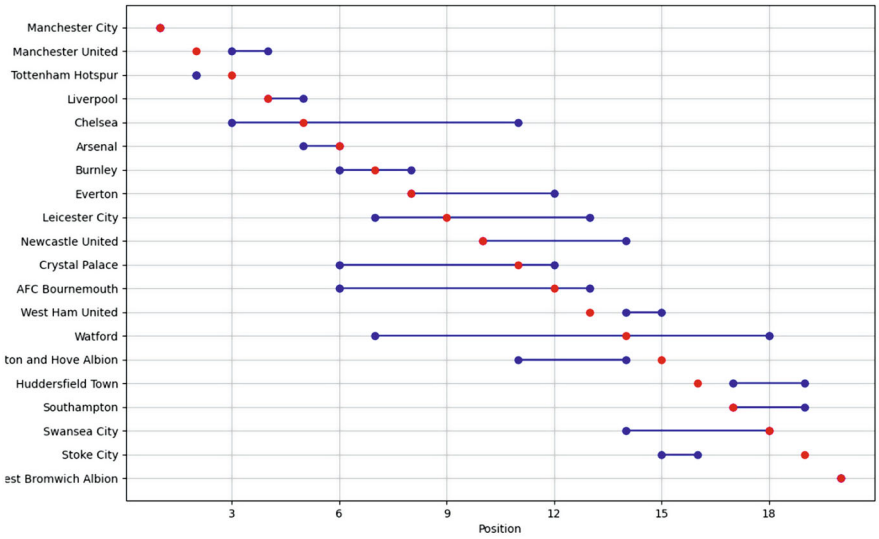

Fig. 2 Ranges of teams positions in LOP across the optimal solution set versus official classification (in red points)

shows. Additionally, some teams, such as Watford, show considerable variability in their positions, suggesting that they did not demonstrate decisively dominance throughout the season.

Conclusion

This chapter illustrates the importance of examining the full set of optimal solutions rather than concentrating on just one of them, as shown on the Linear Ordering Problem. This comprehensive approach provides valuable insights into the structure of solution space, enhances decision-making robustness, and helps reduce potential biases in interpreting results.

The practical implications of considering multiple optimal solutions go beyond theoretical optimization and find it realm into real-world challenges. The case studies demonstrate that understanding the variability in rankings or outcomes fosters fairness and equity while offering a more nuanced view of the data. Effectively summarizing the entire solution space not only enriches the interpretability of the results but also provides actionable insights to the policy-makers.

Given the usual large size of the optimal solution spaces, this work emphasizes the need for methodologies that not only identify these solutions but also represent them effectively. Techniques such as m-farthest models and heuristic-based approaches like Variable Neighborhood Search (VNS) serve as valuable tools for

navigating the complexities of the solution space while ensuring computational feasibility. It is worth noting that the two-phase concept used in the VNS algorithm should be easily extensible to other heuristics such as GRASP or Tabu Search. In particular, the identification of the optimal value first, and the generation of diverse alternate optima, is a simple and effective scheme that can be easily integrated in different metaheuristics. We hope that this initial approach triggers the interest of researchers in the practical topic of identifying multiple optimal solutions, and explore this area in the frontier of the so-called multi-objective optimization.

In conclusion, embracing the concept of alternate optima in combinatorial optimization represents more than just a change in analytical perspective; it is a crucial step toward achieving more robust, fair, and insightful solutions across various application domains. Future research should focus on refining these methods with an emphasis on scalability and practicality to maintain their relevance and applicability to increasingly complex decision-making problems.

Abstract

The complexity of Deep Neural Networks (DNNs) has driven advancements in Neural Architecture Search (NAS), Hyperparameter Optimization (HPO), and Learning Rule Optimization (LRO). This study reviews heuristic methodologies, focusing on Evolutionary Algorithms (EAs) and Swarm Intelligence (SI). We analyze Genetic Algorithms (GAs), Particle Swarm Optimization (PSO), and Multi-Objective Optimization (MOO), emphasizing the Biased Random Key Genetic Algorithm (BRKGA). BRKGA encodes neural architectures and hyperparameters as continuous vectors, enhancing search efficiency in NAS and HPO. We evaluate BRKGA on Feedforward Neural Networks (FNNs), Convolutional Neural Networks (CNNs), and Graph Neural Networks (GNNs), demonstrating their effectiveness in tuning learning rates, dropout rates, and batch sizes. Additionally, we explore its role in LRO, optimizing adaptive weight updates and gradient modulation. Experiments on benchmark datasets show that BRKGA consistently yields promising architectures and hyperparameter configurations, balancing accuracy, efficiency, and adaptability. Our findings highlight BRKGA as a viable alternative for NAS, HPO, and LRO, particularly in complex search spaces where structured exploration is essential. Finally, challenges in heuristic-driven NAS, HPO, and AutoML are examined, along with future research directions in scalable optimization, adaptive learning mechanisms, and neuromorphic computing.

Keywords

Biased random key genetic algorithm · Deep feedforward neural networks · Convolutional neural networks · Graph neural networks · Neural architecture search · Hyperparameter optimization · Learning rule optimization

Introduction and Motivation

Deep Neural Networks (DNNs) have revolutionized artificial intelligence, driving advances in fields such as computer vision, natural language processing, and bioinformatics. However, their increasing architectural complexity and vast

hyperparameter search spaces pose significant challenges in network design, training strategy selection, and optimization. Traditional approaches rely heavily on gradient-based methods such as Stochastic Gradient Descent (SGD) and Adam, which, despite their effectiveness, suffer from issues such as vanishing gradients, local minima stagnation, and sensitivity to initialization [34, 43]. Consequently, there is a growing demand for automated methodologies capable of discovering optimal DNN configurations with minimal human intervention.

Neural Architecture Search (NAS) has emerged as a powerful paradigm for automating the design of deep networks, leveraging search strategies that balance exploration and exploitation. Among these, evolutionary algorithms (EAs) and swarm intelligence (SI) techniques have gained prominence, offering robust solutions for navigating complex, high-dimensional search landscapes [57, 58]. Within this family of metaheuristics, the Biased Random Key Genetic Algorithm (BRKGA) presents a particularly promising approach, introducing a structured bias in genetic inheritance that accelerates convergence while preserving population diversity [25].

While NAS focuses on optimizing network topology and connectivity, Hyperparameter Optimization (HPO) aims to refine key training parameters, such as learning rates, batch sizes, and weight decay coefficients, which significantly impact model convergence and generalization [7]. Similarly, Learning Rule Optimization (LRO) seeks to adapt the learning dynamics themselves, exploring alternative update mechanisms beyond conventional backpropagation [6]. HPO and LRO can be effectively tackled using heuristic-driven approaches, particularly when combined with NAS in an Automated Machine Learning (AutoML) framework.

This chapter provides a comprehensive review of heuristics in NAS, HPO, and LRO, with a particular emphasis on BRKGA as a novel and underexplored technique for optimizing deep learning architectures and hyperparameters. We investigate its application in three neural network paradigms: Deep Feedforward Neural Networks (DFNNs), Convolutional Neural Networks (CNNs), and Graph Neural Networks (GNNs). Unlike traditional NAS techniques, which often require expensive computational resources and large-scale datasets, our study focuses on moderate-sized benchmarks, aiming to illustrate the practical benefits and adaptability of BRKGA for neural network optimization rather than maximizing competitive performance. The experimental results indicate that BRKGA can efficiently discover well-performing architectures while maintaining a favorable balance between accuracy and computational cost.

Beyond the state-of-the-art review, this work contributes to the field by demonstrating how BRKGA can be tailored to different neural network paradigms, highlighting its ability to adapt to various architectural and hyperparameter constraints. Furthermore, the potential of BRKGA in advancing AutoML frameworks, enhancing model interpretability, and paving the way for neuromorphic computing applications is examined. The insights presented in this chapter aim to foster new directions in heuristic-driven NAS, HPO, and LRO, encouraging further research into scalability and integration with hybrid optimization frameworks.

The remainder of this chapter is structured as follows. First, we provide a comprehensive review of heuristic approaches in NAS, HPO, and LRO, analyzing

state-of-the-art methods and their advantages and inherent limitations. Next, we introduce the BRKGA framework, detailing its adaptation for optimizing DFNNs, CNNs, and GNNs. We then describe the experimental setup and results, demonstrating the effectiveness of BRKGA in NAS, HPO, and LRO through moderate-sized benchmark datasets, highlighting its ability to balance exploration and exploitation in architecture optimization. Subsequently, we conduct a critical analysis of the results, comparing BRKGA with existing NAS techniques and discussing its practical implications in deep learning model design. Finally, we present conclusions and outline future research directions, emphasizing the potential of BRKGA in AutoML, scalable NAS frameworks, and energy-efficient deep learning architectures, with particular attention to its applicability in resource-constrained environments and neuromorphic computing.

State of the Art

This section presents the main works in the modern literature that address the optimization of Deep Neural Network (DNN) architectures and the search for optimal DNN structures through the application of optimization models. It provides an overview of existing approaches, highlighting key methodologies, advancements, and challenges in the field. Tables 1 and 2 present the main works discussed in the state of the art and their respective references.

The field of heuristic-driven Neural Network (NN) design has witnessed significant advancements over the past decades, with numerous studies exploring evolutionary algorithms, metaheuristic optimization, and automated search techniques. This section provides a critical analysis of the 15 selected articles, identifying their contributions, limitations, interrelations, and potential impact on the future of Neural Architecture Search (NAS).

The surveyed papers can be broadly categorized into three interrelated research themes: (1) metaheuristic and evolutionary approaches to NN optimization [50, 55, 69, 71], (2) NAS methodologies, particularly those integrating evolutionary strategies [4, 33, 48, 59, 68, 82], and (3) hybrid and automated learning frameworks within AutoML [1, 13, 21, 45, 46].

Despite their distinct focus areas, these works exhibit substantial overlap. Studies on NAS consistently highlight the necessity of robust heuristic strategies to mitigate computational inefficiencies, demonstrating how evolutionary-based NAS [48, 59, 82] outperforms conventional search methods in terms of adaptability and exploration capability. Furthermore, works on hybridization strategies [1, 45] emphasize the synergistic effects of combining evolutionary search with gradient-based techniques, reinforcing the argument for automated, scalable NAS.

Several studies have contributed significant innovations to heuristic-based NN design. Early foundational work, such as [71], pioneered heuristic-driven optimization principles, laying the groundwork for more advanced NAS frameworks. Subsequent research introduced domain-specific improvements: for instance, [55]

Table 1 Summary of key papers in this research (Part 1)

#	Title	Summary
1	Heuristic Principles for the Design of Artificial Neural Networks [71]	This foundational work introduces a heuristic-driven framework for designing artificial neural networks (ANNs), emphasizing the role of expert knowledge in optimizing architecture selection, hyperparameter tuning, and training strategies. The study presents a structured approach to balancing model complexity and generalization, aiming to mitigate overfitting while ensuring computational efficiency
2	Metaheuristic Design of Feedforward Neural Networks: A Review of Two Decades of Research [55]	This survey critically evaluates two decades of research on metaheuristic approaches for optimizing feedforward neural networks (FNNs), contrasting them with traditional gradient-based methods. The review systematically categorizes algorithms based on their convergence properties, search efficiency, and adaptability to complex, high-dimensional optimization landscapes
3	Optimization of Deep Neural Networks: A Survey and Unified Taxonomy [68]	This paper presents a comprehensive taxonomy for deep neural network (DNN) optimization, unifying various approaches under a structured framework. The study explores architecture search, hyperparameter tuning, and weight optimization, with a focus on AutoML techniques and the integration of parallel computing strategies to enhance scalability
4	A Survey of Swarm and Evolutionary Computing Approaches for Deep Learning [13]	This survey investigates the synergy between swarm intelligence, evolutionary computing, and deep learning, detailing how bio-inspired algorithms enhance neural architecture search, hyperparameter selection, and training convergence. The review highlights the computational advantages of hybrid strategies and their applicability to large-scale learning problems
5	A Technical View on Neural Architecture Search [33]	This technical survey provides an in-depth classification of Neural Architecture Search (NAS) methodologies, analyzing reinforcement learning-based NAS, gradient-based approaches, and evolutionary strategies. The paper discusses search space constraints, efficiency-enhancing techniques, and emerging trends in automated neural network design
6	On the Automated, Evolutionary Design of Neural Networks: Past, Present, and Future [4]	This article reviews the historical evolution of neuroevolutionary techniques for designing artificial neural networks, emphasizing their role in optimizing topology, weight initialization, and learning dynamics. The study discusses the computational trade-offs of evolutionary approaches and explores hybrid models that combine neuroevolution with gradient-based learning
7	Neuroevolution in Deep Neural Networks: Current Trends and Future Challenges [21]	This paper examines state-of-the-art neuroevolutionary techniques for deep learning, analyzing their impact on reinforcement learning, recurrent neural networks, and adversarial robustness. The study identifies key challenges in high-dimensional search spaces and discusses the role of evolutionary algorithms in improving scalability and generalization
8	A Comprehensive Survey of Neural Architecture Search: Challenges and Solutions [59]	This survey presents a rigorous analysis of NAS methodologies, emphasizing challenges such as computational cost, search inefficiency, and performance evaluation. The study explores modular search spaces, differentiable architecture search (DARTS), and multi-objective optimization strategies for balancing accuracy, efficiency, and interpretability

Table 2 Summary of key papers in this research (Part 2)

#	Title	Summary
9	A Survey on Evolutionary Construction of Deep Neural Networks [82]	This study systematically reviews evolutionary strategies for deep neural network construction, framing NAS as a large-scale, multi-objective optimization problem. The paper classifies approaches based on direct and indirect encoding schemes, highlighting their applications in hardware-aware NAS, automated hyperparameter tuning, and model compression
10	Evolutionary Neural Networks for Deep Learning: A Review [50]	This review explores Evolutionary Neural Networks (ENNs), emphasizing their role in architecture search, adaptive learning rules, and metaheuristic-driven optimization. The study contrasts ENNs with conventional NAS techniques and discusses their applicability in edge computing and neuromorphic AI
11	A Comprehensive Survey on Optimizing Deep Learning Models by Metaheuristics [1]	This paper reviews metaheuristic-driven optimization techniques for deep learning, classifying strategies based on their exploration-exploitation trade-offs. The study discusses applications in NAS, hyperparameter tuning, and training acceleration, with a focus on hybrid models that integrate evolutionary search with reinforcement learning
12	Evolutionary Design of Neural Network Architectures: A Review of Three Decades of Research [69]	This historical review examines three decades of research in evolutionary neural network design, detailing key advancements in modular learning, hierarchical search, and coevolutionary strategies. The study highlights emerging trends in hardware-efficient deep learning and automated architecture refinement
13	Survey on Evolutionary Deep Learning: Principles, Algorithms, Applications, and Open Issues [46]	This survey explores the intersection of evolutionary algorithms and deep learning, categorizing optimization methodologies based on their adaptability to nonstationary environments. The study discusses coevolutionary techniques, self-adaptive NAS frameworks, and real-world applications in federated learning and autonomous systems
14	A Survey: Evolutionary Deep Learning [45]	This paper investigates the role of evolutionary deep learning (EDL) in the context of AutoML, discussing hybrid optimization techniques that integrate evolutionary search with gradient-based learning. The study highlights key challenges in search efficiency and model interpretability
15	A Survey on Evolutionary Neural Architecture Search [48]	This article reviews Evolutionary Neural Architecture Search (ENAS), providing a comparative analysis of evolutionary, reinforcement learning-based, and gradient-based NAS strategies. The study discusses key challenges in search scalability, architecture transferability, and hardware-aware optimization

systematically compared two decades of metaheuristic NN optimization, providing a robust classification scheme for search algorithms.

The application of evolutionary techniques to NAS has demonstrated notable performance improvements, particularly in handling large search spaces. The incorporation of neuroevolution principles [4, 21] has provided an efficient alternative to reinforcement learning-based NAS methods, which often suffer from high computational costs. Additionally, research on multi-objective NAS [82] has addressed

critical trade-offs between accuracy, efficiency, and model interpretability, further advancing the state of the art.

Despite these advancements, heuristic-driven NN design faces several persistent challenges. A key limitation of evolutionary NAS techniques [48, 59] is their high computational overhead, which remains an obstacle for large-scale deployment in real-world applications. Although surrogate modeling and weight-sharing techniques have been proposed to mitigate this issue [37, 57], they have yet to be fully integrated into mainstream NAS frameworks.

Another significant limitation is the lack of interpretability and theoretical guarantees in heuristic approaches. While studies such as [46] highlight the potential of evolutionary deep learning in improving model robustness, they also underscore the opacity of evolved architectures, making their adoption challenging in critical applications requiring explainability.

One notable research gap lies in the integration of neuromorphic computing with heuristic NAS. Although some studies acknowledge the importance of hardware-aware NAS [11, 34], few explicitly explore the potential of neuromorphic-inspired evolutionary models. Bridging this gap could lead to the development of energy-efficient neural networks tailored for edge AI applications.

Additionally, while hybridization strategies have been extensively discussed [1, 45], there is a need for more systematic benchmarking of hybrid NAS methods. Future research should focus on designing standardized evaluation protocols that compare hybrid, evolutionary, and reinforcement learning-based NAS under uniform conditions.

Looking ahead, heuristic-driven NN design is poised to play a pivotal role in the future of automated machine learning (AutoML) and scalable NAS. The increasing complexity of deep learning models necessitates more efficient search algorithms, and evolutionary strategies are well-positioned to address these challenges. By incorporating adaptive search heuristics, self-supervised learning paradigms, and hardware-aware optimizations, the next generation of heuristic NAS techniques is expected to achieve greater efficiency, adaptability, and interpretability.

Ultimately, the intersection of evolutionary computing, neuromorphic hardware, and AutoML frameworks will define the next frontier of NAS research. As the field progresses, addressing the existing computational bottlenecks and enhancing the theoretical rigor of heuristic optimization methods will be critical in realizing fully automated, high-performance deep learning architectures. The following section provides a more detailed explanation of each of the key works analyzed on the topic of this chapter.

Heuristic Principles for the Design of Artificial Neural Networks

The paper "Heuristic Principles for the Design of Artificial Neural Networks" by Walczak and Cerpa [71] provides a structured framework for heuristic-driven optimization of Artificial Neural Networks (ANNs), emphasizing the integration of domain expertise and algorithmic heuristics to enhance model efficiency, gener-

alization, and interpretability. The authors categorize heuristic methodologies into three critical aspects: input feature selection, learning method selection, and hidden layer configuration, demonstrating that reducing dimensionality through Pearson correlation filtering, chi-square tests, and stepwise regression significantly improves model performance by mitigating noise and redundancy [9, 28]. Additionally, the study highlights that alternative learning paradigms, such as Radial Basis Function (RBF) networks, counter propagation, and Adaptive Resonance Theory (ART), outperform gradient-based methods in noisy and small-sample datasets, reinforcing evidence from deep learning optimization research [32, 43]. The paper further introduces a decision factor (DF) heuristic, correlating the number of hidden neurons with independent decision factors in a given problem, a principle validated in foreign exchange rate forecasting and financial modeling, aligning with Occam's Razor in neural model selection [30, 42]. The study concludes by advocating for automated heuristic-driven Neural Architecture Search (NAS) that integrates evolutionary computation, metaheuristics, and reinforcement learning, fostering a paradigm shift toward interpretable and adaptive ANN design for critical applications in finance, healthcare, and risk assessment.

Metaheuristic Design of Feedforward Neural Networks: A Review of Two Decades of Research

The paper "Metaheuristic Design of Feedforward Neural Networks: A Review of Two Decades of Research" by Ojha et al. [55] presents a structured analysis of metaheuristic-driven optimization techniques for Feedforward Neural Networks (FNNs), addressing the limitations of traditional gradient-based learning in high-dimensional, non-convex search spaces. The study classifies metaheuristic optimization into three key domains: Neural Architecture Search (NAS), weight optimization, and adaptive learning rule selection, systematically comparing single-solution heuristics, such as Simulated Annealing (SA) and Tabu Search (TS), with population-based strategies, including Genetic Algorithms (GAs), Particle Swarm Optimization (PSO), Differential Evolution (DE), and Artificial Bee Colony (ABC). A significant contribution is the differentiation between direct encoding (explicitly defining network structures) and indirect encoding (evolving architectures generatively), where the latter has demonstrated superior scalability and adaptability [58, 65]. Furthermore, the paper explores the role of metaheuristics in hardware-aware NAS, optimizing models under latency, energy efficiency, and memory constraints [16], and highlights heuristic-driven pruning, quantization, and knowledge distillation as effective techniques for enhancing computational efficiency while maintaining accuracy [30]. The study also examines surrogate-assisted optimization and parallel evolutionary searches, mitigating the computational burden of large-scale neural architecture evolution. Despite these advancements, high computational costs, lack of interpretability in evolved architectures, and challenges in convergence stability remain open research questions, with potential solutions in self-adaptive

metaheuristics, neuroevolution-augmented reinforcement learning, and biologically inspired network growth models [34]. The study concludes that metaheuristic-based FNN optimization is positioned as a cornerstone of next-generation deep learning, particularly in applications requiring reinforcement learning, autonomous decision-making, and dynamic model adaptation.

Optimization of Deep Neural Networks: A Survey and Unified Taxonomy

The paper "Optimization of Deep Neural Networks: A Survey and Unified Taxonomy" by Talbi [68] provides a structured and comprehensive review of optimization methodologies for Deep Neural Networks (DNNs), addressing fundamental challenges in NAS, hyperparameter optimization (HPO), and joint NAS-HPO frameworks. Traditional gradient-based techniques, such as stochastic gradient descent (SGD), often struggle in high-dimensional, multimodal, and computationally expensive search spaces, necessitating the integration of metaheuristic and population-based algorithms to enhance search capabilities. The study introduces a unified taxonomy of optimization techniques, categorizing them based on search representation, objective functions, constraints, initialization strategies, and variation operators. It offers a systematic perspective on how different strategies interact [16]. A key focus is on metaheuristic approaches, including GA, DE, PSO, SA, and Reinforcement Learning (RL), which have demonstrated efficiency in evolving neural architectures, balancing exploration-exploitation trade-offs, and enabling multi-objective optimization [58]. The study also highlights the growing role of Bayesian optimization and Monte Carlo Tree Search (MCTS) in refining HPO within AutoML pipelines, significantly reducing computational overhead [20]. Additionally, model compression techniques, such as pruning, quantization, and knowledge distillation, are analyzed as crucial mechanisms for deploying DNNs in resource-constrained environments [30], while hardware-aware NAS leverages constraint-handling strategies for optimizing performance on neuromorphic and edge computing architectures [34]. The study also explores parallel optimization frameworks and surrogate-based modeling, which accelerate large-scale NAS by employing low-fidelity approximations and distributed computing techniques. Despite the advancements in metaheuristic-driven NAS, open challenges persist, including high computational costs, lack of interpretability in evolved architectures, and stability issues in convergence. The author suggests future research should focus on hybrid NAS mechanisms combining evolutionary and gradient-based methods, coevolutionary learning, and biologically inspired models for adaptive deep learning optimization [65]. This taxonomy-based review serves as a key reference for researchers seeking to develop scalable, high-performance, and energy-efficient deep learning models, reinforcing the critical role of heuristic-based optimization in AutoML, reinforcement learning, and dynamic AI frameworks.

Swarm and Evolutionary Computing Approaches for Deep Learning

The paper "A Survey of Swarm and Evolutionary Computing Approaches for Deep Learning" by Darwish et al. [13] provides a comprehensive review of Swarm Intelligence (SI) and Evolutionary Computing (EC) techniques for optimizing DNNs, addressing key challenges in NAS, hyperparameter selection, and model compression. Traditional gradient-based approaches often struggle with local minima, sensitivity to initialization, and high computational cost in large-scale models [53], necessitating the adoption of bio-inspired metaheuristic algorithms such as PSO, GA, DE, ACO, and Cuckoo Search (CS) to enhance search efficiency and model generalization [66]. The study categorizes EC-driven deep learning optimization into three major areas: NAS, hyperparameter tuning, and model compression, highlighting that evolutionary-based NAS leverages mutation, crossover, and selection operators to efficiently explore diverse architectures with multi-objective optimization frameworks balancing accuracy, computational efficiency, and energy consumption [58]. Additionally, swarm-based hyperparameter optimization dynamically tunes learning rates, dropout rates, and weight initializations, enhancing convergence stability and training efficiency [79]. In contrast, EC-based model compression techniques, including pruning, quantization, and knowledge distillation, have effectively reduced model complexity for resource-constrained environments [31]. The survey also explores hybrid NAS strategies integrating reinforcement learning (RL) and differentiable search techniques, demonstrating improved efficiency and convergence properties [16]. Despite significant advances, challenges remain, notably the computational cost of evolutionary searches, the lack of interpretability in EC-based models, and the need for hybrid heuristics that integrate gradient-based learning with evolutionary strategies. The study concludes by discussing the future of neuromorphic computing, federated evolutionary models, and AutoML-driven deep learning architectures, underscoring their potential to drive scalable, autonomous AI systems.

A Technical View on Neural Architecture Search

The paper "A Technical View on Neural Architecture Search" by Hu and Yu [33] provides a structured and in-depth analysis of NAS, a pivotal component of AutoML aimed at optimizing Deep Neural Networks (DNNs) by eliminating manual design overhead. The study categorizes NAS into three primary paradigms—reinforcement learning (RL)-based NAS, gradient-based NAS, and evolutionary algorithm (EA)-based NAS—each addressing distinct optimization challenges. RL-based NAS formulates architecture search as a Markov Decision Process (MDP), where an agent refines network topologies using policy gradient or Q-learning strategies; however, early implementations suffered from high computational

costs, necessitating optimizations like parameter sharing [57], reward shaping, and meta-learning techniques [16]. Gradient-based NAS, exemplified by Differentiable Architecture Search (DARTS) [47], reinterprets NAS as a continuous optimization problem, significantly improving efficiency. However, challenges such as architectural collapse and optimization instability persist [78]. EA-based NAS leverages mutation, crossover, and selection mechanisms to evolve architectures, ensuring broader search space exploration and enabling multi-objective optimization [58], albeit at a high computational cost, prompting recent advancements in surrogate-assisted optimization [37] and hardware-aware NAS [11]. The study further explores search space structuring, advocating for modular and cell-based NAS [84], and discusses low-fidelity evaluation techniques, including early stopping, knowledge distillation, and multi-objective trade-offs, to balance accuracy, efficiency, and resource constraints. The authors emphasize the potential of neuromorphic computing, self-adaptive NAS, and NAS for nonstandard deep learning models, highlighting its growing role in AutoML, scalable AI, and hardware-efficient deep learning.

On the Automated, Evolutionary Design of Neural Networks: Past, Present, and Future

The paper "On the Automated, Evolutionary Design of Neural Networks: Past, Present, and Future" by Baldominos et al. [4] provides a comprehensive review of Neuroevolution, an approach that integrates EAs for optimizing ANNs, extending from early shallow architectures to DNNs. The study classifies neuroevolutionary techniques into topology evolution, refining layer depth, neuron connectivity, and activation functions; weight evolution, enhancing parameter optimization when traditional gradient-based methods struggle; and hybrid Neuroevolution, where evolutionary techniques complement backpropagation, as exemplified in Neuroevolution of Augmenting Topologies (NEATs) [65] and Evolution Strategies (ESs). The paper highlights evolutionary-based NAS, leveraging GA, PSO, DE, and Bayesian Optimization to discover optimal architectures while balancing accuracy, computational efficiency, and model complexity [16, 58]. Additionally, the authors discuss hardware-aware Neuroevolution, where optimization is constrained by latency, energy efficiency, and memory footprint, essential for edge computing and real-time AI applications [30]. While Neuroevolution has demonstrated remarkable progress, key challenges remain, including high computational cost, mitigated through parallelized search strategies and surrogate-assisted optimization, scalability in evolving deep architectures, and interpretability, as evolved models often lack transparency. The study concludes by emphasizing future research directions in self-adaptive evolutionary mechanisms, reinforcement learning-assisted NAS, and neuromorphic computing-inspired models, reinforcing Neuroevolution as a pivotal tool in the future of AutoML and next-generation AI systems [34].

Neuroevolution in Deep Neural Networks: Current Trends and Future Challenges

The paper "Neuroevolution in Deep Neural Networks: Current Trends and Future Challenges" by Galván and Mooney [21] provides an in-depth review of Neuroevolution, where EAs optimize DNNs, particularly in NAS and training optimization. Unlike gradient-based approaches such as stochastic gradient descent (SGD), Neuroevolution explores high-dimensional, multimodal search spaces using GA, DE, Evolution Strategies (ESs), and Neuroevolution of Augmenting Topologies (NEATs), facilitating architecture discovery and hyperparameter tuning [58, 65]. The study emphasizes computational efficiency advancements through hardware-aware NAS, surrogate-assisted optimization, parallel evolutionary strategies, and multi-objective optimization frameworks that balance accuracy, computational cost, and energy consumption, crucial for low-power AI applications [16]. Additionally, the paper explores hybrid neuroevolutionary models, integrating evolutionary search with gradient-based optimization, improving convergence and generalization [34]. Applications include image classification, adversarial robustness, federated learning, and meta-learning, where evolutionary techniques enhance hyperparameter tuning, knowledge distillation, and weight quantization, driving scalability and adaptability [30]. Despite its potential, Neuroevolution faces computational cost and scalability challenges, motivating research into asynchronous parallel search, efficient mutation strategies, and self-adaptive evolutionary mechanisms. The study concludes that Neuroevolution will be instrumental in AutoML and self-learning AI, advancing the field toward autonomous, scalable, and efficient deep learning models [4].

A Comprehensive Survey of Neural Architecture Search: Challenges and Solutions

The paper "A Comprehensive Survey of Neural Architecture Search: Challenges and Solutions" by Ren et al. [59] provides an extensive review of NAS, a core component of AutoML that automates the design of DNNs by optimizing architectures under computational and performance constraints. The study classifies NAS methodologies into search space design, search strategy optimization, and evaluation techniques, analyzing their evolution and identifying persistent challenges such as high computational cost, inefficient search strategies, and the trade-off between model complexity and inference speed. The authors highlight advancements in modular and cell-based search spaces, which improve search efficiency while preserving expressiveness [16], and discuss the impact of continuous search strategies, particularly Differentiable Architecture Search (DARTS), which enables gradient-based optimization in NAS [47]. Additionally, recycling neural architecture, which leverages previously optimized networks to reduce redundant computations, is a promising approach [58].

The paper also explores computational efficiency improvements, particularly in efficient evaluation techniques such as early stopping, weight sharing (e.g., ENAS and one-shot NAS), and surrogate modeling, which significantly reduce training overhead while maintaining ranking fidelity [37,57]. Furthermore, the study emphasizes the growing relevance of multi-objective NAS (MOO-NAS), which optimizes architectures while balancing accuracy, computational cost, and energy efficiency, making it particularly relevant for edge AI and real-time applications [11]. The comparative analysis of reinforcement learning-based NAS, evolutionary NAS, gradient-based NAS, and surrogate-assisted NAS further clarifies their respective advantages and trade-offs, emphasizing the necessity of hardware-aware NAS, where architectures are codesigned with latency, memory footprint, and energy constraints in mind [34].

Given the rapid evolution of NAS, the authors advocate for meta-learning, self-adaptive evolutionary strategies, and hybrid NAS frameworks that integrate gradient-based, reinforcement learning, and evolutionary optimization to achieve scalable and hardware-efficient deep learning models. The study concludes that NAS will be pivotal in the next generation of self-optimizing AI systems, bridging the gap between theoretical advancements and real-world deployment.

A Survey on Evolutionary Construction of Deep Neural Networks

The paper "A Survey on Evolutionary Construction of Deep Neural Networks" by Zhou et al. [82] provides an in-depth analysis of EAs as a heuristic-driven approach to NAS, offering a robust alternative to gradient-based optimization, which often struggles with local optima entrapment, sensitivity to initialization, and poor generalization in complex search spaces. The study systematically categorizes evolutionary deep learning techniques into direct vs. indirect encoding, global vs. modular search, and single-objective vs. multi-objective optimization frameworks, emphasizing the significance of coevolutionary algorithms for simultaneous optimization of network topology and hyperparameters [16, 58]. Moreover, multi-objective evolutionary approaches (MOO-EAs), such as Pareto-based evolutionary search, address key accuracy, computational complexity, and energy efficiency trade-offs, making them particularly relevant for real-world deployment [34].

The paper further explores hardware-aware NAS, where evolutionary search is constrained by latency, memory footprint, and energy consumption, a crucial factor in edge AI applications [11]. Additionally, it examines pruning, quantization, and knowledge distillation techniques, where evolutionary algorithms facilitate model compression without substantial accuracy loss. To mitigate the computational overhead of evolutionary NAS, the study highlights advancements in parallel evolutionary search, surrogate-assisted modeling, and low-fidelity performance estimations, accelerating convergence while preserving exploration capabilities [37,57].

Despite its advantages, the paper acknowledges persistent challenges, such as high computational cost, scalability limitations, and lack of interpretability in

evolved architectures, advocating for emerging solutions like asynchronous parallel search, surrogate-assisted optimization, and self-adaptive evolutionary strategies. Future research directions emphasize interpretable neuroevolution, which enhances model transparency, and neuromorphic-inspired evolutionary computing, aligning neuroevolution with biologically plausible learning models. As Evolutionary Algorithms continue to integrate with AutoML, they are expected to drive the next generation of scalable, efficient, and adaptive deep learning models, fostering autonomous learning with minimal human intervention and optimized resource allocation.

Evolutionary Neural Networks for Deep Learning: A Review

The paper "Evolutionary Neural Networks for Deep Learning: A Review" by Ma and Xie [50] presents an in-depth analysis of Evolutionary Neural Networks (ENNs), which integrate EAs with DNNs to optimize architectures, hyperparameters, and training strategies, mitigating the inherent limitations of gradient-based optimization, such as vanishing gradients, local minima stagnation, and sensitivity to initialization [34, 43]. The study systematically categorizes ENNs into three optimization paradigms: weight evolution, replacing stochastic gradient descent (SGD) with GA, DE, and covariance matrix adaptation evolution strategy (CMA-ES) [65]; neural architecture evolution, leveraging Neuroevolution of Augmenting Topologies (NEAT), hierarchical genetic search, and reinforcement learning-assisted NAS [57, 58]; and learning rule evolution, applying metaheuristic-driven optimization strategies for adaptive training.

A pivotal contribution of this survey is its exploration of encoding strategies, distinguishing between direct encoding, which explicitly defines architectural parameters, and indirect encoding, which employs generative encodings and developmental models for improved search efficiency. The authors further discuss multi-objective evolutionary strategies, optimizing trade-offs between accuracy, computational efficiency, and hardware constraints, making ENNs particularly suited for resource-aware computing and edge AI applications [37, 82]. Additionally, advancements in hardware-aware NAS are reviewed, where architectures are evolved under latency, memory, and energy constraints, facilitating efficient deployment in IoT and low-power AI environments [11, 58].

The paper also examines practical applications of ENNs, including image classification, reinforcement learning, adversarial robustness, and model compression, highlighting pruning, quantization, and knowledge distillation as critical for scalability and computational efficiency [34, 42]. Despite these advancements, challenges such as scalability, interpretability, and computational overhead persist. The study explores emerging solutions, including parallelized evolutionary search, surrogate-assisted evaluation, and neuromorphic-inspired computing, which enhance the feasibility of ENNs in large-scale real-world applications [16, 50].

As Evolutionary Neural Networks continue to evolve, their integration with AutoML frameworks is poised to drive the next generation of self-optimizing

deep learning models, reducing human intervention while ensuring adaptability in dynamic environments.

A Comprehensive Survey on Optimizing Deep Learning Models by Metaheuristics

The paper "A Comprehensive Survey on Optimizing Deep Learning Models by Metaheuristics" by Akay et al. [1] provides a systematic and in-depth analysis of metaheuristic algorithms as optimization strategies for DNNs, addressing the limitations of gradient-based techniques such as SGD and Adam, which often suffer from vanishing gradients, local optima, and hyperparameter sensitivity [34, 43]. By leveraging EAs and swarm intelligence techniques, metaheuristic optimization enables a more exploratory search in high-dimensional, multimodal spaces, leading to improved generalization and computational efficiency [58, 65]. The study categorizes metaheuristic-driven DNN optimization into NAS, hyperparameter tuning, training acceleration, and feature selection, systematically evaluating single-solution-based approaches (e.g., Simulated Annealing (SA), Tabu Search (TS)) and population-based approaches (e.g., GA, PSO, Artificial ABC, and DE). A significant contribution of the survey is its discussion of multi-objective optimization (MOO) frameworks, particularly those employing Pareto-based selection strategies to balance accuracy, model complexity, and computational cost, making them highly relevant for resource-aware AI applications [37, 82].

The study further explores metaheuristic-based NAS, distinguishing between direct encoding, where architectural configurations are explicitly represented, and indirect encoding, which employs evolutionary generative models to optimize network topologies. The authors highlight the importance of hardware-aware NAS, where metaheuristic search is constrained by real-world deployment factors such as memory footprint, energy consumption, and latency, making it a crucial approach for edge computing and IoT applications [11, 58]. Additionally, the paper reviews metaheuristic-driven pruning, quantization, and knowledge distillation as effective strategies for model compression and inference acceleration, particularly in low-power AI systems.

A key challenge in metaheuristic-based DNN optimization is the high computational cost of evolutionary searches. The study discusses solutions such as parallelized metaheuristic frameworks, surrogate-assisted NAS, and hybrid evolutionary-gradient approaches, which integrate reinforcement learning, surrogate modeling, and distributed optimization to enhance efficiency [34, 57]. Moreover, coevolutionary search mechanisms are identified as promising strategies for dynamically adapting mutation strategies and search heuristics, ensuring more robust model convergence.

Despite their advantages, metaheuristic-driven optimization methods still face limitations, including scalability concerns, interpretability challenges, and computational overhead. The authors propose neuromorphic computing-inspired evolutionary approaches, bio-inspired optimization heuristics, and self-adaptive evolu-

tionary NAS as potential directions to enhance adaptability and search efficiency [42,50]. Ultimately, the study advocates for hybrid metaheuristic-based frameworks, combining gradient-based and heuristic search strategies to achieve state-of-the-art performance in Automated Machine Learning (AutoML) and scalable deep learning applications, enabling the next generation of self-optimizing AI models.

Evolutionary Design of Neural Network Architectures: A Review of Three Decades of Research

The paper "Evolutionary Design of Neural Network Architectures: A Review of Three Decades of Research" by Ünal and Başçiftçi [69] provides a comprehensive historical and technical analysis of EC in NAS, tracing advancements from early GA and ES to contemporary hybrid NAS frameworks and hardware-aware evolutionary methods. The study categorizes evolutionary neural network (ENN) design into three primary phases: early ANN optimization (1980s–1990s), hybrid EC-gradient NAS methodologies, and the modern deep learning era, emphasizing the increasing complexity of high-dimensional, multimodal search spaces, where traditional gradient-based optimization, such as SGD, struggles with vanishing gradients, local optima stagnation, and limited adaptability [43, 65]. The paper explores chromosome encoding strategies, distinguishing between direct encoding, where network topologies and weights are explicitly represented, and indirect encoding, leveraging graph-based, hierarchical, and modular representations to enhance scalability and search efficiency [57, 58].

A key contribution of this work is the integration of evolutionary NAS with gradient-based learning, particularly in the context of NEAT and hierarchical NAS frameworks, where multi-objective evolutionary approaches (MOO-EAs) optimize trade-offs between accuracy, computational efficiency, and energy consumption, using Pareto-based selection mechanisms [34, 82]. The study further highlights hardware-aware NAS, where evolutionary optimization is constrained by real-world deployment factors, such as latency, memory footprint, and energy efficiency, making it highly relevant for edge AI, federated learning, and neuromorphic computing [11, 37]. Additionally, surrogate-assisted NAS techniques, employing low-fidelity performance estimation, are examined to mitigate the high computational overhead of evolutionary search [57]. Despite significant advancements, the study identifies key challenges, including search cost, architecture transferability, and lack of interpretability. The authors discuss asynchronous parallel evolution, reinforcement learning-assisted NAS, and self-adaptive evolutionary mechanisms, which dynamically adjust mutation and crossover strategies to enhance search diversity and convergence speed [57, 58]. Furthermore, the potential of bio-inspired coevolutionary strategies, mimicking synaptic plasticity in biological neural systems, is explored as a foundation for lifelong learning and fully automated deep model adaptation. Looking forward, the authors argue that the fusion of evolutionary computation, neuromorphic computing, and AutoML frameworks is expected to

drive the next generation of intelligent, scalable, and hardware-efficient deep learning architectures, significantly reducing human intervention in NAS processes.

Survey on Evolutionary Deep Learning: Principles, Algorithms, Applications, and Open Issues

The paper "Survey on Evolutionary Deep Learning: Principles, Algorithms, Applications, and Open Issues" by Li et al. [46] presents a comprehensive review of Evolutionary Deep Learning (EDL), a paradigm that integrates EC techniques into DNNs to enhance adaptability, efficiency, and automation. The study systematically categorizes EDL into three core components: data preprocessing, model generation, and model deployment, providing a rigorous analysis of search paradigms (single-objective vs. multi-objective optimization), solution representations (linear, hierarchical, and graph-based encoding), and their impact on NAS [16, 57]. The authors highlight the advantages of heuristic-driven, population-based optimization methods, particularly GA, PSO, DE, and neuroevolutionary frameworks, which offer robust exploration capabilities in high-dimensional search spaces where gradient-based methods struggle with local optima and sensitivity to initialization [58, 65]. A pivotal contribution of this work is the detailed examination of multi-objective evolutionary NAS, where Pareto-based search mechanisms effectively balance trade-offs between model accuracy, computational efficiency, and energy constraints, making these approaches particularly relevant for resource-aware deep learning applications [34, 82]. Additionally, the study explores hybrid NAS frameworks, which integrate evolutionary algorithms with gradient-based optimization, accelerating convergence and improving generalization [37]. The authors further investigate evolutionary model compression techniques, including pruning, quantization, and knowledge distillation, essential for deploying DNNs in edge AI and low-power environments [11]. Despite the significant advancements in EDL, computational overhead remains a major limitation, prompting research into surrogate-assisted NAS, hardware-aware evolutionary optimization, and early stopping mechanisms to enhance search efficiency [57]. The paper concludes by emphasizing that EDL is poised to play a transformative role in the evolution of AutoML, driving the development of self-adaptive, scalable, and high-performance AI systems with minimal human intervention.

A Survey: Evolutionary Deep Learning

The paper "A Survey: Evolutionary Deep Learning" by Li and Liu [45] presents a comprehensive and structured review of Evolutionary Deep Learning (EDL), an emerging paradigm that integrates EC with Deep Learning (DL) to optimize neural architectures, hyperparameters, and training strategies. The authors emphasize that traditional deep learning relies on manual design and computationally expensive trial-and-error approaches. In contrast, EDL automates and enhances model con-

struction through heuristic-driven search strategies inspired by biological evolution, such as GA, PSO, DE, and ACO [16, 65]. The study classifies EDL into four primary optimization categories: Learning Rule Optimization (LRO), which adapts training strategies dynamically; Hyperparameter Optimization (HPO), automating the tuning of key parameters; NAS, optimizing the structural configuration of deep networks; and evolutionary approaches for model compression and transfer learning, which improve generalization while reducing computational overhead [34,58]. A key contribution of this survey is its historical review of EC in DL, tracing its evolution from early evolutionary artificial neural networks (EANNs) to modern multi-objective NAS and hardware-aware evolutionary learning [82]. The study critically examines direct encoding (explicit parameter representation) and indirect encoding (generative models and graph-based representations) in evolutionary NAS, alongside hybrid NAS approaches, where evolutionary search is combined with gradient-based optimization for improved efficiency and convergence [37, 57]. Furthermore, the authors explore Pareto-based NAS, which optimizes trade-offs between accuracy, inference latency, energy consumption, and model complexity, making EDL particularly relevant for real-time AI applications and edge computing [11]. Despite advancements, computational cost remains a challenge, prompting research into surrogate-assisted evolutionary search, distributed optimization, and early stopping mechanisms, which reduce evaluation overhead while preserving search quality [34, 57]. The study concludes by highlighting future directions, including self-adaptive neuroevolution, federated evolutionary learning, and neuromorphic computing-inspired EDL, reinforcing that EDL is poised to revolutionize AutoML and self-evolving AI systems.

A Survey on Evolutionary Neural Architecture Search

The paper "A Survey on Evolutionary Neural Architecture Search" by Liu et al. [48] provides a comprehensive and systematic review of Evolutionary Neural Architecture Search (ENAS), a subfield of NAS that leverages EC to automate and optimize DNN design. The authors highlight the computational challenges and human biases inherent in manually crafting DNN architectures, emphasizing that ENAS employs population-based heuristic search to efficiently explore the vast, high-dimensional, and multi-objective NAS space [16, 58]. The study categorizes ENAS into three core components: (1) search space design, where architectural representations range from layer-wise, cell-based, to graph-based encodings, (2) search strategies, encompassing GA, PSO, DE, and Estimation of Distribution Algorithms (EDAs), and (3) evaluation strategies, focusing on surrogate-assisted NAS, weight inheritance, and hardware-aware constraints to optimize architectures under computational limitations [37, 65]. A key contribution of the paper is its critical analysis of ENAS heuristics, particularly hierarchical evolution, multi-objective NAS (MOO-NAS), and energy-efficient architecture design, where Pareto-based methods balance trade-offs between accuracy, computational efficiency, and inference latency [82]. The study further explores parallel and distributed ENAS

frameworks, which exploit cloud computing and multi-GPU training to accelerate search and convergence [11, 57]. Moreover, pruning, quantization, and knowledge distillation via evolutionary strategies are discussed as crucial methodologies for optimizing models in edge AI and mobile computing [34]. Despite its advancements, ENAS still faces challenges in scalability, interpretability, and sample efficiency, prompting future research into self-adaptive ENAS, hybrid gradient-evolutionary NAS, and applications in neuromorphic computing and reinforcement learning [45]. The authors conclude by positioning ENAS as a transformative technology in AutoML, highlighting its role in driving the next generation of self-optimizing and high-performance deep learning models.

Biased Random Key Genetic Algorithm

The Biased Random Key Genetic Algorithm (BRKGA) is an advanced evolutionary metaheuristic derived from the Genetic Algorithm (GA) and represents an improved variation of the Random Key Genetic Algorithm (RKGA) [5]. Initially proposed by [24] and further developed by Ericsson et al. [17], the BRKGA has been widely explored for its effectiveness in solving complex optimization problems [49]. By introducing a bias in the inheritance mechanism, the BRKGA enhances the convergence speed and the quality of solutions compared to its predecessors.

In the BRKGA, each solution is encoded as a chromosome composed of random keys—real-valued numbers in the interval [0, 1]—providing a problem-independent representation. The algorithm commences with generating an initial population of size p, which is then decoded into problem-specific solutions using a dedicated decoder. These solutions are evaluated via a fitness function, and the algorithm proceeds only if a predefined stopping criterion (such as a maximum number of generations or a convergence threshold) has not been met.

The population is partitioned into three groups: an elite subset containing the p_e best-performing individuals, a non-elite subset comprising the remaining $p - p_e - p_m$ individuals, and a mutant subset of p_m individuals generated entirely randomly. This structure facilitates a clear separation between exploitation and exploration within the search space. Elite individuals are carried over to the next generation, ensuring that superior solutions persist, while mutants help maintain genetic diversity and prevent premature convergence.

A key feature of BRKGA is its biased crossover mechanism, which is employed to generate offspring. As shown in Fig. 1, which was adapted from the work of [26], the evolutionary process from generation k to $k + 1$ involves ranking the population by fitness and then producing new individuals through crossover between one elite and one non-elite parent. During the crossover each gene in the offspring's chromosome is determined by generating a random number; if this number is less than the inheritance probability parameter ρ_e (with $\rho_e > 0.5$), the gene is inherited from the elite parent, otherwise from the non-elite parent. This probabilistic scheme ensures that high-quality genetic material is preferentially transmitted while incorporating novel traits to foster diversity.

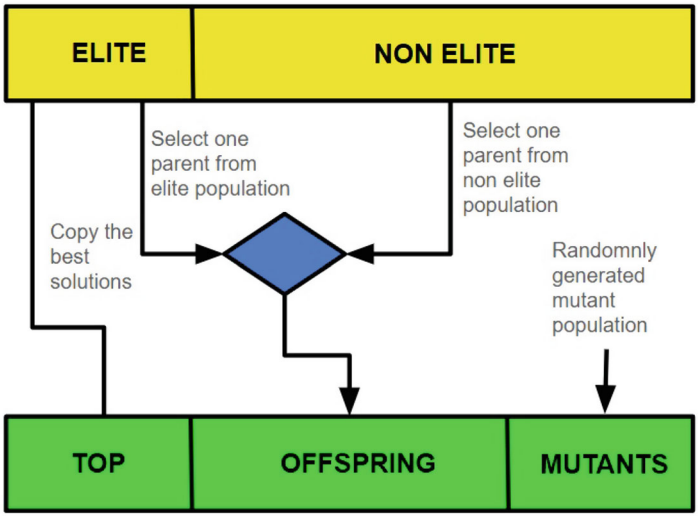

Fig. 1 Evolutionary process from generation k to $k + 1$ in the BRKGA (Source: based on the paper of [26])

The iterative process of selection, biased crossover, mutation, and decoding continues until the stopping criterion is satisfied. The primary advantage of BRKGA over traditional genetic algorithms lies in its systematic bias toward elite solutions, combined with a robust mechanism for introducing random variations. This balance between exploitation and exploration enables efficient navigation of complex search spaces, rendering BRKGA a versatile and powerful tool for combinatorial and continuous optimization problems. Furthermore, its parameterized structure allows for fine-tuning to accommodate specific application requirements, thereby enhancing its overall adaptability and performance.

The iterative process of selection, biased crossover, mutation, and decoding continues until the stopping criterion is satisfied. The primary advantage of BRKGA over traditional genetic algorithms lies in its systematic bias toward elite solutions, combined with a robust mechanism for introducing random variations. This balance between exploitation and exploration enables efficient navigation of complex search spaces, rendering BRKGA a versatile and powerful tool for combinatorial and continuous optimization problems. The algorithm has been successfully applied to a diverse range of optimization problems in the literature. Examples include combinatorial problems such as vehicle routing [52], network design [2], job scheduling [10], and facility location [64]. In addition, BRKGA has been leveraged in real-world applications, including telecommunication network optimization [60], bioinformatics [44, 51], and artificial neural network architecture optimization [18, 62]. These widespread applications underscore the versatility and effectiveness of BRKGA as a state-of-the-art optimization technique.

BRKGA is a sophisticated and widely adopted metaheuristic due to its efficient balance between exploration and exploitation, structured bias toward high-quality solutions, and flexibility in handling various problem domains. Its strong theoretical foundation and empirical success across numerous applications further establish its relevance in the field of optimization. Furthermore, its parameterized structure allows for fine-tuning to accommodate specific application requirements, enhancing its overall adaptability and performance.

BRKGA in Deep Learning Design

This section presents three approaches to applying the Biased Random Key Genetic Algorithm (BRKGA) to the neural architecture design and/or hyperparameter optimization of deep learning models. We will present the proposed methodology to optimize Deep Feedforward Neural Networks (DFNNs), an approach to optimize Convolutional Neural Network (CNN) architectures, and a proposal to optimize Graph Neural Network (GNN) models.

BRKGA-DFNN Proposal

The proposed approach utilizes the Biased Random Key Genetic Algorithm (BRKGA) to optimize Deep Feedforward Neural Network (DFNN) architectures. The optimization framework is governed by a set of key parameters, including population size (p), elite population proportion (p_e), mutant population proportion (p_m), elite inheritance probability (ρ_e), and the algorithm's stopping criterion. Additionally, domain-specific parameters include datasets for training (x_{train}), validation (x_{valid}), and testing (x_{test}). DFNN-related hyperparameters include the number of configurable parameters in hidden layers ($n_{\text{param_hidden}}$) and the maximum number of allowable hidden layers (MaxLayer).

The optimization process follows an evolutionary paradigm, iteratively refining candidate solutions to discover high-performing DFNN architectures. The BRKGA framework is adapted to optimize architectural structures while preserving a balance between exploration and exploitation. The BRKGA-DFNN approach incorporates a multilayer evolutionary strategy, where the algorithm concurrently optimizes architectures with a predefined number of hidden layers. This structured search strategy facilitates scalable and adaptive optimization.

The proposed framework encompasses four core procedures essential for effective search: (1) structured representation of DFNN architectures, (2) robust initialization of individuals and mutants, (3) a lightweight decoder for chromosome-to-architecture mapping, and (4) an efficient fitness evaluation process.

Representation of Feedforward Neural Networks

The representation strategy is crucial when designing optimization algorithms for DFNN architectures. We employ a direct encoding approach, where each indi-

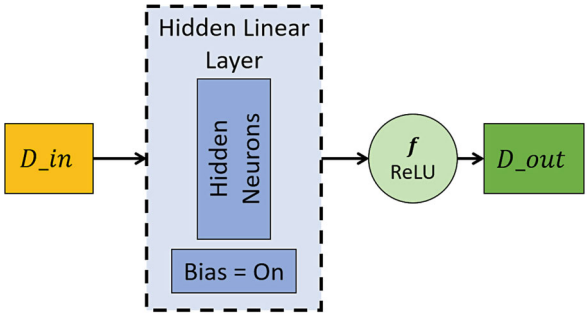

Fig. 2 Schematic representation of a Feedforward Neural Network, comprising an input layer, hidden layer, activation function, and an output layer

vidual's chromosome encodes key architectural properties necessary for defining a trainable DFNN model for classification tasks. Importantly, this study focuses on optimizing the structural composition of DFNNs, excluding weight parameter optimization.

To streamline DFNN optimization, we adopt a linear network structure, as depicted in Fig. 2. This framework includes critical parameters: input feature dimension D_{in} (number of neurons in the input layer), hidden feature dimension (hidden layer neuron count), the inclusion or exclusion of bias terms, and output feature dimension D_{out} (neurons in the output layer). The hidden layer integrates nonlinearity via a predefined activation function (f). Given that input and output dimensions are problem-dependent, they are not treated as hyperparameters. Consequently, BRKGA-DFNN optimizes three key aspects: (1) hidden layer neuron count, (2) bias presence in hidden layers, and (3) activation function type.

The BRKGA-DFNN algorithm (Fig. 3) takes as input the BRKGA parameters, the DFNN-related hyperparameters, and the dataset used for training and evaluation. Initially, the chromosome length for each individual is determined (line 1), corresponding to the number of architectural parameters to be optimized. The number of individuals generated through the crossover process is then calculated (line 2). In line 4, the initial population is randomly generated. Each individual undergoes a decoding step (line 5), where its genetic representation is mapped to a valid DFNN architecture. Following this, each candidate solution is evaluated based on model performance in the validation dataset (line 6). The evolutionary process continues until the predefined stopping criterion is met (line 7). At each iteration, individuals are ranked according to their fitness values, and the population is divided into elite and non-elite groups (lines 8–10). To maintain genetic diversity, a subset of mutants is introduced into the population (line 11). The offspring population is generated through crossover (line 12), where elite individuals contribute with higher probability, preserving beneficial traits while ensuring exploration. The newly generated individuals, along with the mutants and elites, form the next generation of the population (line 13). These individuals undergo decoding (line 14) and fitness reevaluation (line 15) before being reintegrated into the population for the subsequent iteration. To ensure robustness, elite individuals from the previous generation are directly retained (line 16), preventing performance degradation due

to excessive exploration. Throughout the process, the algorithm tracks the best-performing individual found (line 17), continuously updating it as the search progresses. Upon reaching the termination condition, the best solution found undergoes final validation using the test dataset (line 19). This step provides an unbiased estimate of generalization performance, ensuring that the optimized DFNN architecture is evaluated under realistic conditions. The algorithm ultimately returns the best-performing architecture, ready for deployment in classification tasks.

Initialization of Individuals

The initial population and mutant individuals in the BRKGA framework are represented as chromosomes composed of randomly generated keys. The chromosome length is determined by the number of hyperparameters to be optimized. Each gene in the chromosome corresponds to a specific layer or hyperparameter and is represented as L_k and H_p^k, where L_k denotes the position of the gene related to the k-th hidden layer ($k \in 1, \ldots, MaxLayer$). The parameter $MaxLayer$ defines the maximum number of hidden layers allowed in the architecture. H_p^k refers to the gene position associated with the p-th hyperparameter ($p = 1, \ldots, n_param_hidden$, where n_param_hidden is the number of hyperparameters per hidden layer) in the k-th hidden layer. Consequently, the total chromosome length (N) includes all genes encoding the hidden layers and their corresponding hyperparameters, as defined in Eq. (1).

$$N = MaxLayer \times (n_param_hidden + 1) \tag{1}$$

In this representation, we define three hyperparameters for each hidden layer ($n_param_hidden = 3$): H_1^k, H_2^k, and H_3^k. The first hyperparameter (H_1^k) determines the number of neurons in the k-th hidden layer. The second (H_2^k) represents whether bias is applied to the k-th hidden layer. Lastly, H_3^k specifies the activation function assigned to the k-th hidden layer. Figure 4 illustrates the chromosome representation for a BRKGA-DFNN individual with $MaxLayer = 3$.

Decoder

The $Decoder()$ function is responsible for translating the encoded random key chromosome of an individual into a feasible DFNN configuration. This function plays a crucial role in interpreting the encoded genetic information and mapping it to a structured neural architecture. The first $MaxLayer$ genes in the chromosome

Layers			L_1			L_2			L_3		
L_1	L_2	L_3	H_1^1	H_2^1	H_3^1	H_1^2	H_2^2	H_3^2	H_1^3	H_2^3	H_3^3
0.5323	0.1524	0.7419	0.2685	0.8416	0.5361	0.9886	0.0174	0.2542	0.8412	0.0987	0.3683

Fig. 4 Representation of an individual's chromosome for the BRKGA-DFNN approach with $MaxLayer = 3$

determine the activation status of each hidden layer. As defined in Eq. (2), a hidden layer is considered active if its corresponding gene value exceeds 0.5; otherwise, it remains inactive.

$$layers = \begin{cases} 0, & if\ L_k \leq 0.5 \\ 1, & otherwise \end{cases}, \ \forall\, k \in [1, MaxLayer] \tag{2}$$

The number of neurons in each hidden layer (H_1^k) is determined by a transformation that ensures the neuron count remains within a valid range, bounded by the input dimensionality (D_{in}) and the number of output classes (D_{out}). This is defined in Eq. (3). Similarly, the bias status (H_2^k) of each hidden layer is determined using a binary thresholding operation, as outlined in Eq. (4).

Additionally, each hidden layer is assigned an activation function (H_3^k), selected from a predefined set of 17 well-established activation functions, including *Sigmoid*, *Hardshrink*, *Hardtanh*, *LeakyReLU*, *LogSigmoid*, *Tanhshrink*, *PReLU*, *ReLU*, *RReLU*, *ReLU6*, *SELU*, *CELU*, *ELU*, *Softplus*, *Softshrink*, *Softsign*, and *Tanh*. The selection process involves scaling the third gene value by 16 and rounding it to the nearest integer, as specified in Eq. (5).

$$n_neurons = round(H_1^k \times (D_{in} - D_{out}) + D_{out}) \tag{3}$$

$$Bias = \begin{cases} \text{off}, & if\ H_2^k \leq 0.5 \\ \text{on}, & otherwise \end{cases} \tag{4}$$

$$Activation_function = round(H_3^k \times 16) \tag{5}$$

Figure 5 illustrates the decoding process for the chromosome representation depicted in Fig. 4. The Decoder processes only the hyperparameters associated with active layers 1 and 3 (highlighted in blue and green, respectively), while inactive layer 2 (highlighted in pink) is disregarded. Consequently, the final DFNN configuration consists exclusively of active layers, as shown in Fig. 5.

Fitness Evaluation

The $Fitness()$ function evaluates the performance of each individual in the population by assessing the quality of the decoded DFNN model. Each individual undergoes training for 100 epochs using the cross-entropy loss function, the Adam optimizer for parameter updates, and a mini-batch size of 124. After training, individuals are assessed on the validation dataset to guide the evolutionary search. However, only the best-performing individual from the final generation ($best_ind$) is further evaluated on the test dataset to measure its generalization capability.

In our experimental setup, datasets were partitioned into a 70% training subset and a 30% testing subset, with 10% of the test data allocated for validation. For each instance in the dataset, the $Fitness()$ function computes the classification error by comparing the model's predicted output ($\hat{y}_t$) with the actual target label (y_t). The

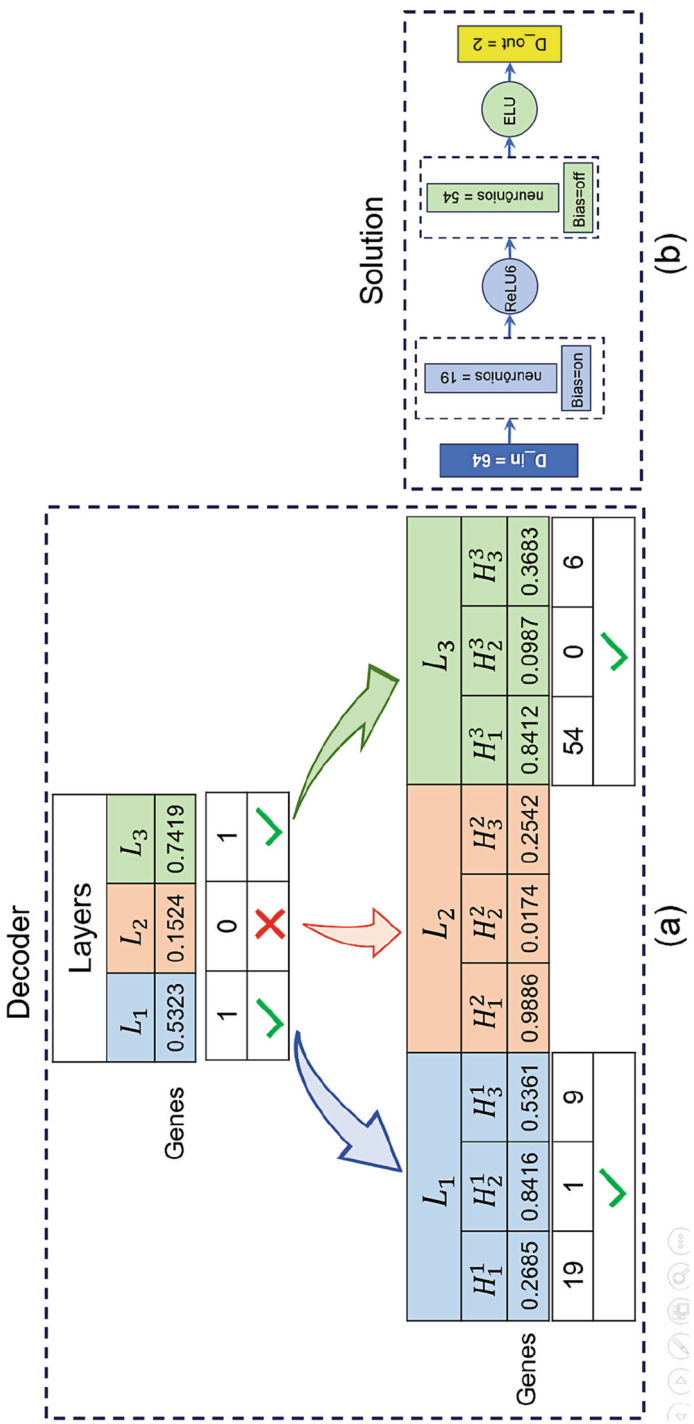

Fig. 5 Illustration of the transformation of an individual's chromosome into a DFNN solution using the BRKGA-DFNN Decoder

overall fitness of an individual is determined by the classification error across the dataset T, as defined in Eq. (6).

$$fitness = \frac{100}{len(T)} \sum_{t=1}^{len(T)} e(t), \quad e(t) = \begin{cases} 0, & if\ \hat{y}_t = y_t \\ 1, & if\ \hat{y}_t \neq y_t \end{cases}, \ \forall\, t \in T \tag{6}$$

BRKGA-CNN Proposal

This section presents the methodology for optimizing Convolutional Neural Network (CNN) architectures using the Biased Random Key Genetic Algorithm (BRKGA), referred to as BRKGA-CNN. The approach incorporates BRKGA parameters, problem-specific settings (tailored for image classification), and hyperparameters defining the CNN architecture. BRKGA-CNN iteratively identifies the best solution by selecting the best-performing individual within the population until a predefined termination criterion is met, adhering to the standard BRKGA framework.

The BRKGA-CNN framework comprises five core procedures that adapt BRKGA for efficient CNN hyperparameter optimization. These include a compact representation of CNN architectures, an encoding scheme for individuals and mutant generation, a robust decoding mechanism for solution interpretation, and an evaluation function for assessing individual performance.

Representation of Convolutional Neural Networks

The proposed methodology is explicitly designed for CNN architectures, focusing on discovering optimal configurations by optimizing key hyperparameters rather than solely adjusting layer weights. In this approach, a BRKGA individual consists of a chromosome with N genes, a fitness score (indicating the quality of the solution), and a corresponding CNN model. The chromosome encodes the essential hyperparameters of each CNN layer, forming the foundation for network construction.

A CNN model is composed of CNN blocks and Fully Connected (FC) blocks. A CNN block integrates a convolutional layer ($Conv$), a Batch Normalization layer (BN), a Pooling layer ($Pool$), and an activation function (f_{CNN}). The FC block includes a Dropout layer, a hidden Linear layer, and an activation function (f_{FC}).

The convolutional layer is characterized by hyperparameters such as the number of output channels ($out_channels$), kernel size, and stride. The Batch Normalization layer requires only the specification of the number of output channels. Given the performance of the Max Pooling method reported in prior works [23, 73], we exclusively use Max Pooling in this study, with kernel size and stride as its primary hyperparameters.

Fig. 6 Representation of the hyperparameters in a CNN block and an FC block

CNN Block					
Output Channels	*kernel*	*stride*	BN	MP	f_{CNN}
0.629	0.413	0.891	0.134	0.597	0.742

FC Block			
Dropout rate	Output	*Bias*	f_{FC}
0.716	0.301	0.552	0.942

For the FC block, the Dropout layer requires defining the dropout rate, while the hidden Linear layer involves hyperparameters such as the number of hidden neurons (output dimension size) and the presence of bias. Additionally, the choice of activation function is a crucial hyperparameter for both CNN and FC blocks due to its significant impact on network performance.

The arrangement of hyperparameters within each block shapes the overall architecture, leading to a vast search space of potential configurations. BRKGA-CNN seeks to identify the optimal combination of hyperparameters across these blocks to construct an efficient CNN for image classification tasks. Figure 6 illustrates the specific hyperparameters optimized for both CNN and FC blocks.

Each CNN block is encoded in the chromosome using six genes, representing (1) number of output channels, (2) kernel size, (3) stride, (4) inclusion of Batch Normalization, (5) presence of a Max Pooling layer, and (6) choice of activation function (f_{CNN}). Similarly, each FC block is encoded using four genes, representing (1) presence and dropout rate of the Dropout layer, (2) number of neurons in the hidden Linear layer ($Output$), (3) bias status, and (4) choice of activation function (f_{FC}).

A CNN model must include at least one CNN block and can incorporate up to MB_{CNN} CNN blocks. Similarly, it must contain at least one FC block, with an upper limit of MB_{FC} FC blocks. The chromosome includes dedicated genes determining the number of CNN and FC blocks used in the model. Each gene within this segment indicates whether a particular block is active, thereby influencing the final architecture of the evolved solution.

Representation of Individuals

The initial and mutant individuals in BRKGA-CNN are generated randomly, with key values ranging from 0 to 1. The number of individuals and the chromosome length are required as input parameters. The chromosome length is determined by the number of CNN and FC blocks and their associated hyperparameters. Each chromosome gene is defined as follows: BC_{kc}, BF_{kf}, HC_{dc}^{kc}, and HF_{df}^{kf}. Here, BC_{kc} and BF_{kf} correspond to the positions in the chromosome that represent the CNN and FC blocks, respectively. Specifically, kc represents the kc-th CNN block ($kc = 1, \ldots, MB_{\text{CNN}}$), and kf represents the kf-th FC block ($kf = 1, \ldots, MB_{\text{FC}}$).

The values of MB_{CNN} and MB_{FC} denote the predefined maximum number of CNN and FC blocks, respectively.

The gene HC_{dc}^{kc} represents the dc-th hyperparameter of the kc-th CNN block ($dc = 1, \ldots, d_{\text{CNN}}$, $kc = 1, \ldots, MB_{\text{CNN}}$), while HF_{df}^{kf} encodes the df-th hyperparameter of the kf-th FC block ($df = 1, \ldots, d_{\text{FC}}$, $kf = 1, \ldots, MB_{\text{FC}}$). Consequently, the total chromosome length (N) of an individual in BRKGA-CNN is given by

$$N = MB_{\text{CNN}} \times (d_{\text{CNN}} + 1) + MB_{\text{FC}} \times (d_{\text{FC}} + 1) \tag{7}$$

Building upon this representation, Fig. 7 details the BRKGA-CNN approach. The algorithm takes as input the standard BRKGA parameters, which include the population size (p), elite size (p_e), mutant size (p_m), elite inheritance probability (ρ_e), and termination criteria defined by the maximum number of generations and stagnation in fitness improvement. Additionally, it requires the CNN-specific parameters: the maximum number of CNN blocks (MB_{CNN}), the maximum number of FC blocks (MB_{FC}), the number of hyperparameters per CNN block ($d_{\text{CNN}} = 6$), and per FC block ($d_{\text{FC}} = 4$). The dataset is also provided, which is split into training (x_{train}), validation (x_{valid}), and test (x_{test}) subsets.

The algorithm begins by determining the chromosome length (line 1), which corresponds to the number of parameters to be optimized. It then sets the population size and defines the number of individuals generated during the crossover process (line 2). The best individual is initially set to an empty state (line 3). The initial population is randomly generated (line 4), and each individual undergoes a decoding process (line 5), where its chromosome representation is mapped to a CNN architecture. Each individual's fitness is then evaluated (line 6), typically based on classification accuracy on the validation dataset. The evolutionary process proceeds iteratively until the stopping criterion is met (line 7). At each generation, individuals are sorted based on fitness values (line 8) and divided into elite and non-elite groups (lines 9–10). A set of mutant individuals is introduced (line 11) to preserve genetic diversity, while the offspring population is generated through crossover (line 12), where genetic material is recombined from elite and non-elite parents according to a predefined inheritance probability. The new population is formed by combining mutants and offspring (line 13). Each individual is then decoded (line 14) to construct a valid CNN architecture and subsequently evaluated (line 15). The elite individuals from the previous generation are carried forward (line 16) to ensure continuity in high-performing solutions. The best individual is updated in each iteration to track the best architecture achieved (line 17). Upon meeting the stopping criterion, the best individual undergoes a final evaluation using the test dataset, ensuring the resulting CNN model generalizes well to unseen data.

To illustrate the encoding strategy, Fig. 8 presents an example chromosome structure with two CNN blocks ($MB_{\text{CNN}} = 2$) and two FC blocks ($MB_{\text{FC}} = 2$), resulting in a chromosome consisting of 24 genes.

Fig. 8 Representation of an individual's chromosome for the proposed BRKGA-CNN. Example with two CNN blocks and two FC blocks

Decoder

The $Decoder()$ function within the BRKGA-CNN framework is designed to translate an individual's random key chromosome into a valid CNN architecture. The activation of CNN and fully connected (FC) blocks is determined by the first MB_{CNN} and MB_{FC} genes, respectively. Equation (8) defines the activation criteria, where $MaxBlock$ represents the total number of CNN and FC blocks. Once the active blocks are identified, the $Decoder()$ assigns values to their respective hyperparameters.

$$blocks[i] = \begin{cases} \text{deactivated}, if\ genes[i] \leq 0.5 \\ \text{activated}, otherwise \end{cases}, \forall\, i \in [1, MaxBlock] \tag{8}$$

The first gene (HC_1^{kc}) in each CNN block determines the number of output channels, scaled by a predefined maximum value ($max_channels$) and rounded to the nearest integer:

$$out_channels = round(HC_1^{kc} \times max_channels) \tag{9}$$

Similarly, the second gene (HC_2^{kc}) encodes the convolutional kernel size, scaled by $max_kernels$:

$$kernel_size = round(HC_2^{kc} \times max_kernels) \tag{10}$$

The third gene (HC_3^{kc}) defines the stride, ensuring its value remains within practical limits:

$$stride = \begin{cases} 1, if\ HC_3^{kc} \leq 0.5 \\ 2, otherwise \end{cases} \tag{11}$$

A Batch Normalization (BN) layer is included based on the fourth gene (HC_4^{kc}):

$$BN = \begin{cases} (out_channels), if\ HC_4^{kc} \leq 0.5 \\ Null, otherwise \end{cases} \tag{12}$$

Max Pooling (MP) layers are similarly determined based on the fifth gene (HC_5^{kc}):

$$\text{MP} = \begin{cases} (kernel_size,\ stride),\ if\ HC_5^{kc} \leq 0.5 \\ Null,\ otherwise \end{cases} \tag{13}$$

To select an activation function for both CNN and FC blocks, the sixth gene (HC_6^{kc}) of each CNN block, or the fourth gene (HF_4^{kf}) of each FNN block, is mapped to one of the 17 predefined activation functions:

$$f_{\text{CNN}} = round(HC_6^{kc} \times 16) \tag{14}$$

$$f_{\text{FC}} = round(HF_4^{kf} \times 16) \tag{15}$$

For FC blocks, the inclusion of a Dropout layer (HF_1^{kf}) depends on the first gene, with the dropout rate computed as

$$dropout = \begin{cases} round(HF_1^{kf},\ 2),\ if\ HF_1^{kf} \leq 0.5 \\ Null,\ otherwise \end{cases} \tag{16}$$

The second gene in the FC block determines the number of hidden neurons:

$$neurons = round(HF_2^{kf} \times (in_feat - D_out) + D_out) \tag{17}$$

Finally, the bias status (HF_3^{kf}) is set based on the third gene:

$$bias = \begin{cases} \text{off},\ if\ HF_3^{kf} \leq 0.5 \\ \text{on},\ otherwise \end{cases} \tag{18}$$

Figure 9 illustrates the decoding process applied to a chromosome depicted in Fig. 8. The first two genes determine the activation of CNN blocks (BC_1, BC_2), while the third and fourth genes determine the activation of FC blocks (BF_1, BF_2). If $BF_1 \leq 0.5$, FC block 1 is deactivated, whereas the fourth gene determines whether FC block 2 is included. The final CNN architecture is then assembled by decoding the active blocks, as illustrated at the bottom of Fig. 9. Finally, if all $MaxBlock$ genes are inactive, a default architecture with one CNN and one FC block is selected, using the highest-ranking genes in each category.

Fitness Evaluation

The $Fitness()$ function evaluates the quality of each individual by assessing its corresponding CNN model. The CNN architecture, decoded by the $Decoder()$ function, undergoes training within the $Fitness()$ function. Each model is trained for a predetermined number of epochs using the Cross-Entropy Loss function and the Adam optimizer [38], with a learning rate set to $1e$–4 and a mini-batch size of 100. The training process is conducted on the training dataset (x_{train}), while the

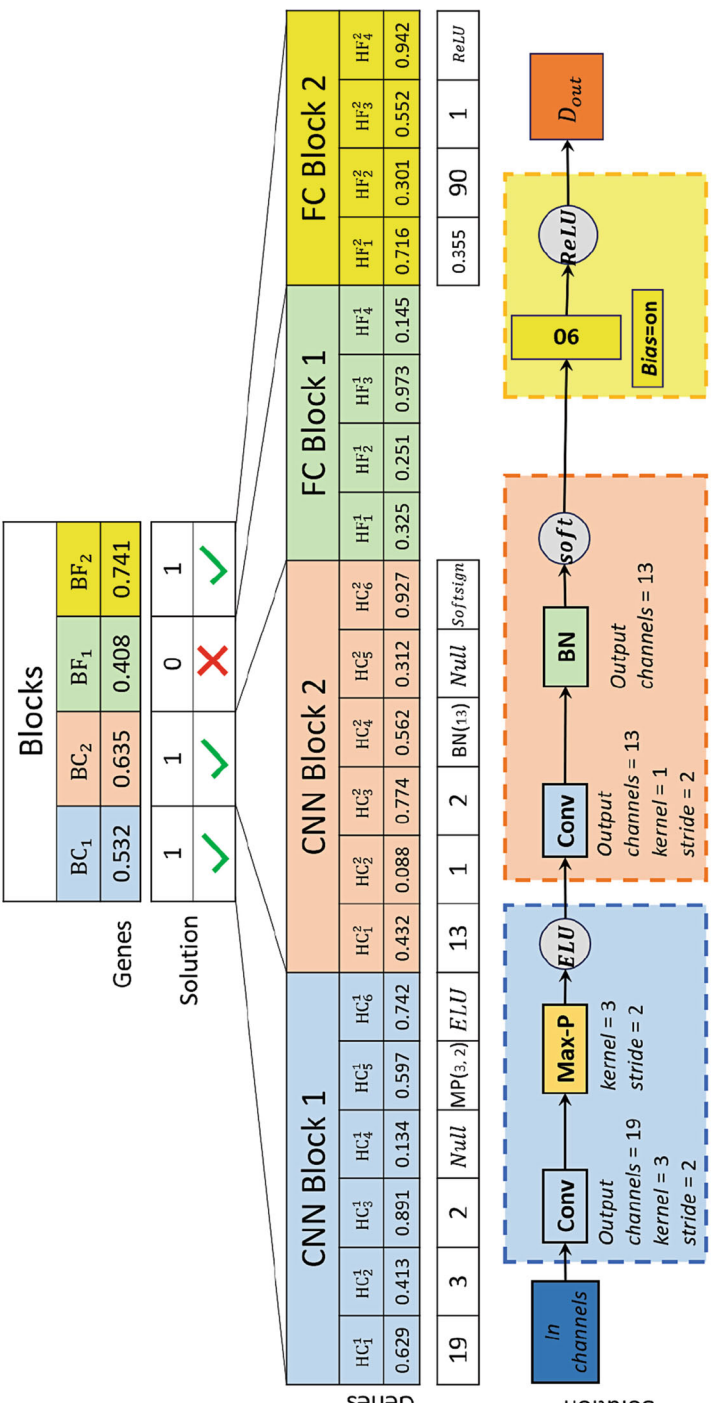

Fig. 9 Illustration of the chromosome decoding process in the BRKGA-CNN framework

validation dataset (x_{valid}) is used to monitor performance. Only the best-performing individual ($best_ind$) is subsequently evaluated on the test dataset (x_{test}), ensuring an unbiased assessment of its generalization capability.

The fitness score of a solution is determined using the classification error metric. For each instance t in the dataset T, Eq. (19) quantifies the discrepancy between the model's predicted output ($\hat{y}_t$) and the true class label (y_t). An error value of 0 is assigned if the prediction ($\hat{y}_t$) is correct; otherwise, the error is 1. Thus, a lower fitness score reflects a more accurate model. Equation (19) formalizes the fitness calculation, which serves as the optimization criterion for guiding the search toward higher-performing CNN architectures.

$$\text{Fitness} = \frac{1}{\text{len}(T)} \sum_{t=1}^{\text{len}(T)} \text{Error}(\hat{y}_t, y_t) \tag{19}$$

BRKGA-GNN Proposal

Representation of Graph Neural Networks

The BRKGA-GNN approach is designed to optimize the architecture of Graph Neural Networks (GNNs), distinguishing itself from methods such as Genetic-GNN, which simultaneously optimize hyperparameters and weights. In BRKGA-GNN, each individual (chromosome) encodes N genes, a fitness value, and a corresponding GNN solution. The chromosome represents key GNN hyperparameters essential for constructing a general GNN model, which consists of an input layer, multiple GNN layers, and an output layer responsible for generating embeddings. Figure 10 illustrates these components. The hyperparameters related to attention are:

- Attention Function: Unlike GraphNAS and Auto-GNAS, which use fixed attention mechanisms, BRKGA-GNN evaluates nine well-known functions (GCN

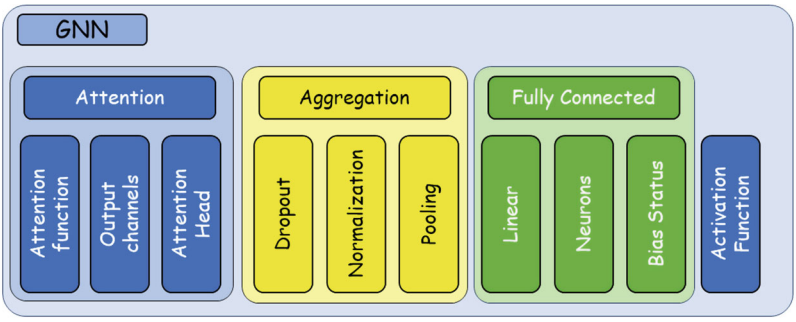

Fig. 10 Representation of the hyperparameters of GNN layers

[39], GraphSAGE [29], GAT [70], GraphConv [54], GIN [76], ChebConv [14], SGC [74], TAG [15], and ARMA [8]) to define node feature aggregation.
- Output channels determine the dimensionality of intermediate representations, with an upper bound defined by $max_out_channels$.
- Attention Heads enhance expressiveness via multi-head mechanisms, with a limit set by $max_attention_head$.

The hyperparameters related to aggregation are:

- Dropout: It regularizes training by randomly deactivating units, reducing overfitting.
- Normalization: Techniques like BatchNorm [35], LayerNorm [3], GraphNorm [12], and PairNorm [80] stabilize training by standardizing input features.
- Pooling Layer: It aggregates node features for graph-level representations using global add, mean, and max pooling methods.
- Linear Layer: It adds flexibility with fully connected layers, transforming features across higher dimensions ($max_out_features$).

Activation Functions: BRKGA-GNN explores 20 activation functions, including ReLU and GELU, to enhance expressiveness, broadening the search space for optimal architectures.

Furthermore, we explore the training hyperparameters: Weight Decay and Learning Rate. Weight Decay is responsible for regularizing by penalizing large weights and mitigating overfitting. The Learning Rate balances optimization speed and stability, which is crucial for effective model convergence.

The hyperparameters considered in BRKGA-GNN fall into four categories: attention mechanisms, aggregation strategies, activation functions, and training hyperparameters.

- **Attention Mechanisms**:
  - Attention Function: Unlike GraphNAS and Auto-GNAS, which use fixed attention mechanisms, BRKGA-GNN explores nine widely used attention functions: GCN [39], GraphSAGE [29], GAT [70], GraphConv [54], GIN [76], ChebConv [14], SGC [74], TAG [15], and ARMA [8].
  - Output Channels define the dimensionality of intermediate representations, constrained by $max_out_channels$.
  - Attention Heads expand expressiveness using multi-head attention mechanisms, with a maximum limit set by $max_attention_head$.
- **Aggregation Strategies**:
  - Dropout: It regularizes training by randomly deactivating neurons, mitigating overfitting effects.
  - Normalization: This incorporates BatchNorm [35], LayerNorm [3], GraphNorm [12], and PairNorm [80] to stabilize training through feature standardization.
  - Pooling Layer: It aggregates node features to construct graph-level representations using global add pooling, mean pooling, and max pooling.

  - Linear Layer: It adds a fully connected layer to facilitate transformations across higher-dimensional feature spaces, constrained by $max_out_features$.
- **Activation Functions**: BRKGA-GNN optimizes among 20 activation functions, including ReLU, GELU, and other common nonlinearities, broadening the search space for expressive and efficient architectures.
- **Training Hyperparameters**: Additionally, BRKGA-GNN explores two training hyperparameters that impact optimization stability and generalization performance:
  - Weight Decay: It regularizes training by penalizing large weight magnitudes, effectively mitigating overfitting.
  - Learning Rate: It controls the step size in optimization updates, balancing convergence speed and stability for improved model training.

Representation of Individuals

In the BRKGA-GNN framework, individuals are encoded as chromosomes that capture the hyperparameters for GNN layers and training configurations. Each chromosome consists of random keys, where each key maps to a specific parameter within the GNN's architecture and training setup. The chromosome length is determined by the number of layers (n_{layers}), the number of hyperparameters per layer (n_{param_gnn}), and the number of training hyperparameters (n_{param_train}), as defined in Eqs. (20) and (21).

$$H = n_{param_gnn} + n_{param_train} \tag{20}$$

$$N = n_{layers} \times (n_{param_gnn} + 1) + n_{param_train} \tag{21}$$

Each gene within the chromosome consists of two components: GL_k and P_h^k. Here, GL_k denotes the position of the gene associated with the k-th GNN layer, where $k \in \mathbb{R}^{|n_{layers}|}$ and $k = 1, 2, \ldots, n_{layers}$, indicating the predefined maximum number of layers. Likewise, P_h^k refers to the position of the gene corresponding to the h-th hyperparameter, where $h \in \mathbb{R}^{|H|}$ and $h = 1, 2, \ldots, H$, where H represents the total number of hyperparameters, as given in Eq. (20).

Thus, the chromosome length N encapsulates genes for the maximum allowable layers, training hyperparameters, and specific hyperparameters for each GNN layer, as defined by Eq. (21).

We define ten hyperparameters per GNN layer ($n_{param_gnn} = 10$), denoted as P_1^k to P_{10}^k for the k-th layer. Additionally, two training hyperparameters ($n_{param_train} = 2$), represented by P_{11} and P_{12}, influence overall training dynamics. Figure 11 illustrates an individual's chromosome for $n_{layers} = 2$, highlighting the first and second layers in green and red.

A detailed breakdown of each hyperparameter and its corresponding search space is provided below. Tables 3 and 4 summarize the search spaces for GNN layer and training hyperparameters, respectively.

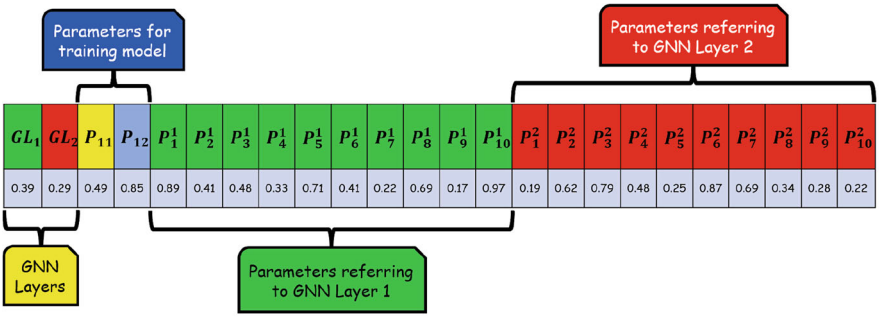

Fig. 11 Illustration of an individual's chromosome from the proposed BRKGA-GNN, with two GNN layers

Table 3 Search space for GNN layer hyperparameters

Component	Parameter	Search space
P_1^k	Attention function	(GCN, GraphSAGE, GAT, GraphConv, GIN, ChebConv, SGC, TAG, ARMA)
P_2^k	Output channels	[1, max_out_channels]
P_3^k	Attention head	[1, max_attention_head]
P_4^k	Dropout	(0.05, 0.1, 0.2, 0.3, 0.4, 0.5, 0.6)
P_5^k	Normalization	(BatchNorm, LayerNorm, GraphNorm, PairNorm)
P_6^k	Pooling	(Global add pool, global mean pool, global max pool)
P_7^k	Linear	(True, False)
P_8^k	Number of hidden neurons	[1, max_out_features]
P_9^k	Bias status	(On, Off)
P_{10}^k	Activation function	(Sigmoid, Hardshrink, Hardtanh, Hardsigmoid, LeakyReLU, LogSigmoid, Tanhshrink, PReLU, ReLU, RReLU, ReLU6, SELU, CELU, ELU, Softplus, Softshrink, Softsign, Tanh, GELU e SiLU)

Table 4 Search space for model training hyperparameters

Component	Parameter	Search space
P_{11}	Weight decay rate	(5e–4, 8e–4, 1e–3, 4e–3)
P_{12}	Learning rate	(5e–4, 1e–3, 5e–3, 1e–2)

- **Attention function** (P_1^k) defines the attention mechanism employed in each GNN layer. The model evaluates nine prominent attention functions: GCN, GraphSAGE, GAT, GraphConv, GIN, ChebConv, SGC, TAG, and ARMA, as available in the PyTorch Geometric library.
- **Output channels** (P_2^k) specifies the number of output channels per attention function, constrained by $max_out_channels$.
- **Attention head** (P_3^k) determines the number of attention heads per layer, limited by $max_attention_head$.

- **Dropout** (P_4^k) defines the dropout rate, ranging from 0.05 to 0.6.
- **Normalization** (P_5^k) specifies the normalization strategy, including BatchNorm, LayerNorm, GraphNorm, and PairNorm, to enhance training stability.
- **Pooling** (P_6^k) determines the pooling technique, choosing among global add pooling, mean pooling, and max pooling.
- **Linear** (P_7^k) indicates whether a fully connected layer is included (True/False).
- **Number of hidden neurons** (P_8^k) specifies the number of neurons in the linear layer, constrained by $max_out_features$.
- **Bias status** (P_9^k) defines whether bias is applied (On/Off).
- **Activation function** (P_{10}^k) determines the activation function per layer, with options including Sigmoid, LeakyReLU, ReLU, and GELU.
- **Weight decay rate** (P_{11}) specifies the weight decay rate for regularization, with values between 5e–4 and 4e–3.
- **Learning rate** (P_{12}) defines the learning rate for training, with values ranging from 5e–4 to 1e–2.

After defining the hyperparameter search spaces, individuals are initialized with fixed chromosome dimensions. BRKGA-GNN follows the standard BRKGA methodology, where the decoder (detailed in the following section) maps each individual's chromosome into a fully configured GNN architecture.

Decoder

The $Decoder()$ function translates a chromosome with random keys into a solution for the problem. The solution returned is a trainable GNN model comprising several GNN layers. Furthermore, the $Decoder()$ function defines two critical training parameters for the model: the learning rate and the weight decay rate.

In the BRKGA-GNN framework, individuals are encoded as chromosomes that capture the hyperparameters for GNN layers and training configurations. Each chromosome consists of random keys, where each key maps to a specific parameter within the GNN's architecture and training setup. The chromosome length is determined by the number of layers (n_{layers}), the number of hyperparameters per layer (n_{param_gnn}), and the number of training hyperparameters (n_{param_train}), as defined in Eqs. (20) and (21).

The first n_{layers} genes of the chromosome correspond to the GNN layers within the solution. To ascertain whether the k-th GNN layer is active, the $active_gnn$ list is constructed for all $k \in [1, n_{layers}]$ as described in Eq. (22).

$$active_gnn[k] = \begin{cases} True, \ if \ GL_k \leq 0.5 \\ False, \ otherwise \end{cases} \tag{22}$$

If $active_gnn[k]$ is True, the corresponding GNN layer is included in the model; otherwise, it is excluded. Each active layer contributes as a component in the finalized GNN structure. Following the layer configuration, the subsequent two genes encode the training hyperparameters. These genes are captured in the array

$genes_train$: $genes_train = genes[n_{layers} : n_{layers} + n_{param_train}]$, where $n_{param_train} = 2$. The weight decay (P_{11}) and learning rate (P_{12}) are defined by Eq. (23) and Eq. (24), respectively:

$$P_{11} = round(genes_train[1] \times len(weight_decays)) \tag{23}$$

$$P_{12} = round(genes_train[2] \times len(learning_rates)) \tag{24}$$

Subsequent genes encode the hyperparameters for each GNN layer. The following process outlines the decoding for a single layer, which is similarly applied to other layers:

- **Attention Function:** The first gene selects an attention function. The gene value, when scaled by the number of available functions, determines the function from the list $attention_list$ (Eq. (25)):

$$P_1^k = attention_list[round(genes[1] \times len(attention_list))] \tag{25}$$

- **Output Channels:** The second gene defines the number of output channels (P_2^k), scaled by $max_out_channels$ and rounded up (Eq. (26)):

$$P_2^k = round(genes[2] \times max_out_channels) + 1 \tag{26}$$

- **Attention Heads:** The third gene determines the number of attention heads (P_3^k), scaled and rounded similarly (Eq. (27)):

$$P_3^k = round(genes[3] \times max_attention_head) + 1 \tag{27}$$

- **Dropout:** The fourth gene decides the inclusion of a dropout layer (P_4^k) based on Eq. (11), with its rate calculated by Eq. (29):

$$P_4^k = \begin{cases} Dropout(p), & if\ genes[4] \leq 0.5 \\ False, & otherwise \end{cases} \tag{28}$$

$$p = drop_rates[round(2 \times genes[4] \times len(drop_rates))] \tag{29}$$

- **Normalization:** The fifth gene determines whether a normalization layer is added, with its type defined in Eq. (31):

$$P_5^k = \begin{cases} (BN), & if\ genes[5] \leq 0.5 \\ False, & otherwise \end{cases} \tag{30}$$

$$BN = norm_list[round(2 \times genes[5] \times len(norm_list))] \tag{31}$$

- **Pooling Layer:** The sixth gene dictates the inclusion of a pooling layer (P_6^k) and its type (Eq. (33)):

$$P_6^k = \begin{cases} (pooling), \ if \ genes[6] \leq 0.5 \\ False, \ otherwise \end{cases} \tag{32}$$

$$pooling = pool_list[round(2 \times genes[6] \times len(pool_list))] \tag{33}$$

- **Linear Layer:** The seventh gene determines the inclusion of a linear layer (P_7^k) (Eq. (14)). If included, the number of hidden units (P_8^k) is calculated (Eq. (17)), followed by the bias status (P_9^k) (Eq. (18)):

$$P_7^k = \begin{cases} \text{Linear(neurons, bias)}, \ if \ genes[7] \leq 0.5 \\ False, \ otherwise \end{cases} \tag{34}$$

$$P_8^k = round(genes[8] \times max_out_features) + 1 \tag{35}$$

$$P_9^k = \begin{cases} Bias(\text{off}), \ if \ genes[9] \leq 0.5 \\ Bias(\text{on}), \ otherwise \end{cases} \tag{36}$$

- **Activation Function:** The activation function (P_{10}^k) is chosen based on the tenth gene, scaled and rounded to select from act_func_list (Eq. (15)):

$$P_{10}^k = act_func_list[round(genes[10] \times n_activations)] \tag{37}$$

Once all layers are processed, the chromosome represents a fully defined trainable GNN model, ready for training and evaluation. For example, Fig. 12 illustrates the decoding of a chromosome with $n_{layers} = 2$, resulting in a two-layer GNN model, with parameters such as $max_out_channels = 250$ and $max_out_features = 100$.

Fitness Evaluation

Once the Decoder function outputs a GNN solution, the fitness evaluation function measures the individual's fitness during model training. The training uses the Negative Log Likelihood Loss (*NLLLoss*) minimized via the Adam optimizer, with hyperparameters P_{11} (weight decay) and P_{12} (learning rate) set during decoding. The model is trained on mini-batches from the training set and managed by a data controller.

Fitness is assessed on the validation set, where the model's accuracy determines its fitness score. The fitness function calculates accuracy as per Eq. (19), with T as the total samples in the validation set, $\hat{y}_t$ as the predicted label, and y_t as the ground truth. A lower fitness score reflects fewer prediction errors, indicating higher accuracy. After evolution, the test set evaluates the top solution from BRKGA-GNN,

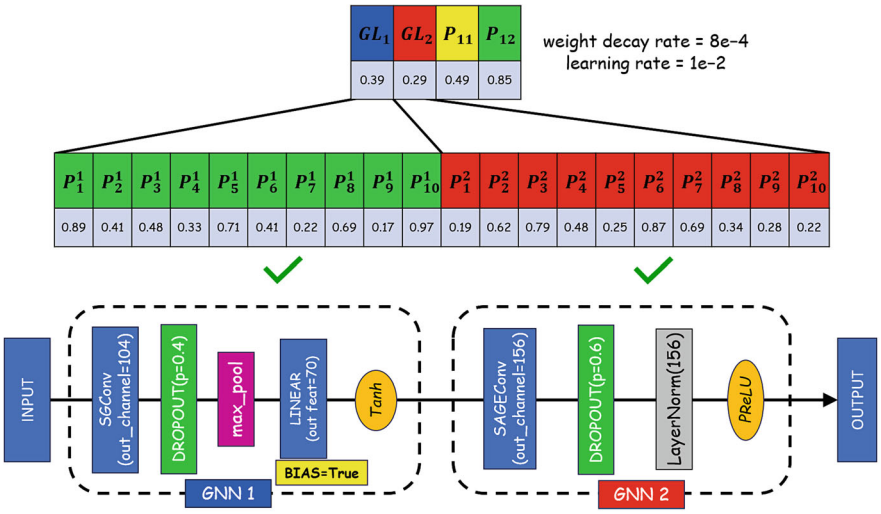

Fig. 12 Illustration of the decoding process of an individual's chromosome in BRKGA-GNN, resulting in a GNN solution with two layers

ensuring an unbiased generalization assessment. This fitness evaluation integrates into the evolutionary process, refining GNN architectures based on training and validation performance for robust development.

Experiments: Datasets, Models, and Configurations of Models

BRKGA-DFNN

To evaluate the performance of our proposed BRKGA-DFNN, experiments were conducted using two established benchmark datasets and a set of state-of-the-art heuristic models, with carefully selected configurations to ensure fair and robust comparisons.

Datasets

The experimental evaluation utilized the MNIST [41] and Fashion-MNIST [75] datasets, both widely recognized in the machine learning community. The MNIST dataset is a widely used benchmark, comprising 70,000 grayscale images of handwritten digits ranging from 0 to 9. Each image has a resolution of 28 $\times$ 28 pixels, with 60,000 samples designated for training and 10,000 for testing. Its extensive use in classification tasks underscores its value for performance evaluation across various algorithms. Fashion-MNIST presents a more complex challenge, replacing digits with images of clothing items across ten categories: T-shirt/top, Trouser, Pullover, Dress, Coat, Sandal, Shirt, Sneaker, Bag, and Ankle Boot. Like MNIST, it contains 70,000 grayscale images of 28 $\times$ 28 pixels, with a 60,000/10,000

split for training and testing, respectively. This dataset has become a standard for benchmarking image classification models in fashion-related contexts.

Comparative Models

To benchmark BRKGA-DFNN, we compared its performance against four heuristic-based models designed for DFNN optimization: TS-DFNN [27], GRASP-DFNN [63], IPSONet [77], and HyperBRKGA [36]. Each model was implemented according to its respective author's specifications, ensuring consistent experimental procedures across all models.

Experimental Configurations

The experiments were executed in the Google Colaboratory environment, leveraging an Nvidia T4 Tensor Core GPU. The local machine used to access the platform featured an Intel Core i5 processor, 16 GB of RAM, and a 512 GB SSD. The BRKGA-DFNN algorithm was implemented in Python 3.10 with PyTorch 1.9.0 [56], adhering to Object-Oriented Programming principles. The code will be made publicly available to facilitate reproducibility.

Preliminary trials determined the optimal configuration for BRKGA parameters. The final settings included a population size of 20, an elite proportion of 0.20, a mutant proportion of 0.15, and a crossover probability of 0.65 for elite parents. Two stopping criteria were applied: a maximum of 20 generations or ten consecutive generations without improvement. Baseline models adhered to the same stopping criteria for consistency, with each experiment repeated 30 times. The best solution for each model was determined by the lowest classification error achieved on the test datasets.

BRKGA-CNN

This subsection outlines the datasets, comparative models, and configurations used in the experiments to evaluate the proposed BRKGA-CNN approach.

Datasets

The experiments were conducted using five datasets summarized in Table 5. A preprocessing step was applied to each dataset to normalize input features and encode target labels for classification tasks. Among the selected datasets were MNIST [41] and four variations of the original MNIST dataset, as proposed by Larochelle et al. [40], which were utilized to create more challenging learning

Table 5 Datasets used in BRKGA-CNN experiments

Datasets	Train set	Test set	Features	Classes
MNIST	60,000	10,000	28×28	10
MNIST-BI	12,000	50,000	28×28	10
MNIST-RB	12,000	50,000	28×28	10
MNIST-RD	12,000	50,000	28×28	10
MNIST-RD+BI	12,000	50,000	28×28	10

environments. These variations aim to test the generalization capabilities of the best-performing models. Each of these datasets includes 10,000 training examples, 2,000 validation examples, and 50,000 testing examples, differing from the original MNIST in the reduced number of training examples, which increases the difficulty level. The variations are described as follows:

- **MNIST-RD (Rotated Digits)** contains digits (0–9) rotated by an angle uniformly sampled between 0 and 2π radians. This variation incorporates the rotation angle in addition to the inherent writing style variations from the original MNIST.
- **MNIST-RB (Random Background)** adds a random background to each digit image, with pixel values uniformly generated between 0 and 255.
- **MNIST-BI (Background Image)** superimposes digit images on 20 randomly selected low-quality black and white images sourced from the Internet.
- **MNIST-RD+BI (Rotated Digits + Background Image)** combines the MNIST-RD and MNIST-BI variations.

Comparative Models

For comparison, models that optimize CNN architectures using metaheuristic algorithms were selected. These models align with the objective of the BRKGA-CNN approach, focusing on image classification tasks. The selected models have demonstrated superior performance on benchmark datasets, making them suitable for assessing the effectiveness of BRKGA-CNN. The models chosen include the IPPSO method by [72], the evoCNN model by [67], and the psoCNN design by [19].

Experimental Configurations

All experiments were executed in the Google Colaboratory environment, utilizing an Nvidia T4 Tensor Core GPU. The system configuration included an Intel Core i5 processor, 16 GB RAM, and a 512 GB SSD. The BRKGA-CNN implementation was developed in Python 3.10, leveraging PyTorch 1.9.0 [56] and adhering to Object-Oriented Programming principles.

Parameter optimization for BRKGA-CNN involved systematic trials using one dataset and performing 20 independent runs of the BRKGA algorithm. The parameters varied included the population size p between [10, 25], elite proportion p_e within [0.05, 0.25], mutant proportion p_m within [0.05, 0.25], and elite inheritance probability ρ_e within [0.51, 0.75]. The selected configuration for BRKGA-CNN was population size $p = 20$, elite proportion $p_e = 0.20$, mutant proportion $p_m = 0.15$, and elite inheritance probability $\rho_e = 0.70$. The algorithm was terminated after 20 generations or 10 consecutive generations without improvement in the best individual.

CNN architecture-specific parameters were set as follows: $MB_{\text{CNN}} = 20$, $MB_{\text{FC}} = 5$, $max_channels = 150$, $max_kernels = 7$, and the number of training epochs fixed at 10. The BRKGA-CNN approach was tested over 30 independent runs with fixed seeds to ensure reproducibility. The optimal solution for each dataset was recorded, and the implementation is publicly available in a repository for community use.

BRKGA-GNN

This subsection details the datasets, baseline models, and configurations employed in the experiments to assess the proposed BRKGA-GNN approach.

Datasets

For our experiments, we utilized a citation network dataset where nodes represent documents, and edges denote citation relationships among them. The Cora dataset [39] contains 2,708 research papers categorized into seven distinct classes, such as Reinforcement Learning and Genetic Algorithms. A total of 5,429 citation links interconnect these nodes. Each paper is represented by a feature vector of 1,433 dimensions, indicating the presence or absence of specific keywords.

Comparative Models

To evaluate the effectiveness of BRKGA-GNN, we compared its performance against both handcrafted and NAS-based GNN models. The handcrafted architectures included Chebyshev [14], GCN (Graph Convolutional Network) [39], GAT (Graph Attention Network) [70], and LGCN (Learnable Graph Convolutional Network) [22]. For the NAS-based approaches, we considered GraphNAS [61], Auto-GNN [83], SNAG (Simplified NAS for GNNs) [81], and Genetic-GNN [61].

Experimental Configurations

We conducted a parameter selection process for BRKGA-GNN to balance computational efficiency with solution quality. The goal was to identify configurations that discover high-performing GNN architectures within a reasonable timeframe.

The parameter selection targeted two categories: BRKGA parameters and GNN architecture parameters. For BRKGA, we evaluated parameters such as population size (p), number of populations (k), elite population proportion (p_e), mutant population proportion (p_m), and elite inheritance probability (ρ_e). For the GNN architecture, parameters included the number of layers (n_{layers}), the maximum number of output channels for the attention mechanism ($max_out_channels$), maximum attention heads ($max_attention_head$), maximum hidden neurons in the linear layer ($max_out_features$), and the number of training epochs per individual ($epochs$) during fitness evaluation. The experiments on the Cora dataset aimed to find the optimal parameter configuration that yielded the highest test accuracy. Each execution adhered to stopping criteria ($criteria$): a maximum of 20 generations or 10 generations without improvement. These criteria ensured meaningful exploration of the parameter space while preventing excessive computational costs.

At the end of the parameter definition runs, we set the following values for the BRKGA parameters: $p = 50$, $k = 2$, $p_e = 0.1$, $p_m = 0.2$, and $\rho_e = 0.65$. For the GNN layer parameters, we set the following values: $n_{layers} = 2$, $max_out_channels = 100$, $max_attention_head = 16$, $max_out_features = 500$, and $epochs = 100$.

Results and Discussion

BRKGA-DFNN

The experimental evaluation involved 30 independent runs for each model, with the lowest classification error rates on the test datasets summarized in Table 6. This table highlights two key metrics for each model: the classification error of the best-performing solution ("best") and the average classification error across all runs ("mean"). The following discussion analyzes the performance of the models on each dataset, focusing on these two metrics for comparison.

For the MNIST dataset, the proposed BRKGA-DFNN model exhibited exceptional performance, achieving the lowest error rates for both the best solution (1.85%) and the mean value (2.83%). Among the competing models, IPSONet delivered competitive results for the best solution (2.00%), while HyperBRKGA secured the second-best mean classification error (2.97%). Conversely, the TS-DFNN model displayed the highest error rates, indicating lower performance than the other approaches.

For the Fashion-MNIST dataset, BRKGA-DFNN also outperformed the benchmark models, recording the lowest classification error for the best solution (11.46%) and the mean metric (12.29%). In contrast, TS-DFNN, IPSONet, and HyperBRKGA exhibited higher error rates for the best solutions, with respective values of 14.50%, 13.48%, and 12.90%. This trend further underscores the robustness of BRKGA-DFNN in tackling more challenging classification tasks.

The analysis of "best" and "mean" metrics revealed a consistent pattern of superior performance by BRKGA-DFNN across both datasets. The "best" metric showcases the model's ability to achieve optimal results under ideal conditions, while the "mean" metric reflects its overall reliability across multiple runs. The BRKGA-DFNN approach demonstrated excellence in both aspects, ensuring its place as the leading model in this comparative study.

Table 6 Results of optimization models for DFNN hyperparameters: best value and average classification error for the datasets

Model	Datasets	
	MNIST	Fashion-MNIST
TS-DFNN	3.16 (best)	14.50 (best)
	4.38 (mean)	15.22 (mean)
GRASP-DFNN	2.32 (best)	12.64 (best)
	4.10 (mean)	15.28 (mean)
IPSONet	2.00 (best)	13.48 (best)
	3.66 (mean)	15.36 (mean)
HyperBRKGA	2.12 (best)	12.90 (best)
	2.97 (mean)	13.38 (mean)
BRKGA-DFNN	**1.85 (best)**	**11.46 (best)**
	2.83 (mean)	**12.29 (mean)**

These findings emphasize the effectiveness and robustness of the BRKGA-DFNN model. Its consistently delivering top-ranking results across diverse datasets highlight its potential as a reliable and efficient solution for optimizing Deep Feedforward Neural Networks.

BRKGA-CNN

After performing 30 independent runs of the BRKGA-CNN algorithm on each dataset, we recorded the best classification error rates on the respective test sets. Table 7 provides a detailed comparative analysis between BRKGA-CNN and other benchmark models. The evaluation primarily focused on performance metrics across the datasets, particularly the classification error of the optimal solution (i.e., the solution with the lowest classification error) and the average classification error observed across the 30 runs.

The psoCNN model [19] achieved the best result for the MNIST-RD dataset, while BRKGA-CNN outperformed the comparative models on MNIST, MNIST-BI, MNIST-RB, and MNIST-RD+BI. These results demonstrate that BRKGA-CNN outperformed the comparative models on these specific datasets.

For the MNIST-RD dataset, the optimal solution obtained by BRKGA-CNN was 3.60%. Although BRKGA-CNN did not surpass the best result of 3.58% achieved by psoCNN for MNIST-RD, its performance remained highly competitive. Additionally, BRKGA-CNN demonstrated superior average performance over 30 runs, with an average classification error of 4.95%, compared to 6.42% achieved by psoCNN, also based on 30 iterations. It is important to note that while psoCNN used a higher maximum output channel count of 256, BRKGA-CNN was restricted to $max_channels = 150$, which may have influenced its performance in MNIST-RD.

Table 7 BRKGA-CNN test set classification error values for the MNIST, MNIST-RD, MNIST-RB, MNIST-BI, and MNIST-RD+BI datasets compared to the comparative models

	Datasets				
Model	MNIST	MNIST-BI	MNIST-RB	MNIST-RD	MNIST-RD+BI
evoCNN (best)	1.18%	4.53%	2.80%	5.22%	35.03%
evoCNN (mean)	1.28%	4.62%	3.59%	5.46%	37.38%
IPPSO (best)	1.13%	–	–	–	34.50%
IPPSO (mean)	1.21%	–	–	–	33.00%
psoCNN (best)	0.32%	1.90%	1.79%	**3.58%**	14.28%
psoCNN (mean)	0.44%	2.40%	2.53%	6.42%	20.98%
BRKGA-CNN (best)	**0.31%**	**1.85%**	**1.50%**	3.60%	**12.45%**
BRKGA-CNN (mean)	0.51%	2.21%	2.89%	4.95%	16.43%

Table 8 Test accuracy performance comparison for architectures on the Cora dataset: state-of-the-art handcrafted architectures and best results found by NAS baselines

Categories	Methods	Cora
Handcrafted	Chebyshev	81.2%
	CGCN	81.5%
	GAT	$83.0 \pm 0.7\%$
	LGCN	$83.3 \pm 0.5\%$
GNN NAS	GraphNAS	$84.2 \pm 1.0\%$
	Auto-GNN	$83.6 \pm 0.3\%$
	SNAG	$83.5 \pm 0.5\%$
	Genetic-GNN	$83.8 \pm 0.5\%$
	BRKGA-GNN	$\mathbf{84.6 \pm 0.2}\%$

BRKGA-GNN

The experimental findings, summarized in Table 8, illustrate the performance comparison of several methods for transductive node classification on the Cora dataset. These include state-of-the-art handcrafted GNN architectures, NAS-based models, and the proposed BRKGA-GNN approach.

The results indicate that BRKGA-GNN consistently surpasses both handcrafted and NAS-based models on the Cora dataset. On the Cora dataset, BRKGA-GNN achieves a test accuracy of 84.6%, outperforming the top NAS-based method, GraphNAS, which reaches $84.2 \pm 1.0\%$, and the best-performing handcrafted model, LGCN, which records $83.3 \pm 0.5\%$. BRKGA-GNN also exhibits remarkable robustness, as evidenced by its low variance (0.2%), highlighting the stability of the proposed approach.

Thus, the BRKGA-GNN consistently achieves the highest accuracy in the benchmark dataset, showcasing its effectiveness in exploring the architectural space and identifying superior configurations. This success is mainly due to the balanced exploration and exploitation mechanisms of the BRKGA algorithm.

Conclusion and Future Research Directions

This chapter explored the role of heuristics in the design and optimization of Deep Neural Networks (DNNs), with a particular focus on Neural Architecture Search (NAS), Hyperparameter Optimization (HPO), and Learning Rule Optimization (LRO). While NAS has become an essential component in deep learning automation, most existing approaches rely on gradient-based optimization or reinforcement learning, which demand extensive computational resources and are highly sensitive to hyperparameter tuning. In contrast, our study introduced BRKGA as a computationally feasible and versatile heuristic that efficiently navigates the NAS search space while maintaining a favorable balance between exploration and

exploitation. Moreover, we emphasized the potential of heuristic-driven approaches to hyperparameter tuning and adaptive learning rule discovery, broadening the applicability of evolutionary techniques beyond architecture search.

We demonstrated the effectiveness of BRKGA in optimizing three distinct neural network paradigms—Deep Feedforward Neural Networks (DFNNs), Convolutional Neural Networks (CNNs), and Graph Neural Networks (GNNs)—across a set of moderate-sized benchmark datasets. The experimental results showed that BRKGA successfully identified competitive architectures with lower computational overhead, highlighting its potential as an alternative to mainstream NAS techniques. Furthermore, we explored how heuristic-driven optimization can enhance HPO by adaptively selecting key training parameters such as learning rates, dropout rates, and activation functions. Additionally, LRO, which focuses on optimizing training dynamics, remains an underexplored but promising avenue for improving network generalization and convergence rates. The results emphasize that evolutionary heuristics remain underutilized across NAS, HPO, and LRO, despite their robust search capabilities in high-dimensional and multi-objective optimization problems. emphasize that evolutionary heuristics remain underutilized across NAS, HPO, and LRO despite their robust search capabilities in high-dimensional and multi-objective optimization problems.

The advancements in NAS, HPO, and LRO present several open research challenges and opportunities, particularly in terms of scalability, integration with Automated Machine Learning (AutoML), and their implications for neuromorphic computing. While this study focused on moderate-sized benchmark datasets, future research should extend heuristic-driven methodologies to broader applications, addressing key issues such as computational complexity, interpretability, and hardware efficiency.

One of the primary challenges remains scalability, particularly when optimizing deep architectures in high-dimensional search spaces. Large-scale datasets demand more efficient NAS frameworks that leverage parallel and distributed computing. Evolutionary algorithms, including Genetic Algorithms (GAs), Estimation of Distribution Algorithms (EDAs), and Biased Random Key Genetic Algorithm (BRKGA), have demonstrated their potential in optimizing neural networks, but further research is required to enhance their performance in large-scale settings. Exploring hybrid approaches that integrate reinforcement learning and gradient-based optimization with evolutionary heuristics could provide new insights into improving search efficiency.

Beyond NAS, hyperparameter selection remains a crucial component of deep learning optimization. Future research should explore evolutionary hyperparameter tuning frameworks, particularly in dynamic learning environments where models must adapt to nonstationary data distributions. Metaheuristic approaches could improve the search for optimal hyperparameters across multiple training scenarios, reducing the reliance on exhaustive grid search and Bayesian optimization techniques.

Another promising direction involves the integration of NAS and HPO into AutoML frameworks. Automating model selection, hyperparameter tuning, and

learning rule discovery are essential to minimizing human intervention in deep learning optimization. Current AutoML tools, such as Auto-Keras and Google's AutoML, have already integrated NAS into their pipelines, but further enhancements could arise from hybrid heuristic approaches. However, the combination of heuristic search techniques with differentiable architecture search and reinforcement learning-based strategies could enhance the efficiency of these systems, particularly in resource-constrained environments.

The emergence of neuromorphic computing introduces further optimization challenges for NAS, HPO, and LRO. The development of spiking neural networks (SNNs) and energy-efficient deep learning models requires specialized architecture search techniques that consider hardware constraints such as latency, power consumption, and memory footprint. Evolutionary strategies have shown potential in optimizing architectures for neuromorphic platforms like Intel Loihi and IBM TrueNorth. However, further research is needed to adapt NAS and HPO for biologically inspired computing paradigms.

Another critical issue in deep learning automation is the interpretability of automatically generated architectures and training procedures. Understanding their decision-making processes becomes increasingly difficult as deep learning models grow in complexity. Explainable AI (XAI) techniques should be integrated into NAS, HPO, and LRO frameworks to ensure transparency, interpretability, and trustworthiness. Future studies should focus on post hoc analysis, feature importance estimation, and neural architecture visualization techniques to enhance human-AI collaboration.

The optimization of NAS, HPO, and LRO for real-time and edge AI applications also remains an open challenge. The increasing demand for low-latency, energy-efficient deep learning models highlights the need for hardware-aware optimization strategies. Neural networks optimized for edge devices, federated learning, and autonomous systems require search algorithms that balance accuracy, inference speed, and computational efficiency. Evolutionary heuristics could be crucial in designing models that meet these requirements.

Beyond traditional feedforward and convolutional networks, research should explore new architectures, such as GNNs and transformer-based models. Evolutionary strategies, including multi-objective optimization techniques, could be instrumental in adapting NAS, HPO, and LRO to complex graph structures and domain-specific tasks in bioinformatics, social network analysis, and scientific computing.

Final Remarks

The integration of evolutionary heuristics into NAS, HPO, and LRO represents a compelling avenue for the future of deep learning automation. As AutoML frameworks continue to evolve, incorporating efficient and adaptive search algorithms such as BRKGA could significantly enhance the scalability and robustness of neural architecture optimization. Additionally, the synergy between NAS, HPO, LRO, and neuromorphic computing opens new possibilities for biologically inspired AI

models that mimic brain-like computation while maximizing energy efficiency. Moving forward, the intersection of heuristics, AutoML, and hardware-aware optimization will likely shape the next generation of self-optimizing deep learning systems.

Abstract

This chapter presents an unified and up-to-date overview of the parallel meta-heuristics field. It synthesizes, classifies, and describes the main concepts and general parallelization strategies for meta-heuristics, including their instantiation for neighbourhood- and population-based methods. It also recalls the main contributions to the field, and identifies open questions and research challenges. The presentation is structured according to a three-dimensional classification

of parallel meta-heuristics design strategies: the number of levels indicating whether decomposition is applied once only or recursively; the decomposition strategy reflecting the sources of parallelism in meta-heuristics, algorithm, search space, or mathematical structure; and the search strategy, given a particular level and decomposition approach, defined by the number of processes controlling the search, the communication and learning mechanism, and the diversity of the individual methods and initial solutions involved. Six major classes of parallel meta-heuristics strategies are thus discussed: low-level decomposition of computing-intensive tasks with no modification to the original algorithm, explicit decomposition of the search space, independent multi-search, as well as synchronous, asynchronous, and knowledge-creating cooperative multi-search.

Keywords

Parallel computation · Meta-heuristic search · Parallelization strategies · Algorithmic design taxonomy

Introduction

This chapter is concerned with the very broad domain of approximate solution methods, generally identified as *heuristics*, developed to address optimization problems of principally a combinatorial nature. More precisely, the chapter targets *meta-heuristics*, that is, heuristics involving at least two solution methods, one of which guides the global search for good solutions while avoiding the traps of local optima. Obviously, at least one of the solution methods involved is heuristic. The meta-heuristic term designates a very large array of neighborhood (the term "trajectory" is also found in the literature) and population-based algorithmic designs, as witnessed by this handbook and several review/synthesis books, chapters, and papers, e.g., [1,3,16,17,53,61,62,69–71,75,80,81,88,92,96,117,120]. We include *matheuristics* [91] and *hyper-heuristics* [18] into the large meta-heuristic solution-method class, but do not address heuristics based entirely on exact solution methods, such as stopping early a Branch-and-Bound search or rounding the continuous values of the optimal solution to a linear relaxation of an integer program.

Two major goals characterize the development of meta-heuristics that take advantage of parallel computing. Common to all parallel computing development efforts, the objective is to solve larger problem instances, faster. That is, address larger problem instances than what is achievable by sequential methods, and do this in reasonable computing times. A second objective characterizes approximate solution methods, and it concerns what some authors call the robustness of the method, that is, its capability to offer a consistently high level of performance over a wide variety of problem settings and instance characteristics. The *algorithmic design* of the parallel meta-heuristic search, also called *parallelization strategy*, correctly coded and implemented on an appropriate computing infrastructure, is core to achieving these objectives.

Indeed, the literature shows that, in appropriate settings, parallel meta-heuristics are more robust than sequential versions, while also generally requiring less extensive and expensive parameter-calibration efforts. The literature also emphasizes that a somewhat limited number of parallelization strategies may be identified, independently of their particular problem settings, initial sequential meta-heuristics, and implementation details. It also shows that most of these parallelization strategies yield new algorithms with behaviors different from those of their sequential counterparts.

The objective of this chapter therefore is to present a unified and up-to-date overview of the parallel meta-heuristics field. It synthesizes, classifies, and describes the main concepts and general strategies for the design of parallel meta-heuristics, including their instantiation for neighborhood- and population-based methods, recalls the main contributions to the field, and identifies a number of open questions and research challenges. The chapter focuses on the *design* of parallel meta-heuristic search algorithms, rather than on their implementation using particular coding languages and computing architectures. It does, however, identify new trends, challenges, and opportunities that some of the new computing-platform developments bring to the field.

The chapter updates and enhances material presented previously, in particular Crainic [29, 30]. The interested reader may further consult a number of surveys, taxonomies, and syntheses, e.g., [2,4,7,27–29,33–36,38,46,47,56,94,103,113,120].

The chapter is organized as follows. Section "Meta-heuristics and Parallelism: A Taxonomy" introduces an enhanced classification of design strategies for parallel meta-heuristics, together with a discussion of the potential for parallel computing in meta-heuristics and a brief description of performance indicators for parallel meta-heuristics. Section "Algorithm-Based Parallelization Strategies" addresses so-called low-level approaches focusing on accelerating computing-intensive tasks without modifying the basic algorithmic design. Methods based on the explicit decomposition of the search space are treated in section "Explicit Search-Space Decomposition," while strategies based on the simultaneous exploration of the search space by several independent meta-heuristics constitute the topic of section "Implicit SSD: Independent Multi-search." General cooperation principles are discussed in section "Cooperative Search" and are detailed in sections "Synchronous Cooperation" and "Asynchronous Cooperation." Section "Knowledge Creation in Cooperative Search" is dedicated to strategies aimed at enhancing the performance of cooperation, by taking advantage of the exchanged data to create new information relevant to both the cooperating solvers and the global search. We conclude in section "Conclusions."

Meta-heuristics and Parallelism: A Taxonomy

Parallel computing for meta-heuristics means decomposing the total task of finding the "best" solution to a given problem, that is, the global computing work associated to the search for that solution, into smaller/simpler computing *tasks*. These tasks are

then assigned to a number of available processors, to be performed concurrently (as much as possible, hopefully completely given sufficient computing resources). In the following, we refer to the *process* performing a given task (one process per task) and to the *solver*, that is, the solution method, associated to that process.

This section introduces the taxonomy used to define, describe, and analyze the parallelization strategies for meta-heuristics and the resulting main classes of parallel meta-heuristics proposed in the literature. The taxonomy unifies and enhances previous versions, in particular Crainic, Toulouse, and Gendreau [40], Crainic and Hail [34], and Crainic [29, 30]. This classification is sufficiently general to encompass the principal parallel meta-heuristic classes, while avoiding a level of detail incompatible with the scope and dimension limits of the chapter. We conclude the section with a brief discussion of performance indicators for parallel meta-heuristics.

The taxonomy is structured along three main dimensions, compactly presented in Fig. 1. The *Number of Levels* indicates whether decomposition is applied once only or recursively. Most parallel meta-heuristics found in the literature implement a *single-level decomposition*, noted *1L*, that is, the decomposition and search strategy are defined for the complete problem, yielding a number of tasks to be addressed concurrently (at each iteration of the parallel meta-heuristic). *Multiple levels* (*nL*) of decomposition are defined when one or several of those tasks may be further decomposed, the number of levels corresponding to the depth of the resulting task tree. Thus, for example, a *2L* strategy means that some initially obtained (first level) tasks are further decomposed, while a *3L* strategy implies a further decomposition of some of the second-level tasks.

The *Decomposition* dimension, detailed in section "Decomposition Strategies: Sources of Parallelism," reflects the sources of parallelism in meta-heuristics, in other words, what is decomposed in order to obtain the tasks to be addressed simul-

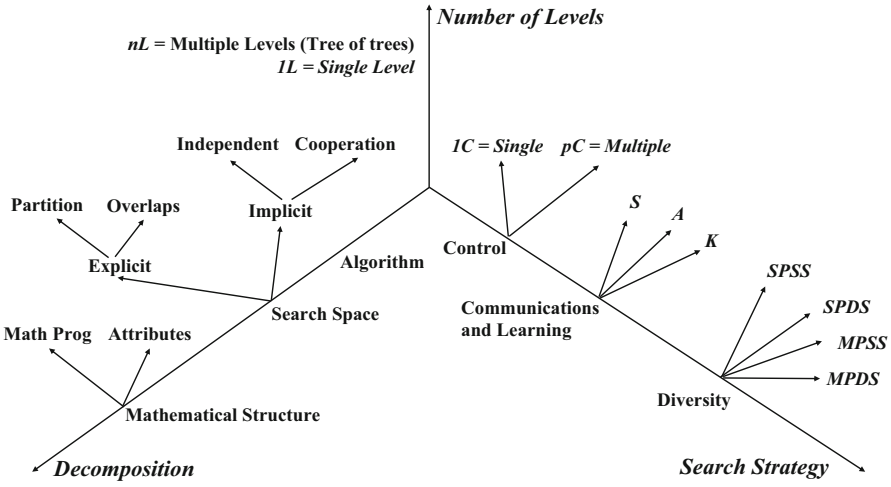

Fig. 1 Parallel meta-heuristic taxonomy

taneously. The decomposition may concern either the *Algorithm* being parallelized, or the *Search Space* one associates to the formulation, or the *Mathematical Structure* of the problem and formulation.

The *Search Strategy* dimension focuses on the main parallelization strategies for meta-heuristics, given a particular level and decomposition approach. (Notice that previous versions of the taxonomy include this dimension only, the other two dimensions being addressed separately.) Section "Search Strategies" details the three components defining a parallel meta-heuristic according to (1) *Control* of the global search with respect to the number of processes involved (one or multiple); (2) *Communication and Learning*, that is, how inter-process communications are handled, **S**ynchronously or **A**synchronously, and whether those communications are used to gather information and build search-guidance **K**nowledge; and (3) *Diversity*, i.e., how the algorithms targeting the individual tasks are defined and instantiated: **S**ame or **M**ultiple initial **P**oints and **S**ame or **D**ifferent **S**earch algorithms.

The parallel meta-heuristic design and literature synthesis of the next sections is based on this taxonomy. The characterization of the methods and contributions is captured through labels of the general form *L/Dec/C/C&L/Div*, where

L: Number of levels
Dec = Decomposition approach (see section "Decomposition Strategies: Sources of Parallelism")
- *A*: Algorithm
- *SE*: Search Space explicit decomposition
- *SI*: Search Space implicit decomposition – Independent multi-search
- *SC*: Search Space implicit decomposition – Cooperative multi-search
- *MM*: Mathematical structure decomposition – Mathematical programming
- *MA*: Mathematical structure decomposition – Attributes

Search Strategy (see section "Search Strategies"):

- *C* = *1C*, *pC*: Type of control of the search strategy
- *C&L* = *S*, *A*, *K*: Communication and learning mechanism
- *D* = *SPSS*, *SPDS*, *MPSS*, *MPDS*: Solver and starting-point diversity

Decomposition Strategies: Sources of Parallelism

Parallel/distributed/concurrent computing means that several processes work simultaneously on several processors to address a given problem instance, aiming to identify the best possible solution for that instance. Parallelism thus follows from a decomposition of the total computational load and the distribution of the resulting tasks to available processors, which run in parallel, possibly exchanging information. According to how "small" or "large" the tasks are in terms of algorithmic work or search space, the parallelization is called *fine-* or *coarse-grained*, respectively. The decomposition may concern the algorithm, the search space, or the problem and formulation mathematical structure.

Also called "functional parallelism," *algorithm*-based decomposition focuses on computing-intensive parts of the algorithm. The goal is to separate the corresponding work into a number of tasks (processes or threads), working on the same data or on dedicated parts of the data, and to allocate them to different processors. The concurrent execution of the innermost loop iterations, e.g., evaluating neighbors, computing the fitness of individuals, or having ants forage concurrently, provides the main source of functional parallelism for meta-heuristics. In fact, this is often also the only source of readily available parallelism in meta-heuristics. Indeed, the execution of most other steps in a meta-heuristic algorithm depends on the status of the search, e.g., what has been performed so far and the values of the decision variables, which requires the computation of the previous steps to be completed. Even when this may be performed in parallel, the corresponding computational tasks must be synchronized to wait for the slowest one to complete, which generally yields significant delays, making such parallel computation non-relevant. Section "Algorithm-Based Parallelization Strategies" reviews the main developments and trends based on this decomposition approach.

Search space separation (*SSD*) constitutes a second major class of decomposition strategies, as parallelism for meta-heuristics may also be found in the domain of the problem formulation or the corresponding search space (for brevity reasons and without loss of generality, the term *search space* is used in this chapter).

The fundamental idea of the *explicit* SSD (the term "domain decomposition" is also found in the literature) is to create as many tasks as the number of resulting subspaces. Each task then addresses the original problem/formulation on its particular subspace. Notice that, theoretically, the parallelism present in the search space is as large as the space itself, provided a processor is assigned to each solution. Obviously, this is not practical. Hence, a coarser decomposition is used in most cases of interest, and an exact or heuristic search method is assigned to each task.

Section "Explicit Search-Space Decomposition" reviews the main developments and trends based on this decomposition approach. The explicit SSD may proceed through a *partition* of the space, i.e., there is no intersection between any two subspaces created, or through a separation that allows *overlaps* between two or more subspaces. Both cases raise a number of issues with respect to the overall meta-heuristic search strategy, e.g., how to separate and create the tasks; how to build a complete solution out of the ones obtained on each subspace; how to allocate resources for an efficient exploration avoiding, for example, regions with poor-quality solutions. Trade-offs must be examined and decided. Thus, for example, partitioning may simplify the treatment of some of these issues, e.g., reconstruction of complete solutions, due to its assurance that no data dependencies exist between the optimization processes of the various tasks, which may therefore be fully performed in parallel, yielding unique solutions for each subspace. Partitioning may hinter exploration; however, as solution transformations (e.g., moves and combinations of individuals) performed close to subspace boundaries overlook possibilities involving solutions on the "other" side of the border. Allowing overlapping subspaces addresses this flaw, but requires a more careful construction

of a complete solution out of partial solutions involving a certain number of the same variables with possibly different values.

Implicit SSD is performed through concurrent explorations of the search space by several solvers, which could implement the same solution method but start their exploration from different points of the search space. The final complete solution to the problem at hand is then selected when all solvers have completed their explorations. Implicit SSD belongs to the larger class of *multi-search* meta-heuristics (the terms "multiple walks" is also to be found in the literature), which also includes the algorithms produced through the attribute-based decomposition of the mathematical structure of the problem and model introduced further.

Two classes of implicit SSD strategies are defined. *Independent* search involves several solvers that do not exchange any information, except at the very end when the best solution is extracted. As discussed in section "Implicit SSD: Independent Multi-search," independent search strategies are very easy to implement and may display interesting performances. They are generally outperformed, however, by well-designed and implemented parallelization strategies based on *Cooperation*. Cooperative search is based on inter-process communication and information-exchange mechanisms. A rather broad spectrum of cooperation strategies may be defined, from the simple exchange of the current best solutions, to learning mechanisms based on exchanged data that yield new information to guide the global and individual searches. Cooperative strategies are at the core of the most successful developments in parallel meta-heuristics and are the object of the last three sections (preceding the "Conclusions").

Parallelism may also be obtained by decomposing along the mathematical structure of the problem and formulation. The tasks generated through such *mathematical structure*-based decomposition strategies address partial problems (called subproblems by a number of authors) obtained either through mathematical programming or attribute-based heuristic approaches. Mathematical-programming decomposition implicitly defines how a complete solution is built out of partial ones. In the latter case, some tasks work on the partial problems corresponding to the particular sets of attributes defined in the decomposition, while others combine the resulting partial solutions into complete solutions to the original problem. As described in section "Knowledge Creation in Cooperative Search," attribute-based mathematical structure decomposition belongs to the class of multi-search strategies and is largely based on cooperation.

Search Strategies

We build upon and enhance the classification of [34], generalizing that of [40], to describe the parallel search strategies for meta-heuristics and their characterizations in terms of how the global problem-solving parallel search is controlled, how information is exchanged among processes creating, eventually, new information, and the diversity of searches involved.

Control makes up the first characteristic (called "Search Control Cardinality" in previous versions). It specifies whether the global search is controlled by a *single* process or by *multiple* processes, which may collaborate or not. The two categories are identified as *1-control (*1C*)* and *p-control (*pC*)*, respectively. A process involved in the control of the global parallel search is named *controller* or *master*. The term *collegial* is used to designate a multiple-process control with collaborating masters, that is, when the controlling masters exchange information while the search proceeds and collectively steer the search path and determine its termination moment. (Recall that this chapter addresses the design of parallel meta-heuristics, not their implementation on particular computing infrastructures, which always identifies a particular process in charge of distributing the initial work and collecting the appropriate information to determine that the search ends.)

The second search characteristic, *Communications and Learning*, addresses the issue of information exchanges among processes and the utilization of those exchanges to build new information, which may be used to control and guide the search (this characteristics was previously named "Search Control and Communications"). Two types of communications are generally identified in parallel computing: *synchronous* and *asynchronous*. In the former case, all concerned processes stop and engage in some form of communication and information exchange at moments exogenously determined (number of iterations, time intervals, specified algorithmic stages, etc.), either hard-coded or imposed by a control (master) process. In the latter case, each process is in charge of its own search and of establishing communications with other processes according to its own internal rules and status.

Learning in this context refers to the integration of mechanisms to (1) store all or part of the information exchanged, (2) derive/extract additional information from these exchanges and stored data, and (3) use this enhanced knowledge to build a global view of the status of the parallel search and guiding information for the individual searches involved and, hence, for the global search.

Three categories are defined to reflect the communication type and the learning capabilities offered by a search strategy:

- *Synchronous* (*S*) communications with no learning ("Rigid Synchronization," RS, previously)
- *Asynchronous* (*A*) communications with no learning ("Collegial," C, previously)
- *Knowledge* (*K*; replaces the previous "Knowledge Synchronous," KS, and "Knowledge Collegial," KC, categories)

More than one solution method or variant may be involved in a parallel meta-heuristic, and the methods may be meta-heuristics or exact. The third component of the Search Strategy dimension of the taxonomy describes the degree of *Diversity* of the global parallel search with respect to the nature of the methods involved and the corresponding starting solutions, the same or different in both cases (this dimension was identified as "Differentiation" in previous versions). Note that one characterizes two solvers as "different" even when based on the same methodology (e.g., Tabu Search, TS, or Genetic Algorithm, GA), provided they use different search strategies

in terms of components (e.g., neighborhoods or selection mechanism) or parameter values. The four classes are:

- *SPSS*: Same initial Point/Population, Same search Strategy
- *SPDS*: Same initial Point/Population, Different search Strategies
- *MPSS*: Multiple initial Points/Populations, Same search Strategies
- *MPDS*: Multiple initial Points/Populations, Different search Strategies

where "point" relates to neighborhood-based single-solution methods, while "population" is used for population-based ones.

Performance Measures

The traditional goal when designing parallel solution methods is to reduce the time required to "solve," exactly or heuristically, given problem instances or to address larger instances without increasing the computational effort. For exact solution methods running until the optimal solution is obtained, this translates into the well-known *speedup* performance measure, computed as the ratio between the wall-clock time required to solve the problem instance in parallel with p processors and the corresponding solution time of the best-known sequential algorithm. A somewhat less restrictive measure replaces the latter with the time of the parallel algorithm run on a single processor. See Barr and Hickman [10] and Schryen [114] for detailed discussions of this issue, including additional performance measures.

Speedup measures are difficult to define, however, when the optimal solution is not guaranteed, including when the exact method is stopped before optimality is reached, which is obviously the case for meta-heuristics, in all senses of the term. Moreover, most strategies designing parallel meta-heuristics yield solutions that are different in value, composition, or both, from those of the sequential versions (when they exist). Hence, other than the acceleration of the search and the computational efficiency given the computing power committed to it, an equally important objective for parallel meta-heuristics is to what extend they outperform their sequential counterparts in terms of solution quality or, at least, support the claim of quality through a broader exploration of the search space. In other words, the parallel method should not require a higher overall computation effort than the sequential method or should justify the effort by higher-quality solutions.

Search *robustness* is another characteristic increasingly expected of parallel heuristics. Here, robustness is defined with respect to a problem setting, in the sense of providing "equally" good solutions to a large and varied set of problem instances, without excessive calibration, neither during the initial development, nor when addressing new instances. As discussed by Crainic and Toulouse [35, 36], multi-search methods, particularly those based on cooperation, are noticeable in this respect. They display a behavior quite different from those of the sequential methods involved and offer enhanced performances compared to sequential methods and other parallelization strategies in terms of solution quality and method robustness.

They are thus generally acknowledged as proper meta-heuristics in their own right [2].

Algorithm-Based Parallelization Strategies

Functional-parallelism-based strategies, exploiting the potential for task decomposition within the inner-loop computations of meta-heuristics, aim to accelerate the search without modifying the algorithmic logic, the search space, and the behavior of the sequential meta-heuristic. Hence, the label *low level* often associated with such strategies, and their still prevalent utilization as the lowest level of hierarchical parallelization strategies, or when addressing problem settings requiring a significant part of the computing effort to be spent in inner-loop algorithmic components or in function evaluations. The utilization of "recent" computing elements increasingly ubiquitous within most computers, such as the *graphical processing units* (*GPU*), is reviving the interest in this class of strategies, as impressive reductions in computing times may be obtained.

Most low-level parallel strategies belong to the 1/A/1C/S/SPSS class and are usually implemented according to the classical *master-worker* parallel programming model (the term "slave" is also abundantly found in the literature, particularly when the task concerns computing only, without any search). Typically, the exploration is initialized from a single solution or population, and the "master" process executes the single-control sequential meta-heuristic, decomposing computation-intensive tasks into subtasks dispatched to "worker" processes. Worker subtasks are obtained from the same unique point, solution or population, and are essentially of the same type. Hence, the SPSS characterization of such strategies. Workers receive their tasks from the master, execute them in parallel, and return the results to the master, which, once all the results are in, resumes the normal logic of the sequential meta-heuristic. The master has thus a complete view and control of the search status and execution; it decides the work allocation for all other processes and initiates communications. No communications take place among worker processes. Figure 2 illustrates this strategy (for a very limited number of processes, as in all figures in the chapter).

The neighborhood-evaluation procedure of the local search heuristics, used alone or as component of neighborhood- or population-based meta-heuristics (the latter implementing advanced "schooling" for offspring) is generally parallelized according to 1/A/1C/S/SPSS designs. The master groups the neighbors into tasks and sends them to workers. Each worker then executes the neighbour evaluation and, possibly, limited exploration (a few moves only out of each received neighbour or best-valued among them) procedure on its respective part of the neighborhood, and sends back the best, or first improving, neighbour found. The master waits for all workers to terminate their computations, selects the best move, and proceeds with the search.

The appropriate decomposition granularity, that is, the size of the tasks, depends upon the particular problem and computer architecture, but is generally computa-

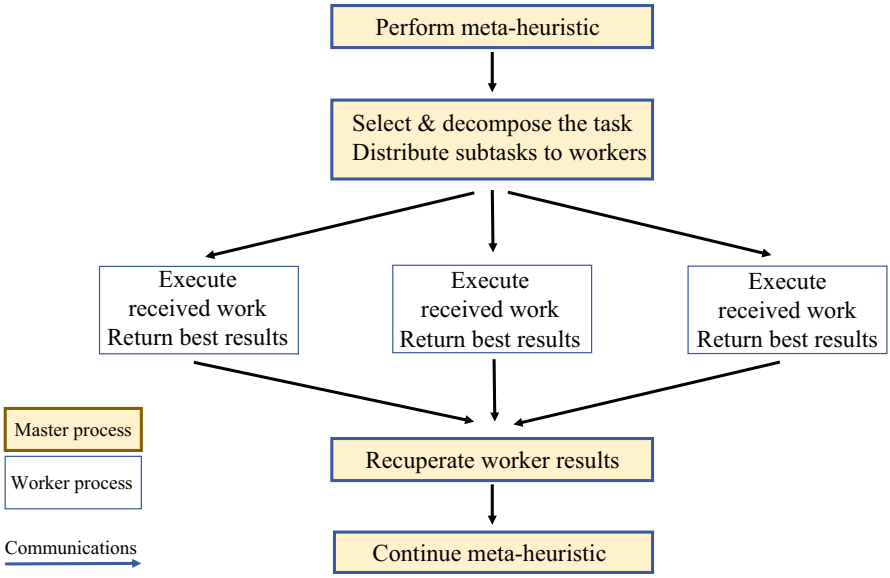

Fig. 2 Low-level 1/A/1C/S/SPSS parallelization strategy

tionally sensitive to inter-processor communication times and work-load balancing. The approach most often encountered in the literature partitions the set of neighbors, uniformly (sequentially) distributing them into subsets of same cardinality, determined by the number of processes available. Such an uniform-partition approach is appropriate when the work associated to each neighbor evaluation is similar and the processors are homogeneous. This is not always the case, however, even when processors are of the same type. The issue is illustrated in [49] for the permutation-based local search neighborhood (which performs very well within a sequential meta-heuristic) applied to the problem of scheduling dependent tasks on homogeneous processors. The dependency yields neighborhoods of unequal sizes, requiring different evaluation efforts. Computational results show that the uniform partition methods are not appropriate, the performance worsening with the amplitude of the variance in evaluation effort. A fixed coarse-grained nonuniform decomposition, based on the estimated computational effort of each subset, offers superior results, but it is not robust as it requires calibration each time the problem size or the number of processors changes. The best performing strategy, called *dynamic fine-grained* by the authors, defines each neighbor evaluation as a single task, the master dynamically dispatching these on a first-available, first-served basis to workers as they complete their tasks. The master still waits until all evaluations are completed, but the dynamic fine-grained strategy provides maximum flexibility and good load balancing.

Similar observations may be made regarding population-based meta-heuristics. In theory, all GA operators may be addressed through a 1/A/1C/S/SPSS design, and

the degree of possible parallelism is equal to the population size. In practice, the computations associated to most operators are not sufficiently heavy to warrant parallelization, while overhead costs may significantly reduce the degree of parallelism and increase the granularity of the tasks. Consequently, the fitness evaluation is often the target of algorithm-based parallelism for genetic-evolutionary methods, usually implemented using the master–worker model. The master partitions the individuals among workers, which compute and return the fitness of each individual, as well as aggregates figures to facilitate the computation by the master of the average population fitness once it receives the worker reports.

The algorithm-based parallelism for Ant-Colony Optimization (ACO) and, generally, swarm-based methods is found at the level of the individual ants. Ants share information indirectly through the pheromone matrix, which is updated once all solutions are constructed. There are no modifications of the pheromone matrix during a construction cycle and, thus, each individual ant performs its solution-construction procedure without data dependencies on the progress of the other ants. Many parallel ACO methods proposed in the literature implement some form of 1C/S/SPSS strategy according to the master-worker model (e.g., [52] and references herein). The master builds tasks consisting of small colonies of one or a few ants and distributes them to the available processors. Workers perform the construction heuristic and return their solution(s) to the master, which updates the pheromone matrix, returns it to the workers, and so on. To further speed up computation, the pheromone update can be partially computed at the worker level, each worker computing the update associated to its solutions. This fine-grained version with central matrix update outperformed the sequential version of the algorithm in most cases. It is acknowledged, however, that it does not scale when implemented on "traditional" processors (i.e., exploiting the central processing units – CPUs), and that, similarly to other meta-heuristics, it is outperformed by more advanced multi-search methods.

Scatter Search (SS) and Path Relinking (PR) implement different population-based evolution strategies, where a restricted number of elite solutions are combined, the result being enhanced through a local search or a full-fledged meta-heuristic, usually neighborhood-based. Consequently, the 1/A/1C/S/SPSS strategies discussed earlier apply straightforwardly, as in [57–59] for the p-median and the feature-selection problems. A different algorithm-based SS decomposition strategy may be obtained by running concurrently the combination and improvement operators on several subsets of solutions in the reference set. Here, the master generates tasks by extracting a number of solution subsets, which are sent to workers. Each worker then combines and improves its solutions, returning the results to the master for the global update of the reference set. Each subset sent to a worker may contain the exact or higher number of solutions required by the combination operator. In the former case, the worker performs an "iteration" of the SS algorithm [57–59]. In the latter case, several combination-improvement sequences could be executed and solutions could be returned to the master as they are found or all together at the end of all sequences. Load-balancing capabilities should be added to the master to avoid differences in work quantity and computing times between workers.

To conclude, algorithm decomposition with 1-control parallel strategies is particularly attractive when neighborhoods or populations are large, or when the neighbor or individual evaluation is costly. Computing-time gains may then be obtained, as illustrated by many early contributions to the field (discussed in the surveys indicated in the Introduction), as well as in the parallelization of the Variable Neighborhood Search (VNS) meta-heuristic proposed by [24]. The proposed parallel algorithm runs a single VNS, which executes in parallel the computations related to three steps: (1) identification of the initial solution: each process runs the local search out of a given starting solution; (2) the randomization ("shaking" in VNS vocabulary) of the solution provided by the local-search run: copies of the solution are distributed and each process performs a random modification; (3) the local search: the neighborhood evaluation is distributed. Each time, the master selects the best alternative.

Impressive gains may be obtained by taking advantage of the current computing platforms integrating multi-core central processing units (CPUs – the "traditional" processor) and more recent types of computing units, graphical processing units (GPUs), in particular. Enhanced with data streaming capabilities, the latter provide hardware data parallelism and the means for each processor to perform the same task on different (but rather small) parts of the distributed data [14, 15]. This hardware technology offers the possibility of extensive very low-level parallelization reminiscent of the work performed by the massively parallel computers of the late 1980s. Neighborhood evaluations, population fitness computation, and, even, the evolution of individuals in swarms may benefit from such a hardware-oriented parallelization, significant speedups having been observed, e.g., [14, 15, 23, 50, 56, 74, 95, 108, 121, 130]. A number of remarks are in order, however. First, the utilization of this technology is not straightforward, and work must be dedicated to its conceptual, technical, and experimental aspects (see, e.g., [93]). Second, there is also the need to examine the sequential and parallel meta-heuristic designs to identify and valuate where this technology would bring the most benefits, besides those already identified. The work of [109] is a step on this research path. Finally, as discussed in the following sections, more advanced multi-search strategies outperform low-level strategies in most cases, in particular with respect to solution quality. Consequently, hierarchical settings combining multi-search strategies and 1/A/1C/S/SPSS evaluation procedures, all on CPU-based architectures, are generally used currently. More research is needed in this area to account for the massively parallel possibilities of new types of computing units.

Explicit Search-Space Decomposition

The basic idea of this class of strategies is intuitively simple and appealing: separate the search space into smaller subspaces, address the resulting subproblems by applying the sequential meta-heuristic on each, collect the respective partial solutions, and reconstruct an entire solution out of the partial ones. This apparently simple idea may take several forms, however, according to the type of separation

performed, the permitted links among the resulting subproblems, the possible iterative modification of the separation, and the type of control of the parallel meta-heuristic.

As indicated in the taxonomy, the decomposition may yield *partition* or a *cover* of the complete search space. In the former case, the resulting subspaces are disjoint, while some overlaps are allowed among groups of subspaces in the latter. Thus, for example, the customer nodes, and the corresponding arc-design variables, of a Vehicle Routing Problem (VRP) may be partitioned into customer subsets (including the depot in each subset), while a cover would allow customers in a subset located "close by" another subset to belong to both. Note that covers may be defined implicitly by allowing the search within a given subspace to reach out to some part of one or several other subspaces through, e.g., neighborhood moves or individual crossovers. The union of the subspaces makes up the complete space in all cases.

Strict partitioning restricts the solvers to their subspaces, resulting in part of the search space being unreachable and the loss of exploration quality for the parallel meta-heuristic. Covers, through explicit or implicit overlapping, partially address this issue. Indeed, to guarantee that all potential solutions are reachable, one must make overlapping cover the entire search space, which would negate the benefits of decomposition. To avoid these drawbacks, one can change the separation and start again. This idea translates into a strategy encountered quite frequently, where the separation is modified periodically, and the search is restarted using the new decomposition. A complete-solution reconstruction feature is almost always part of the procedure. Note that this approach also provides the opportunity to define non-exhaustive separations, i.e., where the union of the subspaces is smaller than the complete search space.

This strategy is naturally implemented using master–worker L/SE/1C/S schemes, with MPSS or MPDS search differentiation (Fig. 3). The master determines the separation and sends partial subsets (or information to define them out of the initial space – this reduces the communication overhead) to workers, synchronizes them and collects their solutions, reconstructs complete solutions, modifies the separation, and determines when stopping conditions are met. Workers concurrently and independently perform the search on their assigned subsets. Most implementations in the literature address problem settings for which a large number of iterations can be performed in a relatively short time and restarting the method with a new decomposition does not require an unreasonable computational effort (see, e.g., [65] for real-time ambulance fleet management), a full-fledged meta-heuristic being generally used on each subspace.

Explicit space separation may also be performed in a multi-control decision-making framework with MPSS or MPDS search-differentiation (Fig. 4). According to an L/S/pC/S strategy, the separation is collegially decided and modified following information-exchange phases (round-robin bilateral or many-to-many exchanges) activated at given synchronization points. Solvers may exchange their best solutions only (e.g., routes in a VRP), or add the so-called context information that may be used when modifying the separation (e.g., unserviced customers and empty vehicles in a VRP [118]), respectively.

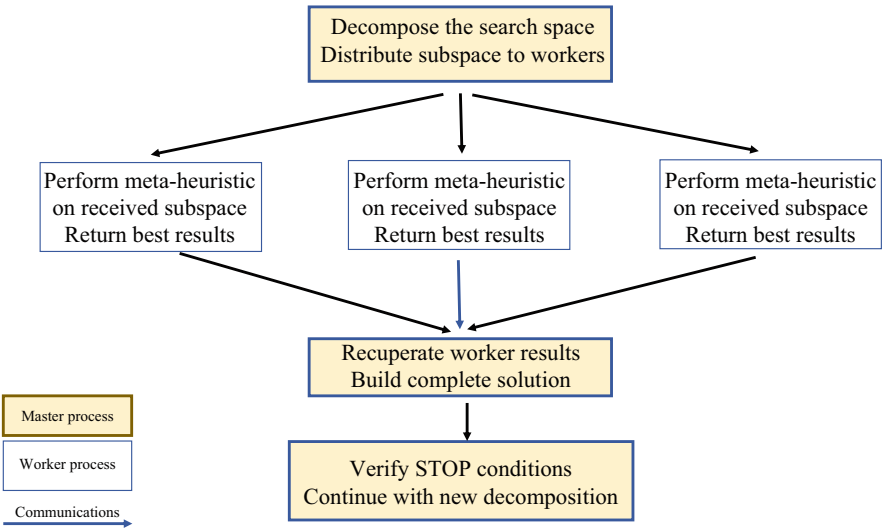

Fig. 3 Explicit search-space single-control decomposition L/SE/1C/S/ strategy

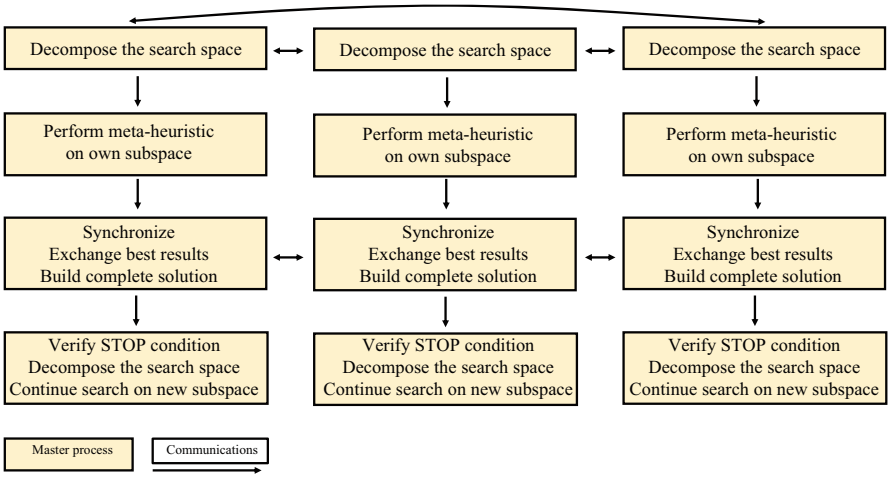

Fig. 4 Explicit search-space multiple-control decomposition L/SE/pC/S strategy

We conclude this section with two observations. First, we notice that explicit search-space decomposition corresponds to imposing restricted value ranges to all the decision variables of the formulation. In practice, this is rather performed by identifying a subset of variables, and corresponding constraints, eventually, and discarding or fixing the other variables and constraints, the goal being to obtain smaller, easier to address subproblems. However, it is not always possible, or even desirable, to discard. To illustrate, consider an explicit search-space decomposition

according to subsets of demands for the VRP and the Multicommodity Capacitated Network Design problem (MCND). VRP demand is defined at customer nodes, and the decomposition separates those into subsets. One may then easily eliminate the VRP customers that do not belong to a given subspace, as well as the network links connecting them (the depot node and the appropriate depot-customer links must be included), and solve the resulting restricted VRP. MCND demand is defined by origin-destination pairs of nodes. Partitioning the set of OD demands is straightforward. But, eliminating the OD pairs not part of a given subset, as well as the links making up the paths connecting them, would result in unconnected networks and infeasible subproblems. Separation by variable fixing (and projection of the corresponding constraints) is thus preferable. It yields the desired search-space decomposition into smaller subproblems. It is also more general, offering increased flexibility, as variables may be fixed at values other than zero. Moreover, considering the complete vector of decision variables provides the opportunity of a more thorough evaluation of solutions and possible changes.

The second observation is that explicit search-space decomposition strategies induce different search behavior and solution quality compared to those of the sequential meta-heuristic. Their performance appears dependent on how well and efficiently one avoids overlooking important regions of the search space, while purposely advancing toward good complete solutions. The effort to achieve these goals if often too high compared to the final benefits, particularly with respect to the performance of an efficient cooperation-based meta-heuristic. Hence, using explicit search-space decomposition as stand-alone strategy does not present significant interest.

On the other hand, one observes a continuous increase in the complexity of the problem settings and the dimensions of the instances one needs to address. In this context, combining search-space decomposition (through variable fixing, principally) and cooperative search appears very promising. The Integrative Cooperative Search [82] is a step in this direction (see section "Knowledge Creation in Cooperative Search").

Implicit SSD: Independent Multi-search

We dedicate a section to the *independent multi-search* search-space decomposition strategy as it was among the first to be proposed in the literature and is also the most simple and straightforward p-control parallelization strategy, generally offering an interesting performance.

Independent multi-search seeks to accelerate the exploration of the search space toward a good solution, compared to the classical multi-start sequential search. It proceeds by initiating simultaneous solvers, with or without different search strategies, from different initial points, and selecting at the end the best among the best solutions obtained by all solvers (Fig. 5).

Independent multi-search methods belong to the L/SI/pC/S class of the taxonomy, with a MPSS or MPDS diversity strategy. They do not change the behavior

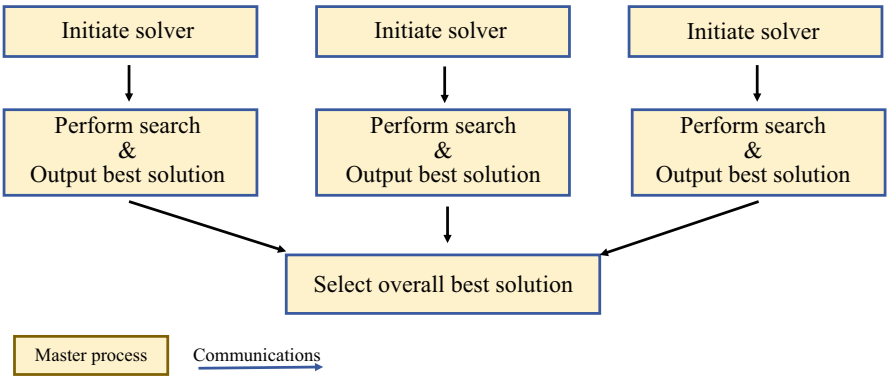

Fig. 5 Implicit search-space multiple-control decomposition L/SI/pC/S strategy

of the corresponding multi-start heuristic. No attempt is made to take advantage of the multiple solvers running in parallel other than to identify the best overall solution at the final synchronization step. The efficiency of independent multi-search follows from the sheer quantity of computing power it allows one to apply to a given problem. The references identified in the Introduction describe numerous applications of the independent multi-search strategy to a variety of combinatorial optimization problems.

Independent multi-search offers an easy access to parallel meta-heuristic computation, offering a tool when looking for a "good" solution without investment in methodological development or coding. Such methods are generally outperformed by cooperative strategies, however, through mechanisms enabling the independent solvers to share, during the search, the information their exploration generates. As explained in the following sections, this sharing and the eventual creation of new information out of the shared one yield in most cases a collective output of superior solutions compared to independent and sequential search.

Cooperative Search

Cooperative (multiple or multi) search has emerged as one of the most successful classes of meta-heuristic methodologies to address hard optimization problems. While independent multi-search seeks to accelerate the multi-start sequential heuristic, search strategies based on cooperation go further and integrate *cooperation mechanisms* to share, *while the search is in progress*, the information obtained from this diversified exploration of the same problem instance. The global search behavior of a cooperative meta-heuristic emerges from those interactions and sharing, including, eventually, the creation of new information out of the exchanged data. (The similarity between this behavior and that of systems where decisions emerge from interactions among autonomous and equal "colleagues" has inspired

the name“collegial control” associated to cooperative-search strategies in earlier versions of the taxonomy.) This behavior is different compared to those of the solvers acting individually or in sequence (as in the multi-start case). It actually makes cooperative search a “new” meta-heuristic class in its own right, which provides in many cases better performances and solutions compared to sequential and parallel independent search [37].

Cooperative-search strategies are defined by the multiple solvers engaged in cooperation (*pC* control) and the *information-sharing cooperation mechanism* defining their interactions. The solvers define trajectories in the search space from possibly different initial points or populations, by using possibly different meta-heuristic or exact-search strategies. The goals of the cooperation mechanism are to (1) improve the performance of the solvers involved, and (2) create as much as possible a “complete” image of the status of the global search to enable guiding it, through participating solvers, toward a better performance, in terms of solution quality and computational efficiency, than the simple concatenation of results obtained by non-cooperating solvers.

A list of questions related to addressing this challenge that was initially proposed by Toulouse, Crainic, and Gendreau [123], and refined in later contributions. It is still relevant today:

- What information to exchange?
- Between what processes to exchange?
- When to exchange?
- How to exchange?
- How to use/act on imported/received data?
- What knowledge to create and use out of exchanged data?

More than implementation details, answers to these questions constitute the core design parameters of a cooperative meta-heuristic. Thus, for example, a (not very good) cooperation mechanism has *all* solvers stop and *synchronize periodically*, exchange their *best local solutions*, and *restart* their individual searches from the newly-identified *best overall solution*. Cooperation mechanisms proposed in the literature to answer these questions are described in the next sections, following a number of general observations.

Exchanged information must be *meaningful* and exchanges must be *timely*. “Good” solutions make up the most often exchanged type of information, usually taking the form of the overall best solution or the current-best solution of a solver being sent to the others. Broadcasting all the new best solutions a solver identifies is counter productive in most cases, however. This is particularly true when the solver performs a series of improving moves or generations, as solutions are generally “similar” (particularly for neighborhood-based procedures), and the receiving solvers either have no chance to act on the in-coming information (unless special receiving mechanisms are embedded in all solvers) before receiving a new solution, or may embark on explorations similar to that of the sending solver. It was also observed that always broadcasting the overall best solution to all cooperating

solvers is generally bad as it rapidly decreases the diversity of the search, increasing the amount of worthless computational work (many solvers will search in the same region) and bringing an early "convergence" to a not-so-good solution. Sending out the local optima after a series of improving moves, groups of solutions, or a random selection of elite solutions, the latter biased toward good or good-and-different solutions, are among the strategies aimed at addressing these issues.

Context information may also be shared profitably when embedded in the mechanisms used to guide the search. Context information refers to data collected by a solver during its own exploration, such as the statistical information relative to the presence of particular solution elements in improving solutions (e.g., the medium and long-term Tabu Search memories), the impact of particular moves on the search trajectory (e.g., the scores of moves of a Large Adaptive Neighborhood Search), population diversity measures, individual resilience across generations, etc. A limited number of studies indicate the interest of context-information exchanges, but more research is needed on this topic.

Cooperating solvers may exchange information directly or indirectly. *Direct* exchanges of information occur either when the concerned solvers agree on a meeting point in time to share information, or when a solver broadcasts its information to one or several other solvers without prior mutual agreement. The latter case is to be avoided as it requires solvers to include capabilities to store received information without disturbing their own search trajectories until they are ready to consider it. Failure to implement such mechanisms generally results in bad performances, as observed for strategies combining uncontrolled broadcasting of information and immediate acceptance of received data.

Indirect exchanges of information are performed through independent data structures that become shared resources of data. Solvers may access them asynchronously and according to their own internal logic to post and retrieve information. Such data structures are called *blackboard* in the computer-science and artificial-intelligence vocabulary, while *memory*, *pool*, and *data warehouse* (*reference* and *elite set* are also sometimes used) are equivalent terms found in the parallel meta-heuristic literature. The term *memory* is used in this chapter.

Centralized-memory mechanisms have been used in most parallel meta-heuristic contributions. They receive, eventually process, and post information received from cooperating solvers, which, in turn, may retrieve this information independently. Distributed memory mechanisms may be contemplated, where a number of memories are interconnected, each servicing a number of solvers. Such hierarchical structures, with several layers of solvers and memories, appear interesting when a large number of processors is involved, when computations are to take place on grids or loosely coupled distributed systems, and for integrative cooperation strategies. Issues related to data availability, redundancy, and integrity must then be addressed, as well as questions relative to the balancing of workloads and the volume of information exchanged. More research is needed on this topic.

Communications proceed according to an interaction topology represented by a *communication graph* specifying the processes that may engage in direct exchanges and, thus, directing the flow of information within the cooperative search. Each

node of the graph represents a solver or a memory. Edges define pairs of solvers or a solver–memory pair, which may engage in direct communications. Figure 6 illustrates two communications graphs involving solvers only, a complete graph on the left, and a grid on the right, while communications pass through a central memory in the setting of Fig. 7. The projection of this graph on the physical interconnection topology of the computer or computers executing the parallel program is generally part of the implementation design.

When and how information is shared specifies the frequency of cooperation activities, who initiates them and when, and whether the concerned solvers must synchronize, each stopping its activities and waiting for all others to be ready, or not. These two cases correspond to the *synchronous* and *asynchronous* characteristics of the Communications and Learning component of the taxonomy and are discussed in the following sections. A general observation for both cases, however, is that exchanges should not be too frequent to avoid excessive communication overheads as well as premature "convergence" to local optima [124, 125, 127, 128].

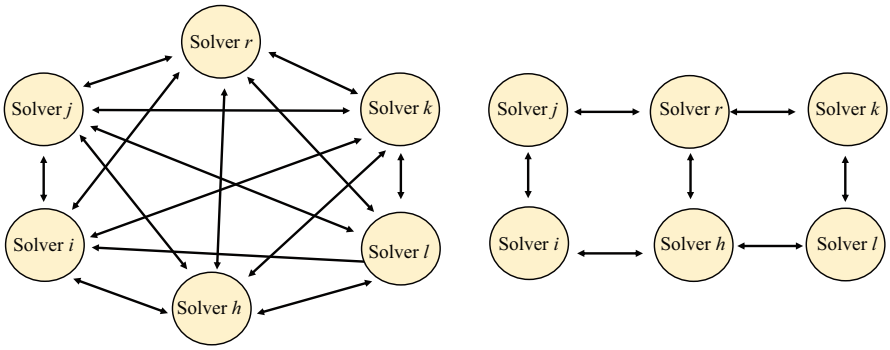

Fig. 6 Interconnection communication graphs

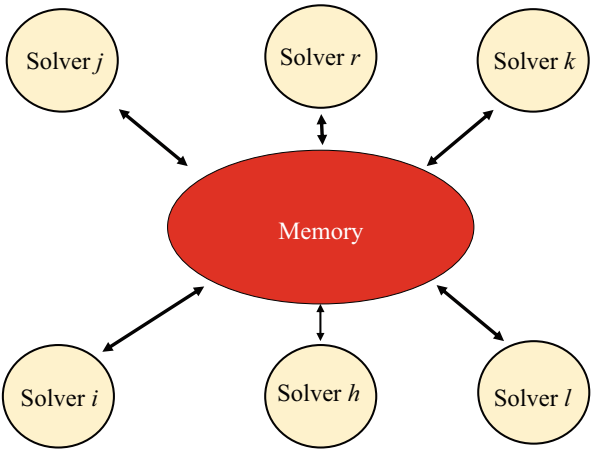

Fig. 7 Indirect memory-based communication graph

Two observations to conclude this general discussion about cooperation. First, it is worth noticing that cooperation is somewhat biased toward intensifying the search in regions of the space that have already been explored and where interesting solutions have been identified. This is particularly true for "simple" cooperation mechanisms based on synchronization or on exchanging current-best solutions only. It is thus important to equip the cooperation strategies with diversification capabilities, such as, solver "welcoming" mechanisms to adapt incoming solutions to the local search environment and status (e.g., a crossover operator applied to the incoming and local solutions [90]), probabilistic or diversity-driven selection of exchanged solutions [131], or creation of new solutions and guidance information [82].

Second, the main principles of cooperative parallelization are the same for neighborhood- and population-based meta-heuristics, even though denominations and implementation approaches may differ. We thus structure the presentation that follows based on these principles and general strategies, rather than by meta-heuristic class.

Synchronous Cooperation

Synchronous cooperation, without knowledge creation, follows a L/SC/pC/S strategy, with any of the SPDS, MPSS or MPDS search diversity approaches. We dedicate this section to recalling the main concepts of synchronous cooperation, some of which found their way into more advanced strategies, encouraging interested readers to consult the contributions indicated in the Introduction for details and references.

All the solvers involved in the cooperation stop their activities at particular moments and engage in an information-exchange phase, which must be completed before any solver can restart its exploration from that synchronization point. Synchronization moments may be determined by conditions imposed exogenously to all solvers (e.g., number of iterations from the last synchronization point) or detected by an a priori designated solver. Synchronization may use a complete communication graph or a more restricted, less densely connected topology (e.g., ring, torus, and grid graph; Fig. 6). *Global* exchanges of information among all cooperating solvers take place in the former case, while information follows a *diffusion* process through *local* exchanges among neighbouring processes in the latter. In all cases, one aims to re-create a state of complete knowledge at particular points in the global search and, thus, to hopefully guide it into a coordinated evolution toward the problem solution.

In a restricted view of the concept, most early 1/SC/pC/S cooperative search meta-heuristics based on global exchanges use a designated *master* process, which may or not include one of the participating solvers. The master manages the synchronization mechanism in a master–worker implementation. It initiates the global search starting the solvers, stops all solvers at synchronization points, gathers the information, updates the global data, verifies the termination criteria of the search and, either effectively terminates it or distributes the shared information

(a good solution, generally, the overall best solution in many cases) and sends a signal to the solvers to continue the search. For coarse-grained island (each island corresponding to a sub-population) implementations of cooperating GA methods, synchronization means the communication master initiates the *migration* operator to exchange among the islands the best or a small group of some of the best individuals in each. A similar approach is seen for ACO systems, dividing the colony into sub-colonies individually assigned to solvers, the master updating the pheromone matrix, and starting a new search phase, based on the received solver results [54]. A more sophisticated approach is proposed in [98] (and alluded to in [6]), where the master dynamically adjusts the search parameters of cooperating TS solvers according to the results each has obtained so far. The method performed well on the 0-1 Multidimensional Knapsack Problem, which is encouraging, as the idea of dynamic adjustment of the search parameters may be generalized to other problem settings and more sophisticated cooperation mechanisms.

A truer global pC/S cooperative scheme empowers solvers to initiate synchronization. Once it reaches a predetermined status, a solver sends the stopping signal, broadcasts its data (current best solution or group of solutions, in most cases), followed by similar broadcasts performed by the other solvers. Once all information is shared, each solver performs its own import procedures on the received data and proceeds with its exploration of the search space until the next synchronization event. Most synchronous coarse-grained island parallelizations of GA-based evolutionary methods fall under this category, where migration operators are applied at regular intervals. Similarly, global synchronization for ACO applications where each colony evolves its own pheromone matrix, generally means that, after a fixed number of iterations, colonies exchange elite solutions that are used to update the pheromone matrix of the receiving colony. Expanding this idea to hierarchical designs, a 2/SC/pC/S strategy for genetic methods may have the fitness computation performed at the second level through a master–worker low-level parallelization [73]. Note that the associated overhead due to the latter parallelization may became significant for larger numbers of processors.

Synchronization based on global exchanges of information generally incurs an excessive communication overhead and computing-time inefficiency as exchanges are initiated only when the slowest solver is ready to start. The overhead may further increase in hierarchical parallel contexts. A second main drawback of synchronous cooperation is that solvers relying heavily on the same information end up exploring the same search-space regions, which results in loss of diversity and favors premature "convergence" to local optima. Two approaches have been proposed to overcome this drawback.

The first approach is to avoid sharing local-best solutions only. The 1/SC/pC/S/MPDS iterated Tabu Search proposed for the VRP by [25] illustrates this approach, where solvers synchronize after a number of consecutive iterations without improvement within each individual search. Solvers then exchange a number of the good solutions obtained and, then, each individual solver builds a new starting solution by selecting routes probabilistically among those received and its own. Computational results show this method to be flexible and efficient for

several classes of routing settings with several depots, periodicity of demands, and time windows.

The second approach is based on *diffusion*, supported by sparse communication graphs (e.g., the grid in Fig. 6). Then, direct communications at synchronization points are possible only with neighboring solvers, i.e., with adjacent nodes in the graph. The quantity of information each solver processes and relies upon is thus significantly reduced. Information is still shared between non-adjacent solvers, but at the reduced diffusion speed of chains of local exchanges and data modifications by the intervening solvers. This idea was less explored compared to the global-exchange strategy, even though synchronous cooperative mechanisms based on diffusion have a less negative impact on the diversity of the exploration and have yielded good results (e.g., [97, 122]).

To conclude, synchronous-cooperation strategies generally outperform the sequential versions and independent multi-search parallelization strategies. Yet, they also display a number of inherent drawbacks. Asynchronous information sharing addresses these challenges and, indeed, cooperation strategies based on asynchronous exchanges generally outperformed synchronous methods. We discuss these strategies in the next two sections.

Asynchronous Cooperation

Historically, multi-search independent and synchronous cooperative methods were the first to be developed. The focus has shifted to asynchronous cooperation, which may be considered as defining the "state-of-the-art" in parallel multi-search meta-heuristics.

A L/SC/pC cooperation strategy, with SPDS, MPSS, or MPDS search diversity, is asynchronous when solvers initiate exchange activities according to their own internal logic, without coordination with other solvers. Thus, e.g., a solver may make available its current best solution by posting it on a memory, or may ask for an external solution when it fails to improve the quality of its best solution for a certain number of iterations. Asynchronous cooperative strategies follow either pC/A or pC/K communication-and-learning principles, the main difference being that the latter create new knowledge based on the information exchanged between solvers; pC/K strategies are addressed in the next section.

Asynchronous communications provide the means to build cooperation and information sharing among solvers without incurring the overheads associated with synchronization. They also bring adaptability to parallel cooperative meta-heuristics, which may more easily react and dynamically adapt to the exploration of the search space than independent or synchronous searches. These benefits come with potential issues one must care for, however. Two major ones are:

- The information related to the global search available to a solver performing its search may be less "complete" than in a synchronous environment; This implies

that some solvers might explore more or less the same regions. The learning mechanisms discussed in the next section help addressing this issue.
- High data-exchange frequency may be damageable; It may disrupt the work of receiving solvers and induce an erratic search behavior, similar to a random walk, particularly when the local search is altered significantly by the incoming data (e.g., the search is restarted from the received solution); Providing solver processes with mechanisms to "quarantine" incoming messages and data alleviates in part this issue, but at a generally high efficiency cost.

Hence, the interest in applying information-sharing principles based on quality, meaningfulness, and parsimony [39,40,123]. With respect to the information shared, these principles mean:

- Exchange very good solutions or individual(s) only, rather than "all" locally improving ones; Many successful contributions in the literature involve sharing local optima only;
- *Diversify* the shared information. A diversifying strategy, for example, (1) collects the very good solutions sent by the solvers into a global *elite set*, and (2) returns to a requesting solver a solution selected randomly, but biased by quality, among the elite set. Such a strategy outperformed sending always the best available solution in the elite set [39].

When to initiate and perform cooperation activities, as well as how to use the incoming information, is part of the parallel design with potentially important impact on performance. Most strategies proposed in the literature implement the same idea, to send and request information jointly. There is no need to do this, however, even though it can decrease the amount of communications. It may thus be interesting for neighbourhood-based methods to make available right away their newly found local optima or improved overall solutions and not wait for the algorithmic step when requesting and examining external information is appropriate. Similarly, population-based methods may migrate a number of individuals when a significant improvement is observed in the quality and diversity of their elite group of individuals.

Regarding the request for external information, it may be based on a a priory fixed number of iterations, but this approach should be restricted to meta-heuristics without search-diversification steps, e.g., Tabu Search based on continuous diversification. In most other cases, the principle of parsimonious communications implies selecting moments when the status of the search changes significantly, e.g., when the best solution or the elite subpopulation did not improve for a number of iterations. At such moments, solvers generally engage into some form of search *diversification* phase involving the choice of a different solution to initiate a new phase, e.g., the TS diversification based on long-term memories, the change of neighborhood in VNS, the random modification of the current local-best solution in GRASP, and the complete or partial regeneration of population in population-based meta-heuristics. External information, which generally includes at least one good solution, may

prove particularity interesting at that moment. How it is to be used depends on the particular logic of the receiving solver. It may be used, for example, to initiate a diversification phase, or to modify the search trajectory through a combination with a "local" solution, or to modify the solver behavior in the long run through an insertion into an elite set. As already mentioned, one tries to avoid frequent imports followed by a replacement of the current solution or population, which generally results in a random search.

Direct and indirect exchange pC/A strategies may be used with any meta-heuristic. Historically, most GA-based asynchronous cooperative meta-heuristics relied on direct exchanges over complete [20] or sparse (e.g., ring) [89] communication graphs. These methods generally implement a coarse-grained island model, migration being triggered by conditions within individual island populations. The selected migrant individuals are then directed toward either adjacent islands when the graph is sparse or, when the graph is complete or dense, to all other populations or a dynamically selected subset. The work of [129] illustrates the latter case, where migration is initiated by an island that identifies a new best solution, which it sends to all other islands. To enforce diversity, the migrant is accepted only when different from the local population and better than the worst individual in that population. We also mention the work of [76], who introduced genetic solvers with different strategies, which was a novelty in the GA-island field (previously, all island populations were evolved by the same algorithm), and observed significant improvements compared to more traditional island-based pC/A models. The parallelization of ACO methods may use the same approach, where partitions of the initial colony play the role of islands. The contribution of [87] is interesting in this context for a novel way of selecting the receiving subcolony (island). Here, a solver initiates an exchange when the evolution of its colony becomes stagnant (no longer improving) by selecting an exchange partner probabilistically based on the relative distance (the most different best solution) and fitness (of the best solution); it then requests the current best solution from the selected partner and, upon reception, updates its pheromone matrix and continues the search. An interesting extension of the island-cooperation idea to a 2-level strategy defines meta-heuristic-specific "archipelagos" of islands, with particular Communication-and-Learning strategies at each level [5]. The authors propose GA and ACO archipelagos with asynchronous cooperation between them, while synchronous exchanges are enforced among the islands of each.

Relatively little attention has been dedicated to direct exchanges for asynchronous cooperation among trajectory-based meta-heuristics. We mention the work of [116] reporting encouraging results for VNS-based 1/SC/pC/A strategies over uni- and bidirectional ring topologies. More research on this topic is needed.

Historically, the sharing of information in most asynchronous cooperative search strategies outside the genetic-evolutionary community is therefore based on some form of indirect communications through a centralized device, the *central memory* illustrated in Fig. 7 [27, 39, 40]. A solver involved in such a cooperation deposits good solutions, local optima generally, into the central memory, from where, when needed, it also retrieves information sent by other cooperating solvers. Classical

retrieval mechanisms are based on random selection, which may be uniform or biased to favor solutions with high rankings based on solution value and diversity. The central memory accepts incoming solutions for as long as it is not full, acceptance becoming conditional to the relative interest of the incoming solution compared to the "worst" solution in the memory, otherwise. Diversity criteria are increasingly considered, a slightly worse solution being preferred if it increases the diversity of solutions in the central memory. Population culling may also be performed (deleting, e.g., the worst half of the solutions in memory).

Central-memory-based cooperative search strategies are described in the literature for most meta-heuristic classes. To the best of our knowledge, the first central-memory approach was proposed in [39] for a 1/SC/pC/A parallel Tabu Search addressing a multi-commodity location problem with balancing requirements. In the proposed strategy, individual TSs send to the memory their local-best solutions when improved and import a solution selected probabilistically biased by rank before engaging in a diversification phase. This method outperformed, in terms of solution quality, the sequential version as well as several synchronous and broadcast-based asynchronous cooperative strategies. The same approach was applied to the fixed cost, capacitated, multicommodity network design problem with similar results [32].

Asynchronous cooperation strategies with some form of central memory were proposed for a variety of problem settings, e.g., cutting [12], container loading [13], labor-constrained scheduling [22], and VRP with time windows (VRPTW) [84]. Another set of studies focused on asynchronous cooperation with indirect communications applied to particular classes of meta-heuristics, including Simulated Annealing (SA), e.g., [9, 86, 111]; VNS, e.g., [41, 105], the latter proposing a self-adapting mechanism for the main search parameters based on recent performance, and solution selection out of the ten best present in memory; GRASP with cooperation based on applying Path Relinking to solutions from memory [107]; and TS with memory hosting a reference set and long-term global memories built on short-term local memories sent by solvers [77].

Notice that cooperating solvers need not belong to the same meta-heuristic class. The next section presents several examples where different meta-heuristics collaborate within pC/K strategies. In the classical pC/A case, we find contributions following the same broad strategy described earlier when calling sequentially on meta-heuristics belonging to different types. The two-phase approach of [60] for the VRP with Time Window (VRPTW) is a typical example of such a method, where each solver first applies an evolution strategy to reduce the number of vehicles, followed by a TS to minimize the total distance travelled. A somewhat different two-phase pC/A parallel strategy is proposed in [11] for the Steiner problem, where each phase, using Reactive TS and PR respectively, implements the pC/A asynchronous central memory strategy, all processes switching from the first to the second phase simultaneously.

Multi-level cooperative search proposes a different pC asynchronous cooperative strategy based on controlled diffusion of information [126]. Solvers are arrayed in a linear, conceptually vertical, communication graph and a local memory is associated

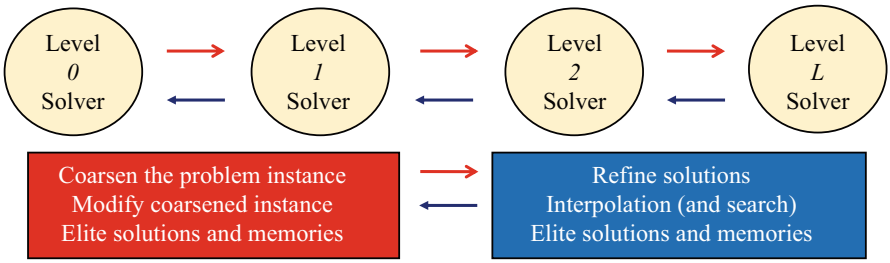

Fig. 8 Multi-level cooperation

with each. Each solver works on the original problem but at a different level of aggregation or "coarsening" of the problem data (e.g., selected network arcs being collapsed into nodes that inherit some of the arc attributes). The solver addressing the complete original problem works at the lowest aggregation level, identified in Fig. 8 as Level 0. Level L identifies the highest coarsening defined for the problem. Solvers communicate exclusively with the two solvers directly above and below, that is, at higher and lower aggregation levels, respectively (obviously, workers at levels 0 and L exchange with the next higher and lower level, respectively).

Coarsening reduces the dimensions of the problem instance at hand, which becomes easier to address. One may thus identify very good solutions faster. Moreover, one expects that a very good solution to an aggregated version of the problem will yield at least a good solution when projected on a more disaggregated problem setting. This projection process is called *refinement*. The idea of a coarsen-refine method therefore is to successively coarsen the instance until the desired resolution level and then to successively refine that solution until feasible to the original problem setting. The multi-level cooperation builds on this idea through asynchronous up and down communications among adjacent solvers, each taking advantage of the structure and quality of the solution received from the next lower or higher solver. Communications are regulated by the local memories that receive the information coming from the immediate neighbors and make it accessible to the local solver at moments dynamically determined according to its internal logic.

In the original implementation, solvers were exchanging improved solutions, incoming solutions not being transmitted further until modified locally for a number of iterations to enforce the controlled diffusion of information. Excellent results were obtained for various problem settings including graph and hypergraph partitioning [101, 102], network design [43], feature selection in biomedical data [99], and covering design [48]. It is noteworthy that one can implement multi-level cooperative search through a central memory by adequately defining the communication protocols. Although not yet fully defined and tested, this idea is interesting as it opens opportunities for richer exchange mechanisms combining controlled diffusion and general availability of global information.

Central-memory asynchronous cooperation strategies are generally offering very good results, yielding high-quality solutions. They are also computationally efficient

as no overhead is incurred for synchronization. No broadcasting is taking place, and there is no need for complex mechanisms to select the solvers that will receive or send information and to control the cooperation. It has also proved efficient in handling the issue of premature "convergence" in cooperative search, by diversifying the information received by the solvers through probabilistic selection from the memory and by a somewhat large and diverse population of solutions in the central memory; solvers may thus import different solutions even when their cooperation activities are taking place within a short time span. The central memory is thus an efficient algorithmic device that allows for a strict asynchronous mode of exchange, with no predetermined connection pattern, where no solver is interrupted by another for communication purposes, but where any solver may access at all times the data previously sent out by the other solvers.

The performance of central-memory cooperation and the availability of the exchanged information kept in the memory have brought up the question of whether one could design more advanced cooperation mechanisms taking advantage of the information exchanged among cooperating solvers. The pC/K strategies described in the next section are the result of this area of research.

Knowledge Creation in Cooperative Search

Cooperation, particularly in the central-memory asynchronous form, offers many possibilities for algorithm development. Particularly noteworthy are the flexibility in terms of the different meta-heuristic and exact methods that can be combined, and the population of elite solutions being hosted in the central memory and continuously enhanced by the cooperating solvers. One can thus select cooperating methods that complement each other, some of which heuristically construct new solutions, execute neighborhood-based improving meta-heuristics, evolve populations of solutions, or perform post-optimization procedures on solutions in memory.

The study of [31] illustrates the interest of these ideas. The authors combine a GA solver and several solvers executing the pC/A Tabu Search for multicommodity location-allocation with balancing requirements of [39]. The TSs aggressively explore the search space, building the elite solution set in the central memory, while the GA contributes toward increasing the diversity, and hopefully the quality, of the solutions in the central memory, to be imported by the cooperating TSs when needed. The GA launches with a population composed of the initial set of elite solutions generated by the TS solvers. Asynchronous migration subsequently transfers the best solution of the genetic pool to the central memory and solutions in the central memory toward the genetic population. This strategy did perform well, especially on larger instances. It also yielded the interesting observations that (1) including different types of solvers in the cooperation is beneficial, and (2) while the best overall solution might have never been found by the genetic solver, its inclusion allowed the TS solvers to find better solutions, more diversity among solutions in memory translating into a more effective diversification of the global search.

Following the studies on memory and learning preformed for Tabu Search and synthesized in [70], several contributions in the parallel meta-heuristic literature, including the pioneering [31, 110], focused on the utilization of the information exchanged among cooperating solvers to construct and continuously enhance an understanding of the history and status of the global search. The analysis of the elite population solvers build in memory, together with associated context data, becomes a *learning mechanism* providing information relative to, e.g., regions of the search space already explored and the relative quality of solutions identified in those regions, the performance of the cooperating solvers given the information received from the central memory, the behavior of critical decision variables (e.g., arc or node selection in network design) relative to good solutions, etc. This information may then be used to create new *knowledge* to guide the search. Such knowledge may include new and diverse solutions or components, "ideal" target solutions, attribute-based patterns to bias probabilistic selections of solver moves, etc.

Cooperative strategies including mechanisms to create new information belong to the *p-control, knowledge communications-and-learning* pC/K class of the taxonomy. Most contributions to this field have cooperating solvers work on the complete problem, a few being dedicated to the learning mechanism. The bulk of the section is dedicated to these strategies. We conclude the section with a discussion on developments targeting the *attribute-based decomposition of the mathematical structure* of the problem at hand, where solvers work on particular parts of the problem or on integrating the resulting partial solutions into complete ones.

Historically, two main classes of pC/K cooperative mechanisms are found in the literature, both based on the idea of exploiting a set of elite solutions exchanged by cooperating solvers working on the complete problem, but differing in the information kept in memory. *Adaptive-memory* methods [110, 119] store and score partial elements of good solutions and combine them to create new complete solutions that are then improved by the cooperating solvers. *Central-memory* methods exchange complete elite solutions among neighborhood and population-based meta-heuristics and use them to create new solutions and knowledge to guide the cooperating solvers [27, 36, 39]. Notice that the latter method generalizes the former and, thus, the two are becoming increasingly unified.

The adaptive-memory terminology for parallel meta-heuristics was coined in a paper [110] proposing TS-based heuristics for routing problems (see [8] for a thorough application of the concept to the VRPTW). More comprehensive presentations of adaptive-memory concepts, applications, and challenges may be found in [68, 119]. The main idea is to keep in memory the individual components (vehicle routes in VRP) making up the elite solutions found by the cooperating solvers, together with memories counting for each component the frequency of inclusion in the best solutions encountered so far, as well as its score and rank among the population in memory, computed in particular from the objective value of its respective solutions. Solvers construct solutions out of probabilistically selected (biased by rank) solution components in memory, enhance them (TS in the initial contribution), and deposit their best solutions in the adaptive memory.

The probabilistic selection yields, in almost all cases, a new solution made up of components from different elite solutions, thus inducing a diversification effect.

A number of early developments provided insights into algorithmic design. Applying the concept to the VRP, [115] proposes a set-covering heuristic to select from the memory the components to generate the new initial solution of a cooperating solver. At about the same time, [64] explores 2-level hierarchical strategies in the context of real-time vehicle routing and dispatching. A cooperating adaptive-memory SC/pC/K/MPSS strategy is applied at the first level, where each TS solver implements a SE/1C/S route decomposition with the help of several workers on the second level.

Generalizing the pC/A and adaptive-memory strategies, pC/K central-memory mechanisms keep full solutions, as well as attributes and context information sent by the solvers involved in cooperation (in later versions, partial solutions may also be kept). The central memory also keeps newly created information out of the exchanged data. Classical statistics-based memories recording the performance of individual solutions, solution components, and solvers provide part of this new knowledge. More advanced strategies include information extraction and creation [85], machine learning mechanisms [19], and new solution-creation procedures (population-based, generally). Search guidance mechanisms based on this knowledge may thus be gradually built.

Solvers indirectly exchange complete elite solutions and context information though the central memory. Solvers may perform constructive, improving and post-optimization heuristics [82, 84, 85], neighborhood-based methods like TS and GRASP [21, 51, 78, 79, 82], population-based methods like GA [51, 82, 84, 85], SS [104], and PR [42], as well as exact solution methods [72] on possibly restricted versions of the problem. The particular solvers to include in cooperation depend on the application. They should be efficient for the problem at hand, of course. Additionally, they should also aim to cover different regions of the search space in such a way that they contribute not only to the quality but also to the diversity of the elite population being built in the central memory.

Central-memory mechanisms thus perform two main tasks: data-warehousing and communications with solvers, on the one hand, information-creation and search-guiding, on the other hand. To distinguish between the two, we single out the latter as the *Search Coordinator* (*SC*). The simplest SC mechanism was used in the pC/A strategies of the previous section, where solutions in memory were ordered and rank-biased randomly extracted to answer solver requests. More sophisticated mechanisms are briefly described in the following.

The cooperative meta-heuristic proposed by [84] for the VRPTW uses a simple pC/K mechanism, involving four solvers, two GAs, with order and edge recombination crossovers, respectively, and two acknowledged TSs, Unified Tabu Search [26] and TABUROUTE [63]. The cooperating solvers share their improved best solutions, and request solutions as needed, i.e., the GAs for crossover operations, the Unified Tabu at regular intervals, and TABUROUTE at diversification time. The central-memory SC performs post-optimization procedures, to reduce the number of vehicles and the total traveled distance, on the received solutions before making

them available for sharing. This algorithm, without any calibration or tailoring, proved to be competitive with the best meta-heuristics of its day in linear speedups.

A general learning and guidance mechanism based on atomic network-optimization elements, arcs in particular, is proposed in [85]. The arc-based SC is independent of particular problem characteristics (e.g., routes in the original VRPTW application), and may thus be broadly applied to network-based problem settings. Starting from the classical memory concepts pioneered for TS [66, 67, 70], the authors combined two ideas: first, that an arc appearing often in good solutions and less frequently in bad solutions may be worthy of consideration for inclusion in a tentative solution, and vice versa; second, that this worthiness increases when the behavior appears stable in time. The authors thus consider the evolution of the frequency of inclusion of arcs in solutions of different quality, that is, in the elite (e.g., the 10% best), average (between the 10% and 90% best), and worst (the last 10%) groups of solutions in the central memory. *Patterns* of arcs are then defined representing subsets of arcs (not necessarily adjacent) with similar frequencies of inclusion in particular population groups. Guidance is obtained by transmitting arc patterns to individual solvers, indicating whether the arcs in the pattern should be "fixed" or "prohibited" to intensify or diversify the search, respectively. Solvers account for these instructions by using the patterns to bias the selection of arcs for move or reproduction operations. A four-phase fixed schedule (two phases of diversification at the beginning to broaden the search, followed by two intensification phases to focus the search around promising regions) was used with excellent results in terms of solution quality and computing efficiency compared to the best-performing methods of the day (see [83] for a dynamic version of this mechanism).

A different SC mechanism for a pC/K meta-heuristic with TS solvers was proposed by [79] for the VRP. Data sharing is relatively simple; solvers periodically (after a number of iterations or when the solution did not improve for a number of iterations) send best solutions to the central memory, and receive a solution back from it, the search being resumed from the received solution. The SC mechanism's objective is to identify and extract information from the solutions in memory to guide solvers toward intensification and diversification phases. This is obtained by dynamically (on reception) clustering solutions according to the number of edges in common. Thus, solutions in a given cluster share a certain number of edges, this set of edges and solutions being assumed to represent a region of the search space. Search history indicators are associated with clusters giving the number of solutions in the cluster and the quality of the solutions. This information is used to infer how thoroughly the corresponding region has been explored and how promising it might still be. Clusters are sorted according to the average solution value of their feasible solutions, and the cluster with the lowest value, that is, with the largest number of very good solutions, is selected for intensification, while the solution with the lowest number of good solutions is selected for diversification (recall that the authors were addressing a minimization optimization problem). A solution is then selected in the corresponding cluster, and it is sent to the requesting solver. Excellent results were obtained in terms of solution quality and computation effort (an almost linear

speedup was observed with up to 240 processors) compared to the state-of-the-art methods of the day.

The study of [19] focuses on the issue of flexibility and adaptability of cooperative parallel meta-heuristics. The proposed cooperation involves a number of solvers of different types exchanging through a central memory. An additional process is connected to the central memory and is in charge of the SC mechanism, collecting information from the other solvers and sending guidance instructions to modify their behavior. The SC is based on a set of fuzzy rules initially instantiated through a supervised knowledge extraction process. The rules are meant to decide when to reinitialize a solver either with the current best solution or a new set of parameter values. The former aims at changing the behavior of the currently "worst" performing solver, bringing it within a portion of the search space closer to the overall best solution. The latter also focuses on the "worst" performing solver, changing the parameter values which did not change for some time. Encouraging results were obtained on $\{0, 1\}$-knapsack problem, which indicates that more research is needed on this topic. The flexibility and adaptability issue is also at the core of the work of [100]. Set within the hyperheuristic context [17, 18], the cooperation involves three solvers based on, respectively, a GA, a SA, and an AOC. The solvers stop after a certain number of solver-specific measures and store their best solutions in the central memory. The SC mechanisms rank the solvers based on performance, e.g., computing time and solution value. The idling solver with the highest ranking then receives a new intital solution from memory and restarts its search.

The pC/K/MPDS method proposed in [72] for the VRP illustrates how specialized solvers may address different issues in a cooperative meta-heuristic, including the generation of new knowledge. Two types of solvers were defined. The so-called heuristic solvers improve solutions received from the SC associated with the central memory. On completing the task, the solvers return a given number of the best solutions found and the corresponding routes (a post-optimization procedure is first run on each route). Simultaneously, exact solvers aim at identifying new solutions by solving series of set covering problems, starting from a limited set of routes. Each time a set covering problem is solved, the solution is returned to the central memory and a predefined number of the current best solutions is retrieved for the next run. Set-covering solvers have also access to the ordered list of best routes in memory, and they select within to complete their problems. The number of routes selected to set up a set covering problem is dynamically modified during the search to control the corresponding computational effort. The method performed very well, both in terms of solution quality and computational effort (an almost-linear speedup was observed).

The inclusion of specialized solvers in cooperation is also part of the algorithmic design proposed in [112]. The cooperative algorithm involves meta-heuristic solvers to construct and improve solutions, as well as a somewhat exact solver generating new variables (column generation of partial solutions, heuristically extended to complete ones through) to further diversify the search. The SC mechanism guides

the cooperative meta-heuristic by sending solutions to the appropriate solvers to intensify or diversify the search.

The parallel GRASP algorithm proposed in [21] makes use of different information-sharing strategies at different stages of the parallel meta-heuristic. Each solver runs the same GRASP meta-heuristic, sharing not only its best solutions but also results of intermediate computations, which reduces the computing time spent performing redundant operations over diverse solvers. Thus, the data updates and corresponding evaluations performed by a solver while building its initial solution are immediately stored in the common central memory for access by all other solvers. Solvers also make immediately available their improved best solutions found during their local search phases. Finally, the parallel meta-heuristic proceeds in two phases. The first runs the solvers without external limits for a given duration. Solvers synchronize at the end of the first phase, their best solutions and context information are evaluated and aggregated, yielding a restricted set of data on which solvers will work during the second phase. The parallel meta-heuristic proved very efficient on three different problem settings.

We complete this section by reviewing developments targeting multi-attribute, "rich," problem settings displaying a large number of attributes characterizing their feasibility and optimality structures. Traditionally in the literature, such problems are simplified, or sequentially solved through a series of particular cases, where part of the overall problem is fixed or ignored, or both. The main idea of this generation of pC/K meta-heuristics is to decompose the mathematical structure of the formulation along sets of decision variables, called *decision-set attribute decomposition* in [82]. The goal of this decomposition is to obtain simpler but meaningful problem settings, in the sense that efficient solvers can be "easily" obtained for the partial problems either by opportunistically using existing high-performing methods or by developing new ones. Thus, an opportunistic rule may decompose the multi-depot periodic VRP (MDPVRP) along the depot and period decision sets to create two partial problems, a periodic VRP (PVRP) and a multi-depot VRP (MDVRP), high-quality solvers being available in the literature for both problems. The central-memory asynchronous cooperative search framework then brings together these partial problems and their associated solvers, together with integration mechanisms, reconstructing complete solutions, and search-guidance mechanisms.

According to our best knowledge, [42, 51] were the first to propose such a methodology in the context of designing wireless networks, where seven attributes were considered simultaneously. The proposed 1/MA/pC/K/MPDS meta-heuristic has TS solvers working on limited subsets of attributes, the others being fixed, and a GA combining the partial solutions generated by the TS procedures into complete solutions to the initial problem.

The general method, called *Integrative Cooperative Search* (*ICS*), was introduced in [82] (see [44, 45] for initial developments) and illustrated through an application to the MDPVRP. As illustrated in Fig. 9, the main components of ICS, which need to be instantiated for each application, are the

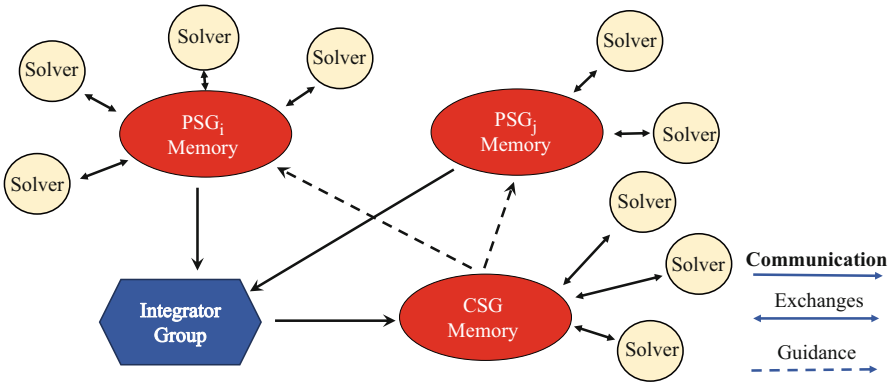

Fig. 9 Integrative cooperative search

- Decomposition rule
- *Partial Solver Groups* (*PSG*) addressing the partial problems resulting from the decomposition
- *Integrator Group* (*IG*) selecting partial solutions from PSGs, combining them, and sending the resulting complete solutions to the
- *Complete Solver Group* (*CSG*), which provides the central memory functionalities of ICS and, possibly, enhances the complete solutions.

Notice that, in order to facilitate the cooperation, a unique solution representation, obtained by fixing rather than eliminating variables when defining partial problems, is used throughout ICS. Also notice that memories associated to the PSGs and the CSG need not be distributed on different computing units (the display in Fig. 9 is for illustration only). As for all parallelization strategies discussed in this chapter, the implementation is specific to the available computing infrastructure.

A Partial Solver Group may contain one or several solvers targeting the particular partial problem assigned to the group. When several solvers are involved, the PSG is organized according to a pC/K strategy, with its own central memory keeping partial elite solutions and associated context information. The PSG's SC manages the central memory and the exchanges with the other components of the ICS, the CSG in particular. Two PSGs were defined in [82], one for the PVRP and the other for the MDVRP. The same two algorithms were used as partial solvers within each PDG, the hybrid genetic algorithm HGSADC [131] and GUTS, a generalized version of the Unified Tabu Search [26].

Integrator procedures build complete solutions by mixing partial solutions with promising features extracted from the central memories of the PSGs. The resulting complete solutions, together with critical features extracted from the partial solutions, are transmitted to the CSG. Integrators aim for solution quality and diversity, as well as computational efficiency. Because partial solutions are defined by variable fixing rather than deletion, the simplest Integrator consists of selecting high-quality

partial solutions (with respect to solution value or the inclusion of particular decision combinations) and passing them directly to the Complete Solver Group. Population-based meta-heuristics make natural integrators, as well as solvers of optimization formulations combining solutions or solution elements (e.g., set covering for VRP) to yield complete solutions to the problem at hand. The work of [55] belongs to the latter category, proposing particular optimization models for rich VRP settings, which preserve desired critical variables and attributes, present in partial solutions, when selecting and combining routes. Several Integrators can be involved in an ICS meta-heuristic, increasing the diversity of the population of complete solutions. Four Integrators were thus included in the MDPVRP application, the simple one passing good solutions to the CSG, the HGSADC individual enhancement operator (crossover and education), and two of the methods proposed by [55], the first transmitting the attributes for which there was "consensus" in the input solutions, while the second "promoted" them only through penalties added to the objective function. The last three integrators start from pairs of partial solutions randomly selected among the best 25% of the central memory populations of the two PSGs.

The Complete Solver Group includes the ICS central memory together with the SC learning, guidance, and monitoring mechanism. Complete solutions, together with the context information, are received from Integrators. When the CSG includes solvers, these solutions are further enhanced and new ones may be created. Following the concepts described earlier on in this section, knowledge is extracted from the solutions and context data received and created (e.g., the frequency of appearance of each (customer, depot, pattern) triplet in the complete solution set for the MDPVRP, together with the cost of the best solution containing it). This new information is used to build guiding instructions (solutions, patterns of variables to favour or avoid, etc.) sent to the appropriate PSGs according to a monitoring process.

Monitoring is performed by following the evolution of the PSGs (e.g., the number of improving solutions generated during a certain time period) to detect undesired situations, such as loss of diversity in the partial or complete populations, stagnation in improving the quality of the current best solution, awareness that some zones of the search space – defined by particular values for particular decision sets – have been scarcely explored, etc. Whenever one of these situations is detected, the CSG sends guidance instructions to the particular PSG. The particular type of guidance is application-specific, but one may inject new solutions or elements, modify the values of the fixed attributes for the PSG to orient its search toward a different area, change the attribute subset under investigation (i.e., change the decomposition of the decision-set attributes), or modify/replace the solution method in a Partial Solver or Integrator. The last two should not occur too frequently. Guidance in [82] takes the form of three solutions, either randomly selected from the complete solution set, or built by the CSG out of promising solution elements with respect to the search history.

Very good results are reported even when compared to the state-of-the-art meta-heuristic for the MDPVRP [82]. The experimental results also indicated that (1) one should use solvers with similar time performances in order to have them contributing

reasonably equally to the cooperation; (2) using the PSG central memory as population for all cooperating GA solvers appears beneficial for short computation runs, while creating solver-specific populations offers better performances for longer runs; (3) embedding good solvers in the CSG enhances slightly the already excellent performance of the ICS parallel meta-heuristic.

Conclusions

This chapter presented a synthesis and state-of-the-art survey of the main parallel meta-heuristic ideas, discussing main parallelization concepts and general algorithm-design principles and strategies. The presentation is structured by an enhanced three-dimensional classification of design strategies for parallel meta-heuristics: the number of levels indicating whether decomposition is applied once only or recursively; the decomposition strategy reflecting the sources of parallelism in meta-heuristics, algorithm, search space, or mathematical structure; and the search strategy, given a particular level and decomposition approach, defined by the number of processes controlling the search, the communication and learning mechanism, and the diversity of the individual methods involved and their initial solutions.

Six major classes of parallel meta-heuristics strategies were discussed: low-level decomposition of computing-intensive tasks with no modification to the original algorithm, explicit decomposition of the search space, independent multi-search, as well as synchronous, asynchronous, and knowledge-creating cooperative multi-search. It is noteworthy that this series also reflects the historical sequence of the development of parallel meta-heuristics, which are now acknowledged to make up their own class of meta-heuristics.

The literature survey reveals a rich tapestry of contributions based on one of these strategies in wide array of applications. Two observations strongly indicate, however, that more research is still needed.

First, let us not forget that most optimization problems of interest are complex and computationally difficult. Addressing these problems is increasingly challenging. On the one hand, the dimensions of the instances one faces keep increasing. On the other hand, the problem settings are becoming more complex, illustrated by the network optimization problems involving several layers of interwoven design decisions, the integrated hierarchical hub location and scheduled service network design problems, and the general trend toward explicitly addressing the uncertainty inherently present in most planning and management problems. Harnessing and developing the power of parallel meta-heuristics are crucial to efficiently address realistically dimensioned instances of such problem settings. To achieve these goals requires to study the behaviour of the parallelization strategies within each particular context and to identify the most appropriate one or combination thereof.

These developments are linked to the research needs coming from the second observation. Namely, that knowledge and expertise have not progressed equally across parallelization approaches, meta-heuristic designs, and problem settings. It

must be emphasized that each of the strategy classes identified in the chapter fulfills a particular type of task, and all are needed in some circumstances. Thus, the idea that everything seems to be known regarding low-level parallelization strategies is not true. Most studies on accelerating computing-intensive tasks targeted the evaluation of a population or neighborhood in classic meta-heuristic frameworks but, as a number of recent studies show, the best strategy to accelerate a local-search procedure may prove less effective when the local search is embedded into a full meta-heuristic or hierarchical solution method. On the other hand, the evolution of computing infrastructure, in particular, the integration of graphical processing units within computing platforms, opens up interesting but challenging perspectives. In both cases, more research is needed to understand their behavior and identify the most appropriate combination of strategies, particularly low-level and cooperative search, for various meta-heuristics, problem settings, and computing platforms.

Search-space decomposition also seems to have been thoroughly studied and has been overlooked in the last years, maybe due to the rapid and phenomenal increase in the memory available and the speed of access. Yet, the increased challenges of the evolving combinatorial optimization problem settings, alluded to above, require more research related, in particular, to dynamic search-space decomposition and the combination of cooperative search and search-space decomposition (the Integrative Cooperative Search appears as a first step in this direction).

Asynchronous cooperation, particularly when relaying on memories as communication mechanisms, provides a powerful, flexible, and adaptable framework for parallel meta-heuristics that consistently achieved good results in terms of computing efficiency and solution quality for many meta-heuristic and problem classes. A number of challenging research issues are worth investigating.

A first issue concerns the exchange and utilization of context data gathered locally by cooperating solvers, to infer the status of the global search and generate appropriate guiding instructions. Thus, contrasting and aggregating the information reflecting the various search trajectories of the cooperating solvers may be used to identify regions of the search space that were neglected or over explored. The information could also be used to evaluate the relative performance of the solvers conducting, eventually, to adjust the search parameters of particular solvers or even change the search strategy. The so-called "strategic" decision variables or parameters could thus be more easily identified, which could prove very profitable in terms of search guidance.

A related issue concerns the learning processes and the creation of new information out of the shared data. Important questions concern the identification of information that may be derived from the exchanged solutions and its usefulness in inferring the status of the global search, and determining the appropriate guiding information to be sent to solvers. Research in this direction is still at the very beginning but has already proved its worth, in particular in the context of the integrative cooperative methods.

A third broad issue concerns the cooperation of different types of meta-heuristics, as well as the cooperation of meta-heuristics with exact solution methods. The so-called hybrid, hyper, and matheuristic methods represent significant types of method

combinations in the sequential optimization field, but very few studies explicitly have targeted associated parallelization strategies. How different methods behave when involved in cooperative search and how the latter behaves given various combinations of methods is an important issue that should yield valuable insights into the design of parallel meta-heuristic algorithms, cooperative ones in particular. A particularly challenging but fascinating direction for cooperative search and ICS is represented by the multi-scenario representation of stochastic optimization formulations, for which almost nothing beyond low-level scenario-decomposition has been proposed yet. The work of [106] on parallel Benders decomposition illustrates the interest of asynchronous cooperation and the challenges of applying them for stochastic network design. Transversal studies comparing the behavior and performance of particular parallel meta-heuristic strategies over different problem classes, and of different parallel strategies and implementations for the same problem class, would be very valuable in this context, as in the broader field of parallel meta-heuristics.

Abstract

Theoretical analyses of stochastic search algorithms, albeit few, have always existed since these algorithms became popular. Starting in the 1990s, a systematic approach to analyze the performance of stochastic search heuristics has been put in place. This quickly increasing basis of results allows, nowadays, the analysis of sophisticated algorithms such as population-based evolutionary algorithms, ant colony optimization and artificial immune systems. Results are available concerning problems from various domains including classical combinatorial and continuous optimization, single- and multi-objective optimization, and noisy and dynamic optimization as well as more advanced applications in emerging technologies such as automated algorithm configuration, automated algorithm design, and genetic programming. This chapter introduces the mathematical techniques that are most commonly used in the runtime analysis of stochastic search heuristics in discrete search spaces. Careful attention is given to the very popular artificial fitness levels and drift analysis techniques for which several variants are presented. To aid the reader's comprehension of the presented mathematical methods, these are applied to the analysis of simple evolutionary algorithms for artificial example functions. The chapter is concluded by providing references to more complex applications and further extensions of the techniques for the obtainment of advanced results.

Introduction

Stochastic search algorithms, also called randomized search heuristics, are general-purpose optimization algorithms that are often used when it is not possible to design a specific algorithm for the problem at hand. Common reasons are the lack of available resources (e.g., enough money and/or time) or because of an insufficient knowledge of the complex optimization problem which has not been studied extensively before. Other times, the only way of acquiring knowledge about the problem is by evaluating the quality of candidate solutions.

Well-known stochastic search algorithms are random local search (▸ Chap. 17, "Theory of Local Search") and simulated annealing. Other more complicated approaches are inspired by processes observed in nature. Popular examples are evolutionary algorithms (EAs) (▸ Chap. 6, "Evolutionary Algorithms") inspired by the concept of natural evolution, ant colony optimization (ACO) (▸ Chap. 19, "Ant Colony Optimization: A Component-Wise Overview") inspired by ant foraging

behavior, and artificial immune systems (AIS) inspired by the immune system of vertebrates.

The main advantage of stochastic search heuristics is that, being general-purpose algorithms, they can be applied to a wide range of applications without requiring hardly any knowledge of the problem at hand. Also, the simplicity for which they can be applied implies that practitioners can use them to find high-quality solutions to a wide variety of problems without needing skills and knowledge of algorithm design. Indeed, numerous applications report high-performance results which make them widely used in practice. However, through experimental work and applications, it is difficult to understand the reasons for these successes. In particular, given a stochastic search algorithm, it is unclear on which kind of problems it will achieve good *performance* and on which it will perform poorly. Even more crucial is the lack of understanding of how the parameter settings influence the performance of the algorithms. The goal of a rigorous theoretical foundation of stochastic search algorithms is to answer questions of this nature by *explaining* the success or the failure of these methods in practical applications. The benefits of a theoretical understanding are threefold: (a) guiding the choice of the best algorithm for the problem at hand, (b) determining the optimal parameter settings (see also Chap. "Automatic Tuning of Parameters"), and (c) aiding the algorithm design, ultimately leading to the achievement of better algorithms.

Theoretical studies of stochastic optimization methods have always existed, albeit few, since these algorithms became popular. In particular, the increasing popularity gained by evolutionary (▸ Chap. 6, "Evolutionary Algorithms") and genetic algorithms (▸ Chap. 22, "Genetic Algorithms") in the 70s led to various attempts at building a theory for these algorithms. However, such initial studies attempted to provide insights on the *behavior* of evolutionary algorithms rather than estimating their performance. The most popular of these theoretical frameworks was probably the *schema theory* introduced by Holland [39] and made popular by Goldberg [33]. In the early 90s, a very different approach appeared to the analysis of evolutionary algorithms and consequently randomized search heuristics in general, driven by the insight that these heuristics are indeed randomized algorithms, albeit general-purpose ones, and as such they should be analyzed in a similar spirit to that of classical randomized algorithms [58, 59]. For the last 35 years, this field has kept growing considerably, and nowadays several advanced and powerful tools have been devised that allow the analysis of the performance of involved stochastic search algorithms for problems from various domains. These include problems from classical combinatorial and continuous optimization, dynamic optimization, and noisy optimization. The generality of the developed techniques has allowed their application to the analyses of several families of stochastic search algorithms including evolutionary algorithms, local search, metropolis, simulated annealing, ant colony optimization, artificial immune systems, particle swarm optimization (▸ Chap. 28, "Particle Swarm Optimization"), and estimation of distribution algorithms (▸ Chap. 20, "Estimation of Distribution Algorithms"). Recently, they have also been applied to the analysis of emerging technologies such as algorithm

configurators, automated algorithm design (hyper-heuristics) (▸ Chap. 24, "Hyper--heuristics"), and the evolution of computer programs (genetic programming).

The aim of this chapter is to introduce the reader to the most common and powerful tools used in the performance analysis of randomized search heuristics. Since the main focus is the understanding of the methods, these will be applied to the analysis of very simple evolutionary algorithms for artificial example functions. The hope is that the structure of the functions and the behavior of the algorithms are easy to grasp so the attention of the reader may be mostly focused on the mathematical techniques that will be presented. At the end of the chapter, references to complex applications of the techniques for the obtainment of advanced results will be pointed out for further reading.

Computational Complexity of Stochastic Search Algorithms

From the perspective of computer science, stochastic search heuristics are randomized algorithms although more general than problem-specific ones. Hence, it is natural to analyze their performance in the classical way as done in computer science. From this perspective, an algorithm should be *correct*, i.e., for every instance of the problem (the input), the algorithm halts with the correct solution (i.e., the correct output), and it should be efficient in terms of its *computational complexity* i.e., the algorithm uses the computational resources wisely. The resources usually considered are the number of basic computations to find the solution (i.e., time) and the amount of memory required (i.e., space).

Differently from problem-specific algorithms, the goal behind general-purpose algorithms such as stochastic search heuristics is to deliver good performance independently of the problem at hand. In other words, a general-purpose algorithm is "correct" if it *visits the optimal solution* of *any problem* in finite time. If the optimum is never lost afterward, then a stochastic search algorithm is said to *converge* to the optimal solution. In a formal sense, the latter condition for convergence is required because most search heuristics are not capable of recognizing when an optimal solution has been found (i.e., they do not halt). It has been known for over two decades that a few relatively simple conditions suffice to ensure convergence [69]. Hence, what is more relevant and can make a huge difference on the usefulness of a stochastic search heuristic for a given problem is its *time complexity*. In each iteration, the evaluation of the quality of a solution is generally far more expensive than its other algorithmic steps. As a result, it is very common to measure *time* as the number of evaluations of the fitness function (also called objective function) rather than counting the number of basic computations. Since randomized algorithms make random choices during their execution, the runtime of a stochastic search heuristic A to optimize a function f is a random variable $T_{A,f}$. The main measure of interest is:

1. The *expected runtime* $\mathbb{E}\left[T_{A,f}\right]$: The expected number of fitness function evaluations until the optimum of f is found.

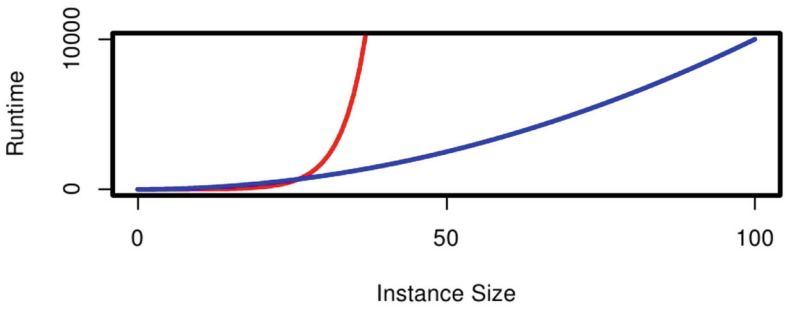

Fig. 1 An efficient search heuristic (blue) versus an inefficient search heuristic (red) for a given instance

For skewed runtime distributions, the expected runtime may be a deceiving measure of algorithm performance. The following measure therefore provides additional information.

2. The *success probability in t steps* $\Pr\left(T_{A,f} \leq t\right)$: The probability that the optimum is found within t steps.

Just like in the classical theory of efficient algorithms, the time is analyzed in relation to growing input length and usually described using asymptotic notation [4]. A search heuristic A is said to be *efficient* for a function (class) f if the runtime grows as polynomial function of the instance size. On the other hand, if the runtime grows as an exponential function, then the heuristic is said to be *inefficient*. See Fig. 1 for an illustrative distinction.

Evolutionary Algorithms

A general framework of a *steady-state* genetic algorithm is the (μ+λ) GA defined in Algorithm 1. The algorithm evolves a population of μ candidate solutions, generally called the *parent population*. At each generation, an *offspring population* of λ individuals is created. Each of the λ individuals is generated by selecting two individuals from the parent population uniformly at random and by applying a *uniform crossover* operator to create an offspring to which a *standard bit mutation* operator is then applied. The generation is concluded by selecting the μ fittest individuals out of the $\mu + \lambda$ parents and offspring. Algorithm 1 presents a formal definition.

In order to apply the algorithm for the optimization of a fitness function $f : \{0, 1\}^n \to \mathbb{R}$, some parameters need to be set: the population size μ, the offspring population size λ, and the mutation rate p_m. Traditionally, $p_m = 1/n$ is considered a good setting for the mutation rate. Also, in practical applications, a stopping criterion has to be defined since the algorithm does not halt. A fixed number of generations or a fixed number of fitness function evaluations are usually decided

Algorithm 1: Steady-state (μ+λ) GA

1: **Initialisation**:
Initialise $P_0 = \{x^{(1)}, \ldots, x^{(\mu)}\}$ with μ individuals chosen uniformly a random from $\{0, 1\}^n$;
$t \leftarrow 0$;
2: **for** $i = 1, \ldots, \lambda$ **do**
3: **Selection for Reproduction**: Choose $x, y \in P_t$ uniformly at random with replacement;
4: **Crossover**: Create $z^{(i)}$ by picking each bit from either parent with probability $1/2$;
5: **Mutation**: Flip each bit in $z^{(i)}$ with probability p_m;
6: **end for**
7: **Selection for Replacement**
Create the new population P_{t+1} by choosing the best μ individuals out of $\{x^{(1)}, \ldots, x^{(\mu)}, z^{(1)}, \ldots, z^{(\lambda)}\}$;
8: $t \leftarrow t + 1$; Continue at 2;

in advance. Since the objective of the analysis is to calculate the time required to reach the optimal (approximate) solution for the first time, no stopping condition is required, and one can assume that the algorithms are allowed to run forever. The + symbol in the algorithm's name indicates that *elitist truncation selection* is applied, which is typical of steady-state genetic algorithms. This means that the whole population consisting of both parents and offspring are sorted according to fitness and the best μ are retained for the next generation. Some criterion needs to be decided in case the best μ individuals are not uniquely defined. Ties between solutions of equal fitness may be broken uniformly at random. Often offspring are preferred over parents of equal fitness. The crossover operator employed is referred to as *uniform crossover*. If no crossover is employed, then only one individual is selected for reproduction in Line 3, and the offspring is created by only applying the mutation operator. In this case, the algorithm is typically referred to as $(\mu + \lambda)$ EA. In the latter case, if $\mu = \lambda = 1$ are set, then the standard (1+1) EA is obtained, a very simple and well-studied evolutionary algorithm. On the other hand, if some stochastic selection mechanism was used instead of the elitist mechanism, then Algorithm 1 would become a *generational* genetic algorithm (GA) if the crossover operator was retained or a *generational* EA otherwise. Given the importance of the (1+1) EA in this chapter, a formal definition is given in Algorithm 2.

Algorithm 2: (1+1) EA

1: **Initialisation**:
Initialise $x^{(0)}$ uniformly a random from $\{0, 1\}^n$;
$t \leftarrow 0$;
2: **Variation**:
Create y by flipping each bit in $x^{(t)}$ with probability $p_m = 1/n$;
3: **Selection for Replacement**
4: **if** $f(y) \geq f(x^{(t)})$ **then**
5: $x^{(t+1)} \leftarrow y$
6: **end if**
7: $t \leftarrow t + 1$; Continue at 2;

The algorithm is initialized with a random bitstring. At each generation, a new candidate solution is obtained by flipping each bit with probability $p_m = 1/n$. The number of bits that flip can be represented by a binomial random variable $X \sim \text{Bin}(n, p)$ where n is the number of bits (i.e., the number of trials) and $p = 1/n$ is the probability of a success (i.e., a bit actually flips), while $1 - p = 1 - 1/n$ is the probability of a failure (i.e., the bit does not flip). Then, the expected number of bits that flip in one generation is given by the expectation of the binomial random variable, $\mathbb{E}[X] = n \cdot p = n \cdot 1/n = 1$.

The algorithm behaves in a very different way compared to the random local search (RLS) algorithm that flips *exactly* one bit per iteration. Although the (1+1) EA flips exactly one bit in expectation per iteration, many more bits may flip or even none at all. In particular, the (1+1) EA is a *global optimizer* because there is a positive probability that any point in the search space is reached in each generation. As a consequence, the algorithm will find the global optimum in finite time. On the other hand, RLS is a local optimizer since it gets stuck once it reaches a local optimum because it only flips one bit per iteration.

The probability that a binomial random variable $X \sim \text{Bin}(n, p)$ takes value j (i.e., j bits flip) is

$$\Pr(X = j) = \binom{n}{j} p^j (1-p)^{n-j}.$$

Hence, the probability that the (1+1) EA flips exactly one bit is

$$\Pr(X = 1) = \binom{n}{1} \cdot \left(\frac{1}{n}\right) \cdot \left(1 - \frac{1}{n}\right)^{n-1} = \left(1 - \frac{1}{n}\right)^{n-1} \geq 1/e \approx 0.37.$$

So the outcome of one generation of the (1+1) EA is similar to that of RLS only approximately 1/3 of the generations. The probability that two bits flip is exactly half the probability that one flips:

$$\begin{aligned}
\Pr(X = 2) &= \binom{n}{2} \left(\frac{1}{n}\right)^2 \left(1 - \frac{1}{n}\right)^{n-2} \\
&= \frac{n(n-1)}{2} \left(\frac{1}{n}\right)^2 \left(1 - \frac{1}{n}\right)^{n-2} \\
&= \frac{1}{2} \left(1 - \frac{1}{n}\right)^{n-1} \approx 1/(2e).
\end{aligned}$$

On the other hand, the probability no bits flip at all is

$$\Pr(X = 0) = \binom{n}{0} (1/n)^0 \cdot (1 - 1/n)^n \approx 1/e.$$

The latter result implies that in more than 1/3 of the iterations no bits flip. This should be taken into account when evaluating the fitness of the offspring, especially for expensive fitness functions.

In general, the probability that i bits flip decreases exponentially with i

$$\Pr(X = i) = \binom{n}{i} \cdot \frac{1}{n^i} \cdot \left(1 - \frac{1}{n}\right)^{n-i} = \frac{1}{i!} \cdot \left(1 - \frac{1}{n}\right)^{n-i} \approx \frac{1}{i! \cdot e}.$$

In the worst case, all the bits may need to flip to reach the optimum in one step. This event has probability $1/n^n$. Since this is always a lower bound on the probability of reaching the optimum in each generation, by a simple waiting time argument, an upper bound of $O(n^n)$ may be derived for the expected runtime of the (1+1) EA on any pseudo-Boolean function $f : \{0, 1\}^n \to \mathbb{R}$. It is simple to design an example trap function for which the algorithm actually requires $\Theta(n^n)$ expected steps to reach the optimum [31]. This simple result further motivates why it is fundamental to gain a foundational understanding of how the runtime of stochastic search heuristics depends on the parameters of the problem and on the parameters of the algorithms.

Conclusions

Elitist steady-state genetic algorithms [73, 74, 76] were introduced later compared to traditional generational ones [33]. It was originally thought that steady-state EAs/GAs induce a much higher selective pressure compared to the generational model due to the truncation selection for replacement operator (i.e., elitism) and thus are prone to faster premature convergence [34]. For this reason, it has been common to select parents for reproduction uniformly at random rather than using selection operators that prefer better individuals (e.g., tournament or linear ranking selection) which are instead necessary in the generational model [8]. Only recently Corus et al. have shown that in fact the steady-state model allows to control the selective pressure much more carefully than is possible with the generational model and as a result allows for a better balance between exploration and exploitation [11, 14]. Nevertheless, a class of functions has been recently presented where all $(\mu + \lambda)$ steady-state EAs require exponential time as they get trapped with high probability in local optima, while generational EAs are efficient by being able to make good use of their non-elitism to eventually escape [18].

This section focused on the widely used standard bit mutation (SBM) operator and its traditional mutation rate $p_m = 1/n$. This parameter setting is widely considered appropriate as a rule of thumb for mutation-based EAs. For instance, it is the best setting for the (1+1)-EA optimizing linear functions which is also the optimal standard bit mutation-based algorithm for the problem [79]. However, runtime analyses have increasingly suggested the use of higher mutation rates in crossover-based steady-state GAs which may be beneficial both for hillclimbing [5, 6], making them even faster than the (1+1)-EA for ONEMAX, and for escaping

from local optima [17, 30]. In recent years, theory-driven heavy-tailed "power law" mutation operators that have a higher probability of mutating many bits have gained increasing popularity also in mutation-only algorithms [27, 44]. The use of operators with higher mutation rates has been shown to enhance the capabilities of steady-state evolutionary algorithms at escaping from local optima and is naturally present in artificial immune systems [9, 10, 12, 13].

Test Functions

Test functions are artificially designed to analyze the performance of stochastic search algorithms when they face optimization problems with particular structures. These functions are used to highlight characteristics of function classes which may make the optimization process easy or hard for a given algorithm. For this reason, they are often referred to as *toy problems*. The analysis on test functions of simple and well-understood structure has allowed the development of several general techniques for the analysis. Afterward, these techniques have allowed to analyze the same algorithms for more complicated problems with practical applications such as classical combinatorial optimization problems. Furthermore, in recent years, several standard techniques originally developed for simple algorithms have been extended to allow the analyses of more realistic algorithms. In this section, the test functions that will be used as example functions throughout the chapter are introduced.

The most popular test function is ONEMAX (x) := $\sum_{i=1}^{n} x_i$, which simply counts the number of one-bits in the bitstring. The global optimum is a bitstring of only one-bits. ONEMAX is the easiest function with unique global optimum for the (1+1) EA.

A particularly difficult test function for stochastic search algorithms is the *needle-in-a-haystack* function. NEEDLE(x) := $\prod_{i=1}^{n} x_i$ consists of a huge plateau of fitness value zero apart from only one optimal point of fitness value one represented by the bitstring of only one-bits. This function is hard for search heuristics because all the search points apart from the optimum have the same fitness. As a consequence, the algorithms cannot gather any information about where the needle is by sampling search points.

Both ONEMAX and NEEDLE (as defined above) have the property that the function values only depend on the number of ones in the bitstring. The class of functions with this property is called *functions of unitation*.

$$\text{UNITATION}(x) := f\left(\sum_{i=1}^{n} x_i\right).$$

Throughout this chapter, functions of unitation will be used as a general example class to demonstrate the use of the techniques that will be introduced. For simplicity of the analysis, the optimum is assumed to be the bitstring of only one-bits.

For the analysis, the function of unitation will be divided into three different kinds of subblocks: linear blocks, gap blocks, and plateau blocks. Each block will

be defined by its length parameter m (i.e., the number of bits in the block) and by its position parameter k (i.e., each block starts at bitstrings with $m + k$ zeroes and ends at bitstrings with k zeroes). Given a unitation function, it is divided into subblocks proceeding from left to right from the all-zeroes bitstring toward the all-ones bitstring. If the fitness increases with the number of ones, then a *linear block* is created. The linear block ends when the function value stops increasing with the number of ones.

$$\textsc{Linear}(|x|) = \begin{cases} a|x| + b & \text{if } k < n - |x| \leq k + m \\ 0 & \text{otherwise.} \end{cases}$$

See Fig. 2 for an illustration.

If the fitness function decreases with the number of ones, then a *gap block* is created. The gap block ends when the fitness value reaches for the first time a higher value than the value at the beginning of the block.

$$\textsc{Gap}(|x|) = \begin{cases} a & \text{if } n - |x| = k + m \\ 0 & \text{otherwise.} \end{cases}$$

See Fig. 3 for an illustration.

If the fitness remains the same as the number of ones in the bitstrings increases, then a *plateau block* is created. The block ends at the first point where the fitness value changes.

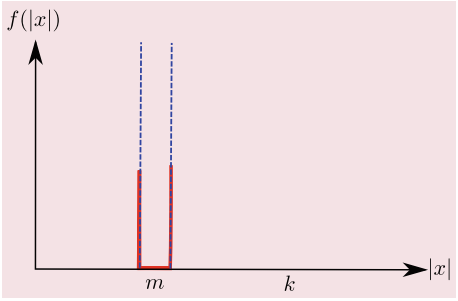

Fig. 3 A gap unitation block of length m starting at position $m + k$ and ending at position k. A gap unitation block of length $n - 1$ is the NEEDLE function

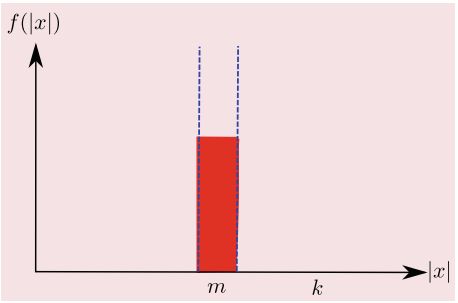

Fig. 4 A plateau unitation block of length m starting at position $m + k$ and ending at position k

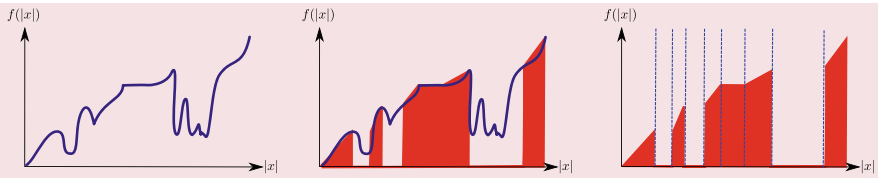

Fig. 5 An illustration of how the search space of a unitation function may be subdivided into blocks of the three kinds

$$\textsc{Plateau}(|x|) = \begin{cases} a & \text{if } k < n - |x| \leq k + m \\ 0 & \text{otherwise.} \end{cases}$$

See Fig. 4 for an illustration.

By proceeding from left to right, the whole search space is subdivided into blocks. See Fig. 5 for an illustration. Let the unitation function be subdivided into r sub-functions $f_1, f_2, \ldots f_r$, and let T_i be the runtime for an elitist search heuristic to optimize each sub-function f_i. Then by linearity of expectation, an upper bound on the expected runtime of an elitist stochastic search heuristic for the unitation function is

$$\mathbb{E}[T] \leq \mathbb{E}\left[\sum_{i=1}^{r} T_i\right] = \sum_{i=1}^{r} \mathbb{E}[T_i].$$

Hence, an upper bound on the total runtime for the unitation function may be achieved by calculating upper bounds on the runtime for each block separately. Once these are obtained, summing all the bounds yields an upper bound on the total runtime. Attention needs to be taken when calculating upper bounds on the runtime to overcome a plateau block when this is followed by a gap block because points straight after the end of the plateau will have lower fitness values, hence will not be accepted. In these special cases, the upper bound for the PLATEAU block needs to be multiplied by the upper bound for the GAP block to achieve a correct upper bound on the runtime to overcome both blocks. In the remainder of the chapter, upper and lower bounds for each type of block will be derived as example applications of the

presented runtime analysis techniques. The reader will then be able to calculate the runtime of the (1+1) EA and other evolutionary algorithms for any such unitation function.

By simply using waiting time arguments, it is possible to derive upper and lower bounds on the runtime of the (1+1) EA for the GAP block. Assuming that the algorithm is at the beginning of the gap block, then to reach the end it is *sufficient* to flip m zero-bits into one-bits and leave the other bits unchanged. On the other hand, it is a *necessary* condition to flip at least m zero-bits because all search points achieved by flipping less than m zero-bits have a fitness value of zero and would not be accepted by selection. Given that there are $m + k$ zero-bits available at the beginning of the block, the following upper and lower bounds on the probability of reaching the end of the block follow

$$\left(\frac{m+k}{nm}\right)^m \frac{1}{e} \leq \binom{m+k}{m}\left(\frac{1}{n}\right)^m \frac{1}{e} \leq p \leq \binom{m+k}{m}\left(\frac{1}{n}\right)^m \leq \left(\frac{(m+k)e}{nm}\right)^m.$$

Here the outer inequalities are achieved by using $\left(\frac{n}{k}\right)^k \leq \binom{n}{k} \leq \left(\frac{en}{k}\right)^k$ for $k \geq 1$. Then by simple waiting time arguments, the expected time for the (1+1) EA to optimize a GAP block of length m and position k is upper and lower bounded by

$$\left(\frac{nm}{(m+k)e}\right)^m \leq \binom{m+k}{m}^{-1} n^m \leq \mathbb{E}[T] \leq en^m \binom{m+k}{m}^{-1} \leq e\left(\frac{nm}{m+k}\right)^m.$$

Tail Inequalities

The runtime of a stochastic search algorithm A for a function (class) f is a random variable $T_{A,f}$, and the main goal of a runtime analysis is to calculate its expectation $\mathbb{E}\left[T_{A,f}\right]$. Sometimes the expected runtime may be particularly large, but there may also be a high probability that the actual optimization time is significantly lower. In these cases, a result about the *success probability* within t steps helps considerably the understanding of the algorithm's performance. In other occasions, it may be interesting to simply gain knowledge about the probability that the actual optimization time deviates from the expected runtime. In such circumstances, *tail inequalities* turn out to be very useful tools by allowing to obtain bounds on the runtime that hold with high probability. An example of the expectation of a random variable and its probability distribution is given in Fig. 6.

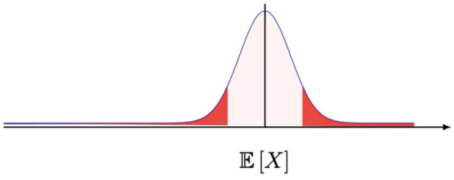

Fig. 6 The expectation of a random variable and its probability distribution. The tails are highlighted in red

Given the expectation of a random variable, which often may be estimated easily, tail inequalities give bounds on the probability that the actual random variable deviates from its expectation [58, 59]. The most simple tail inequality is Markov's inequality. Many strong tail inequalities are derived from Markov's inequality.

Theorem 1 (Markov's Inequality). *Let X be a random variable assuming only nonnegative values. Then for all $t \in \mathbb{R}^+$,*

$$\Pr(X \geq t) \leq \frac{\mathbb{E}[X]}{t}.$$

The power of the inequality is that no knowledge about the random variable is required apart from it being nonnegative.

Let X be a random variable indicating the number of bits flipped in one iteration of the (1+1) EA. As seen in the previous section, one bit is flipped per iteration in expectation, i.e., $\mathbb{E}[X] = 1$. One may wonder what is the probability that more than one bit is flipped in one time step. A straightforward application of Markov's inequality reveals that in at least half of the iterations either one bit is flipped or none:

$$\Pr(X \geq 2) \leq \frac{\mathbb{E}[X]}{2} = \frac{1}{2}.$$

Similarly, one may want to gain some information on how many *ones* are contained in the bitstring at initialization, given that in expectation there are $\mathbb{E}[X] = n/2$ (here X is a binomial random variable with parameters n and $p = 1/2$). An application of Markov's inequality yields that the probability of having more than $(2/3)n$ ones at initialization is bounded by

$$\Pr(X \geq (2/3)n) \leq \frac{\mathbb{E}[X]}{(2/3)n} = \frac{n/2}{(2/3)n} = 3/4. \tag{1}$$

Since X is binomially distributed, it is reasonable to expect that, for large enough n, the actual number of obtained ones at initialization would be more concentrated around the expected value. In particular, while the bound is obviously correct, the probability that the initial bitstring has more than $(2/3)n$ ones is much smaller than $3/4$. However, to achieve such a result, more information about the random variable should be required by the tail inequality (i.e., that it is binomially distributed). An important class of tail inequalities used in the analysis of stochastic search heuristics are Chernoff bounds.

Theorem 2 (Chernoff Bounds). *Let $X_1, X_2, \ldots X_n$ be independent random variables taking values in $\{0, 1\}$. Define $X = \sum_{i=1}^{n} X_i$, which has expectation $E(X) = \sum_{i=1}^{n} \Pr(X_i = 1)$:*

(a) $\Pr(X \leq (1-\delta)\mathbb{E}[X]) \leq e^{\frac{-\mathbb{E}[X]\delta^2}{2}}$ *for* $0 \leq \delta \leq 1$.

(b) $\Pr(X > (1+\delta)\mathbb{E}[X]) \leq \left(\frac{e^{\delta}}{(1+\delta)^{1+\delta}}\right)^{\mathbb{E}[X]}$ *for* $\delta > 0$.

An application of Chernoff bounds reveals that the probability that the initial bitstring has more than $(2/3)n$ one-bits is exponentially small in the length of the bitstring. Let $X = \sum_{i=1}^{n} X_i$ be the random variable summing up the random values X_i of each of the n bits. Since each bit is initialized with probability $1/2$, it holds that $\Pr(X_i = 1) = 1/2$ and $\mathbb{E}[X] = n/2$. By fixing $\delta = 1/3$, it follows that $(1+\delta)\mathbb{E}[X] = (2/3)n$, and finally by applying inequality (b),

$$\Pr(X > (2/3)n) \leq \left(\frac{e^{1/3}}{(4/3)^{4/3}}\right)^{n/2} < \left(\frac{29}{30}\right)^{n/2}.$$

In fact, an exponentially small probability of deviating from $n/2$ by a constant factor of the search space c/n for any constant $c > 0$ may easily be obtained by Chernoff bounds, and even for a deviation of $\Omega(\sqrt{n})$.

For a comprehensive overview of tail inequalities and other probabilistic tools that have proven to be useful in the analysis of randomized search heuristics, we refer to the book chapter by B. Doerr [19].

Artificial Fitness Levels (AFL)

The artificial fitness levels technique is a very simple method to achieve upper bounds on the runtime of elitist stochastic optimization algorithms. Albeit its simplicity, it often achieves very good bounds on the runtime.

The idea behind the method is to divide the search space of size 2^n into m disjoint fitness-based partitions $A_1, \ldots A_m$ of increasing fitness such that $f(A_i) < f(A_j)$ $\forall i < j$. The union of these partitions should cover the whole search space, and the level of highest fitness A_m should contain the global optimum (or all global optima if there is more than one) (see Fig. 7).

Definition 1. A tuple $(A_1, A_2, \ldots, A_m)$ is an f-**based partition** of $f : \mathcal{X} \to \mathbb{R}$ if:

1. $A_1 \cup A_2 \cup \cdots \cup A_m = \mathcal{X}$
2. $A_i \cap A_j = \emptyset$ for $i \neq j$
3. $f(A_1) < f(A_2) < \cdots < f(A_m)$
4. $f(A_m) = \max_x f(x)$

For functions of unitation, a natural way of defining a fitness-based partition is to divide the search space into $n+1$ levels, each defined by the number of

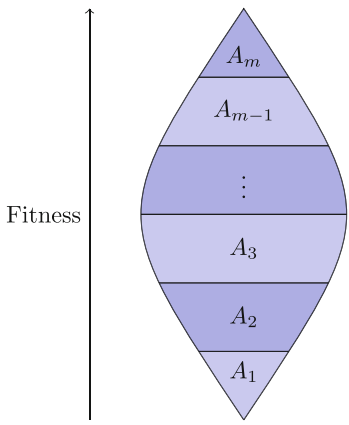

Fig. 7 A partition of the search space satisfying the conditions of an f-based partition

ones in the bitstring. For the ONEMAX function, where fitness increases with the number of ones in the bitstring, the fitness levels would be naturally defined as $A_i := \{x \in \{0,1\}^n \mid \text{ONEMAX}(x) = i\}$.

AFL: Upper Bounds

Given a fitness-based partition of the search space, it is obvious that an elitist algorithm using only one individual will only accept points of the search space that belong to levels of higher or equal fitness to the current level. Once a new fitness level has been reached, the algorithm will never return to previous levels. This implies that each fitness level has to be left at most once by the algorithm. Since in the worst case all fitness levels are visited, the sum of the expected times to leave all levels is an upper bound on the expected time to reach the global optimum. The artificial fitness levels method simplifies this idea by only requiring a lower bound s_i on the probability of leaving each level A_i rather than asking for the exact probabilities to leave each level.

Theorem 3 (Artificial Fitness Levels). *Let $f : \mathcal{X} \to \mathbb{R}$ be a fitness function, $A_1 \dots A_m$ a fitness-based partition of f, and $s_1 \dots s_{m-1}$ be lower bounds on the corresponding probabilities of leaving the respective fitness levels for a level of better fitness. Then the expected runtime of an elitist algorithm using a single individual is $\mathbb{E}\left[T_{A,f}\right] \leq \sum_{i=1}^{m-1} 1/s_i$.*

The artificial fitness level method will now be applied to derive an upper bound on the expected runtime of (1+1) EA for the ONEMAX function. Afterward, the bound will be generalized to general linear blocks of unitation.

Theorem 4. *The expected runtime of the (1+1) EA on* ONEMAX *is $O(n \log n)$.*

Proof. The artificial fitness levels method will be applied to the $m = n + 1$ partitions defined by the number of ones in the bitstring, i.e., $A_i := \{x \in \{0,1\}^n \mid \textsc{Onemax}(x) = i\}$. This means that all bitstrings with i ones and $n - i$ zeroes belong to fitness level A_i. For each level A_i, the method requires a lower bound on the probability of reaching any level A_j where $j > i$. To reach a level of higher fitness, it is necessary to increase the number of ones in the bitstring. However, it is sufficient to flip a *zero* into a *one* and leave the remaining bits unchanged. Since the probability of flipping a bit is $1/n$ and there are $n - i$ zeroes that may be flipped, a lower bound on the probability to reach a level of higher fitness from level A_i is

$$s_i \geq (n-i) \cdot \frac{1}{n} \cdot \left(1 - \frac{1}{n}\right)^{n-1} \geq \frac{n-i}{en},$$

where $(1 - 1/n)^{n-1}$ is the probability of leaving $n - 1$ bits unchanged and the inequality follows because $(1 - 1/n)^{n-1} \geq 1/e$ for all $n \in \mathbb{N}$.

Then by the artificial fitness levels method (Theorem 3),

$$\begin{aligned}\mathbb{E}\left[T_{(1+1)\ EA,\textsc{Onemax}}\right] &\leq \sum_{i=1}^{m-1} 1/s_i \leq \sum_{i=0}^{n-1} \frac{en}{n-i} = en \sum_{i=1}^{n} \frac{1}{i} \\ &= en \ln n + O(n) = O(n \log n).\end{aligned}$$

□

Theorem 5. *The expected runtime of the (1+1)-EA for a* linear block *of length m ending at position k is* $O(n \log((m+k)/k))$.

Proof. Apply the artificial fitness levels method where each partition A_i consists of the bitstrings in the block with i zeroes. Then the probability of leaving a fitness level is bounded by $s_i \geq i/n \cdot (1 - 1/n)^{n-1} \geq i/en$. Given that at most m fitness levels need to be left and that the block starts at position $m + k$ and ends at position k, by Theorem 3, the expected runtime is

$$\mathbb{E}[T] \leq \sum_{i=k+1}^{k+m} \frac{en}{i} \leq en \sum_{i=k+1}^{k+m} \frac{1}{i} \leq en \left(\sum_{i=1}^{k+m} \frac{1}{i} - \sum_{i=1}^{k} \frac{1}{i}\right) \leq en \ln\left(\frac{m+k}{k}\right).$$

□

The AFL method may also be applied for the analysis of the $(\mu+1)$ EA which uses a parent population of size μ. Apart from having a population, the algorithm differs from the (1+1)-EA in another aspect: The selection for replacement step selects uniformly at random among the individuals with lowest fitness rather than favoring the offspring. Since different individuals may be on different fitness levels

during the optimization process, a potential function tracking the fitness level of the best individual can be used to measure the progress of the algorithm toward the optimum. Then, the (1+1)-EA's bounds on the probability to leave a given level A_i may be used, and by considering that the best individual is selected with probability $1/\mu$, a trivial upper bound of $E[T_{A,f}] \leq \sum_{i=1}^{m-1} \mu/s_i$ on the runtime of the (μ+1) EA is provided by the AFL method. This bound is a factor of μ larger than that of the (1+1)-EA.

A more careful insight is that the probability of leaving a level would be considerably higher if more individuals were on the current level rather than just one, and such an increase can happen quickly since it just requires that an individual on the level is selected and creates a copy of itself by not flipping any bits, which in turn occurs with constant probability. The probability of leaving the level is indeed the same as that of the (1+1)-EA if all the individuals are on the current level. Thus, by waiting for a sufficient amount of individuals of the population to *take over* a given fitness level A_i before calculating the probability to reach a fitness level of higher fitness, a tight upper bound on the expected runtime of the (μ+1) EA can be derived by pessimistically assuming that the current level is not left before the take-over has happened. The method may be formalized as follows.

Theorem 6 (Artificial Fitness Levels for Elitist Populations). *Let $f : \mathcal{X} \to \mathbb{R}$ be a fitness function, $A_1 \ldots A_m$ a fitness-based partition of f, and let the algorithm be in the fitness level A_i of the best individual of the population. Furthermore, let $s_1 \ldots s_{m-1}$ be lower bounds on the corresponding probabilities of leaving the respective fitness levels for a level of better fitness given that there are at least $\chi(i)$ individuals on level $A(i)$ and $E[T_{\chi(i)}]$ an upper bound on the expected time to create such a number of individuals on the respective level. Then the expected runtime of an elitist population-based algorithm is $\mathbb{E}\left[T_{A,f}\right] \leq \sum_{i=1}^{m-1} \left(1/s_i + E[T_{\chi(i)}]\right)$.*

We now use the method to derive an upper bound on the expected runtime of the (μ+1) EA for ONEMAX.

Theorem 7. *The expected runtime of the (μ+1) EA on* ONEMAX *is $O(\mu n + n \log n)$.*

Proof. We estimate the time required for the algorithm to reach a population on the level of size at least $\min\{n/(n-i), \mu\}$ when it is on level A_i. If there are j individuals on the level, it suffices to select one of them and create a copy by not flipping any bits to create another individual on the same level. Since this happens with probability at least

$$\frac{j}{\mu}\left(1 - \frac{1}{n}\right)^n \geq \frac{j}{e\mu},$$

the expected time for the population to reach the desired size is at most

$$E[T_{\chi(i)}] \leq \sum_{j=1}^{\lceil n/(n-i)\rceil - 1} \frac{2e\mu}{j} \leq 2e\mu \ln\left(\frac{en}{n-i}\right)$$

if the fitness level is not left before.

Now the expected times to reach the desired number of individuals on each of the n levels can be bounded from above by

$$2e\mu \sum_{i=0}^{n-1} \ln\left(\frac{en}{n-i}\right) = 2e\mu \ln\left(\frac{e^n n^n}{n!}\right) \leq 2e\mu \ln(e^{2n}) = 4e\mu n,$$

where we used Stirling's approximation $n! \geq (n/e)^n$ for the inequality. All that remains to be calculated is the expected time to leave each level given that we have at least $\min\{n/(n-i), \mu\}$ individuals on the level. Let j be the number of individual on fitness level A_i. Then the probability of leaving level A_i is at least,

$$\begin{aligned} s_i &\geq \frac{j}{\mu}\frac{n-i}{n}\left(1-\frac{1}{n}\right)^{n-1} \geq \frac{j(n-i)}{e\mu n} \geq \frac{\min\{n/(n-i), \mu\}(n-i)}{e\mu n} \\ &= \frac{\min\{n, \mu(n-i)\}}{e\mu n}. \end{aligned}$$

Thus the expected time to leave all the fitness levels is at most

$$\sum_{i=0}^{n-1}\left(\frac{e\mu n}{n} + \frac{e\mu n}{\mu(n-i)}\right) \leq en\ln n + e\mu n.$$

Finally, taking into account the μ evaluations at initialization and summing also the $4e\mu n$ evaluations required to fill up each level, we get a total expected runtime of at most $\mu + en\ln n + 5e\mu n = O(n\log n + \mu n)$. □

The AFL method may be further extended to analyze the expected runtime of crossover-based algorithms such as the (μ+1)-GA. For the crossover operator to be useful, it is necessary that the population has diversity. A crossover between two identical individuals produces an offspring that is identical to the parent. On the other hand, if diversity is present, the probability that an offspring assumes the bit values of a given parent where the two parents differ is higher compared to relying on mutation, because a bit is inherited from either parent with probability $1/2$, while a bit is only mutated with probability $1/n$.

One may use the basic AFL method (Theorem 3) to derive trivial upper bounds on the runtime of the (μ+1)-GA by considering that the best individual is selected twice for reproduction with probability $1/\mu^2$, or that a copy of an individual on the current level may be created with probability at least $1/(e\mu^2)$ for an application

of the AFL method for populations (Theorem 6). If s_i is a lower bound on the probability of mutation to leave the level for a better one, then the expected time of the (μ+1)-GA is at most $\mathbb{E}\left[T_{(\mu+1)-GA,f}\right] \leq \sum_{i=1}^{m-1} \mu^2/s_i$. This, for instance, leads to an upper bound of $O(\mu^2 n \log n)$ for ONEMAX using the basic method which however is only asymptotically tight for populations of constant size. Similarly one may hope to get a slightly better bound of $O(\mu^2 n + n \log n)$ on the expected runtime using the artificial fitness levels for elitist populations method. However, the result does not provide any insights into what population sizes are more appropriate and relies on crossover being applied only when diversity is not present in the population, thus not being useful at all. The following extension of the AFL method for the analysis of genetic algorithms allows to better appreciate the effectiveness of populations and crossover at hillclimbing.

We now consider the algorithm to be in fitness level A_i if the whole population is on the level. A Markov chain (MC_i), $1 \leq i \leq m$, as illustrated in Fig. 8, may be used to track whether the population on the current fitness level has diversity or not. Thus m Markov chains are considered, one per fitness level. State $S_{1,i}$ refers to no diversity, i.e., all the individuals have the same genotype, while state $S_{2,i}$ refers to the population having at least two individuals on the level with different genotypes. Thus, from the second state, crossover may exploit the present diversity. For the method to be applicable, from a diversity-less population in state $S_{1,i}$, it has to be possible to create the diversity via mutation with probability p_d. Then, however, from state $S_{2,i}$, it may also be possible to lose the diversity again with some *relapse* probability p_r, for example, if one diverse individual is taken over by the others by creating a copy. The absorbing state $S_{3,i}$ is reached when a solution at a better fitness level is found. This may happen via mutation with probability p_m from state $S_{1,i}$ (because crossover is ineffective when no diversity is present) and via crossover followed by mutation from state $S_{2,i}$. Formally, when the fitness level is left by one individual, the algorithm is not in level A_i anymore. We then wait for this individual to take over the whole population, and we pessimistically assume that the algorithm does not make any further progress in the mean time. Thus, by summing up the absorbing times of the $m-1$ Markov chains, one for each fitness level, and taking into account the $m-1$ take over times before the optimum is hit, we get a valid upper bound on the expected runtime of the (μ+1)-GA. In the following, we formalize the method.

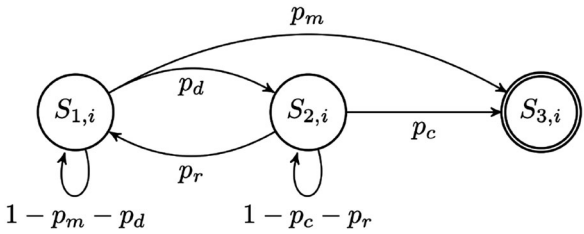

Fig. 8 An illustration of the Markov chain for level A_i designed to distinguish between the algorithm having a diverse population (State $S_{2,i}$) and having one that is not diverse (State $S_{1,i}$)

Theorem 8 (Artificial Fitness Levels for Elitist Populations and Crossover). *Let $f : \mathcal{X} \to \mathbb{R}$ be a fitness function, and $A_1 \dots A_m$ a fitness-based partition of f. Let M be a Markov chain with the topology of Fig. 8. Let $p'_m(i) > 0$, $p'_d(i) > 0$, $p'_c(i) > 0$ be lower bounds, respectively, on the probabilities $p_m(i)$, $p_d(i)$ and $p_c(i)$, and $p'_r(i) > 0$ an upper bound on $p_r(i)$. Then if also $p'_c(i) > p'_m(i)$,*

$$\mathbb{E}\left[T_{A,f}\right] \leq \sum_{i=1}^{m-1} \left(\frac{p'_c(i) + p'_r(i)}{p'_c(i)p'_d(i) + p'_c(i)p'_m(i) + p'_m(i)p'_r(i)} + \frac{1}{p'_c(i)} + E[T_{\chi_\mu(i)}] \right),$$

where $E[T_{\chi_\mu(i)}]$ is the expected time for an individual who has left level A_i to take over the rest of the population.

By calculating the transition probabilities, the method can be applied to prove the following theorem which shows that the (μ+1)-GA is faster than the (1+1)-EA for ONEMAX. In fact, since the (1+1)-EA with mutation rate $1/n$ is the fastest algorithm using standard bit mutation for ONEMAX, the theorem shows that the (μ+1)-GA is faster than any possible algorithm using only standard bit mutation as variation operator.

Theorem 9. *The expected runtime of the (μ+1)-GA for* ONEMAX *is at most* $(3/4)en \ln n(1 + o(1))$ *if* $3 \leq \mu = o(\log n / \log \log n)$.

AFL: Lower Bounds

The artificial fitness levels method has been extended to obtain lower bounds on the runtime of stochastic search algorithms. Since lower bounds are aimed for, the method also needs to take into account the probability that some levels may be skipped by the algorithm, apart from the probabilities of leaving each fitness level.

Theorem 10 (Artificial Fitness Levels for Lower Bounds). *Consider a fitness function $f : \mathcal{X} \to \mathbb{R}$ and $A_1 \dots A_m$ a fitness-based partition of f. Let u_i be the probability of starting in level A_i,s_i be an upper bound on the probability of leaving A_i, and $p_{i,j}$ be an upper bound on the probability of jumping from level A_i to level A_j. If there exists some $0 < \chi \leq 1$ such that for all $j > i$*

$$p_{i,j} \geq \chi \cdot \sum_{k=j}^{m-1} p_{i,k},$$

then the expected runtime of an elitist algorithm using a single individual is

$$\mathbb{E}\left[T_{A,f}\right] \geq \chi \cdot \sum_{i=1}^{m-1} u_i \sum_{j=i}^{m-1} \frac{1}{s_j}.$$

The method will first be illustrated for the (1+1) EA on the ONEMAX function. Afterward, the result will be generalized to general linear blocks of unitation.

Theorem 11. *The expected runtime of the (1+1) EA on* ONEMAX *is* $\Omega(n \log n)$.

Proof. Apply the artificial fitness levels method on the $n+1$ partitions defined by the number of ones in the bitstring, i.e., $A_i := \{x \in \{0,1\}^n \mid \text{ONEMAX}(x) = i\}$. This means that all bitstrings with i ones and $n-i$ zeroes belong to fitness level A_i. To apply the artificial fitness levels method, bounds on s_i and χ need to be derived. An upper bound on the probability of leaving fitness level A_i is simply $s_i \leq (n-i)/n$ because it is a necessary condition that at least one zero flips to reach a better fitness level. The bound follows because each bit flips with probability $1/n$, and there are $n-i$ zeroes available to be flipped. In order to obtain an upper bound on χ, the method requires a lower bound on $p_{i,j}$ and an upper bound on $\sum_{k=j}^{m-1} p_{i,k}$. For the lower bound on $p_{i,j}$, notice that in order to reach level A_j, it is sufficient to flip $j-i$ zeroes out of the $n-i$ zeroes available and leave all the other bits unchanged. Hence, the following bound is obtained:

$$p_{ij} \geq \binom{n-i}{j-i} \left(\frac{1}{n}\right)^{j-i} \left(1-\frac{1}{n}\right)^{n-(j-i)}.$$

For an upper bound on the sum, notice that to reach any level A_k $k \geq j$ from level A_i, it is necessary to flip at least $j-i$ zeroes out of the $n-i$ available zeroes. So,

$$\sum_{k=j}^{n-1} p_{i,k} \leq \binom{n-i}{j-i} \left(\frac{1}{n}\right)^{j-i},$$

and for $\chi := 1/e$, the condition of Theorem 10 is satisfied as follows:

$$p_{i,j} \geq \left(1-\frac{1}{n}\right)^{n-(j-i)} \cdot \sum_{k=j}^{n-1} p_{i,k} \geq \chi \cdot \sum_{k=j}^{n-1} p_{i,k}.$$

By Eq. (1), the probability that the initial search point has less than $(2/3)n$ 1-bits is at least

$$\sum_{i=1}^{(2/3)n} u_i \geq 1 - \frac{3}{4}.$$

The statement of Theorem 10 now yields

$$\begin{aligned}
\mathbb{E}\left[T_{A,f}\right] &\geq \left(\frac{1}{e}\right) \cdot \sum_{i=1}^{n-1} u_i \sum_{j=i}^{n-1} \frac{1}{s_j} \\
&> \left(\frac{1}{e}\right) \cdot \left(\sum_{i=1}^{(2/3)n} u_i\right) \sum_{j=(2/3)n}^{n-1} \frac{1}{s_j} \\
&\geq \left(\frac{1}{e}\right) \cdot \left(1 - \frac{3}{4}\right) \sum_{j=(2/3)n}^{n-1} \frac{n}{n-j} \\
&\geq \left(\frac{n}{4e}\right) \cdot \sum_{j=1}^{n/3} \frac{1}{j}.
\end{aligned}$$

It now follows that $\mathbb{E}\left[T_{A,f}\right] = \Omega(n \log n)$. □

Similarly, the following result may also be proved for linear blocks of unitation functions by defining the fitness partitions as $A_i := \{x : n - |x| = k + m - i\}$ for $0 \leq i \leq m$.

Theorem 12. *The expected runtime of the (1+1)-EA for a* linear block *of length m ending at position k is* $\Omega(n \log((m+k)/k))$.

Level-Based Analysis of Non-elitist Populations

A weakness of the classical artificial fitness level technique is that it is limited to search heuristics that use elitism such as steady-state EAs. The so-called *level-based analysis* is a generalization of fitness level theorems for non-elitist evolutionary algorithms which is also applicable to search heuristics using higher arity operators such as crossover.

The theorem applies to any algorithm that can be expressed in the form of Algorithm 3, such as genetic algorithms and estimation of distribution algorithms. The main component of the algorithm is a random operator D which given the current population $P_t \in \mathcal{X}^\lambda$ returns a probability distribution $D(P_t)$ over the search space $\mathcal{X}$. The next population P_{t+1} is obtained by sampling individuals independently from this distribution.

In contrast to classical fitness level theorems, the level-based theorem (Theorem 13) only assumes a partition $(A_1, \ldots, A_{m+1})$ of the search space $\mathcal{X}$, and not an f-based partition (see Definition 1). Each of the sets A_j, $j \in [m+1]$ is called a *level*, and the symbol $A_j^+ := \bigcup_{i=j+1}^{m+1} A_i$ denotes the set of search points above level A_j. Given a constant $\gamma_0 \in (0, 1)$, a population $P \in \mathcal{X}^\lambda$ is considered to be at

Algorithm 3: Population-based algorithm with independent sampling

1: **Initialisation**:
$t \leftarrow 0$; Initialise P_t uniformly at random from $\mathcal{X}^\lambda$.
2: **Variation and Selection**:
3: **for** $i = 1 \ldots \lambda$ **do**
Sample $P_{t+1}(i) \sim D(P_t)$
4: **end for**
5: $t \leftarrow t + 1$; Continue at 2

level A_j with respect to γ_0 if $|P \cap A_{j-1}^+| \geq \gamma_0 \lambda$ and $|P \cap A_j^+| < \gamma_0 \lambda$ meaning that at least a γ_0 fraction of the population is in level A_j or higher.

Theorem 13 (Level-Based Theorem). *Given any partition of a finite set $\mathcal{X}$ into m nonoverlapping subsets $(A_1, \ldots, A_{m+1})$, define $T := \min\{t\lambda \mid |P_t \cap A_{m+1}| > 0\}$ to be the first point in time that elements of A_{m+1} appear in P_t of Algorithm 3. If there exist parameters $z_1, \ldots, z_m, z_* \in (0, 1]$, $\delta > 0$, and a constant $\gamma_0 \in (0, 1)$ such that for all $j \in [m]$, $P \in \mathcal{X}^\lambda$, $y \sim D(P)$, and $\gamma \in (0, \gamma_0]$, it holds:*

(C1) $\Pr\left(y \in A_j^+ \mid |P \cap A_{j-1}^+| \geq \gamma_0 \lambda\right) \geq z_j \geq z_*$

(C2) $\Pr\left(y \in A_j^+ \mid |P \cap A_{j-1}^+| \geq \gamma_0 \lambda \text{ and } |P \cap A_j^+| \geq \gamma \lambda\right) \geq (1 + \delta)\gamma$, *and*

(C3) $\lambda \geq \frac{2}{a} \ln\left(\frac{16m}{ac\varepsilon z_*}\right)$ *with* $a = \frac{\delta^2 \gamma_0}{2(1+\delta)}$, $\varepsilon = \min\{\delta/2, 1/2\}$ *and* $c = \varepsilon^4/24$

then

$$\mathbb{E}[T] \leq \frac{2}{c\varepsilon}\left(m\lambda(1 + \ln(1 + c\lambda)) + \sum_{j=1}^{m} \frac{1}{z_j}\right).$$

The theorem provides an upper bound on the expected optimization time of Algorithm 3 if it is possible to find a partition $(A_1, \ldots, A_{m+1})$ of the search space $\mathcal{X}$ and accompanying parameters $\gamma_0, \delta, z_1, \ldots, z_m, z_*$ such that conditions (C1), (C2), and (C3) are satisfied. Condition (C1) requires a nonzero probability z_j of creating an individual in level A_{j+1} or higher if there are already at least $\gamma_0 \lambda$ individuals in level A_j or higher. In typical applications, this imposes some conditions on the variation operator. The condition is analogous to the probability s_j in the artificial fitness level technique. Condition (C2) requires that if in addition there are $\gamma\lambda$ individuals at level A_{j+1} or better, then the probability of producing an individual in level A_{j+1} or better should be larger than γ by a multiplicative factor $1 + \delta$. In typical applications, this imposes some conditions on the strength of the selective pressure in the algorithm. Finally, condition (C3) imposes minimal requirements on the population size in terms of the parameters above.

As an example application of the level-based theorem, the (μ, λ) EA is analyzed, which is the non-elitist variant of the $(\mu + \lambda)$ EA shown in Algorithm 1 (without crossover). The two algorithms differ in the selection step (line 7) where the new

population P_{t+1} in (μ, λ) EA is chosen as the best μ individuals out of $\{y_1, \ldots, y_\lambda\}$ and breaking ties uniformly at random. While the $(\mu + \lambda)$ EA always retains the best μ individuals in the population (hence the name elitist), the (μ, λ) EA always discards the old individuals $x^{(1)}, \ldots, x^{(\mu)}$.

At first sight, it may appear as if the (μ, λ) EA cannot be expressed in the form of Algorithm 3. The μ individuals $x^{(1)}, \ldots, x^{(\mu)}$ that are kept in each generation are not independent due to the inherent sorting of the offspring. However, taking a different perspective, the population of the algorithm at time t could also be interpreted as the λ offspring $y^{(1)}, \ldots, y^{(\lambda)}$. In this alternative interpretation, the new population is now created by sampling uniformly at random among the μ best individuals in the population and applying the mutation operator. The operator D in Algorithm 3 can now be defined as in Algorithm 4.

Algorithm 4: Operator D corresponding to (μ, λ) EA

1: **Selection**:
Sort the population $P_t = (y^{(1)}, \ldots, y^{(\lambda)})$ such that $f(y^{(1)}) \geq f(y^{(2)}) \geq \ldots \geq f(y^{(\lambda)})$.
Select x uniformly at random among $\{y^{(1)}, \ldots, y^{(\mu)}\}$.
2: **Variation (mutation)**:
Create x' by flipping each bit in x with probability χ/n.
3: **return** x'

The following lemma will be useful when estimating the probability that the mutation operator does not flip any bit positions.

Lemma 1. *For any $\delta \in (0, 1)$ and $\chi > 0$, if $n \geq (\chi + \delta)(\chi/\delta)$, then*

$$\left(1 - \frac{\chi}{n}\right)^n \geq (1 - \delta)e^{-\chi}.$$

Proof. Note first that $\ln(1 - \delta) < -\delta$, hence

$$\left(\frac{n}{\chi} - 1\right)(\chi - \ln(1 - \delta)) \geq n + \frac{n\delta}{\chi} - (\chi + \delta) \geq n.$$

By making use of the fact that $(1 - 1/x)^{x-1} \geq 1/e$ and simplifying the exponent n as above

$$\left(1 - \frac{\chi}{n}\right)^n \geq \left[\left(1 - \frac{\chi}{n}\right)^{(n/\chi)-1}\right]^{\chi - \ln(1-\delta)} \geq (1 - \delta)e^{-\chi}.$$

□

The expected optimization time of the (μ, λ) EA on ONEMAX can now be expressed in terms of the mutation rate χ/n and the problem size n assuming some constraints on the population sizes μ and λ. The theorem is valid for a wide range

of mutation rates χ/n. In the classical setting of $\chi = 1$, the expected optimization time reduces to $O(n\lambda \ln \lambda)$.

Theorem 14. *The expected optimization time of the (μ, λ) EA with bitwise mutation rate χ/n where $\chi \in (0, n/2)$, and population sizes μ and λ satisfying for any constant $\delta \in (0, 1)$*

$$\frac{\lambda}{\mu} \geq \left(\frac{1+\delta}{1-\delta}\right) e^{\chi}, \quad \text{and} \quad \lambda \geq \frac{4}{\delta^2 e^{\chi}} \ln\left(\frac{24576n(n+1)}{\delta^7 \chi}\right)$$

on ONEMAX *is for any $n \geq (\chi + \delta)/(\chi/\delta)$ no more than*

$$\frac{1536n}{\delta^5}\left(\lambda \ln(\lambda) + \frac{e^{\chi} \ln(n+2)}{\chi(1-\delta)}\right) + O(n\lambda).$$

Proof. Apply the level-based theorem with the same $m := n + 1$ partitions as in the proof of Theorem 11. Since the parameter δ is assumed to be some constant $\delta \in (0, 1)$, it also holds that the parameters a, ε, and c are positive constants. The parameters $\gamma_0, z_1, \ldots, z_m$, and z_* will be chosen later.

To verify that conditions (C1) and (C2) hold for any $j \in [m]$, it is necessary to estimate the probability that operator D produces a search point x' with $j + 1$ one-bits when applied to a population P containing at least $\gamma_0\lambda$ individuals, each having at least j one-bits (formally $|P \cap A^+_{j-1}| \geq \gamma_0\lambda$). Such an event is called a *successful sample*.

Condition (C1) asks for bounds z_j for each $j \in [m]$ on the probability that the search point x' returned by Algorithm 4 contains $j + 1$ one-bits. First choose the parameter setting $\gamma_0 := \mu/\lambda$. This parameter setting is convenient, because the selection step in Algorithm 4 always picks an individual x among the best $\mu = \gamma_0\lambda$ individuals in the population. By the assumption that $|P \cap A^+_{j-1}| \geq \gamma_0\lambda$, the algorithm will always select an individual x containing at least $j + i$ one-bits for some nonnegative integer $i \geq 0$.

Assume without loss of generality that the first j-bit positions in the selected individual x are one-bits, and let k, $j < k \leq n$, be any of the other bit positions. If there is a zero-bit in position k or if $i \geq 2$, then a successful sample occurs if the mutation operator flips only bit position k. If there is a one-bit in position k, and if $i = 1$, then the step is still successful if the mutation operator flips none of the bit positions. Since the probability of not flipping a position is higher than the probability of flipping a position, i.e., $1-\chi/n \geq \chi/n$, the probability of a successful sample is therefore in both cases at least

$$(n - j)(\chi/n)(1 - \chi/n)^{n-1}. \tag{2}$$

By Lemma 1, the probability above is at least $z_j := (n - j)(\chi/n)e^{-\chi}(1 - \delta)$. The parameter z_* is chosen to be the minimal among these probabilities, i.e., $z_* := (\chi/n)e^{-\chi}(1 - \delta)$.

Condition (C2) assumes in addition that $\gamma\lambda < \mu$ individuals have fitness $j+1$ or higher. In this case, it suffices that the selection mechanism picks one of the best $\gamma\lambda$ individuals among the μ individuals and that none of the bits are mutated in the selected individual. The probability of this event is at least

$$\frac{\gamma\lambda}{\mu}(1-\chi/n)^n \geq \frac{\gamma\lambda}{\mu}e^{-\chi}(1-\delta).$$

Hence, to satisfy condition (C2), it suffices to require that

$$\frac{\gamma\lambda}{\mu}\exp(-\chi)(1-\delta) \geq \gamma(1+\delta),$$

which is true whenever

$$\frac{\lambda}{\mu} \geq \left(\frac{1+\delta}{1-\delta}\right)e^{\chi}.$$

To check condition (C3), notice that $\varepsilon = \delta/2$, and $c = \delta^4/384$, hence

$$a = \frac{\delta^2(\lambda/\mu)}{2(1+\delta)} \geq \frac{\delta^2 e^{\chi}}{2(1-\delta)}, \text{ and}$$

$$ac\varepsilon z_* \geq \frac{\delta^2\chi}{2n}c\varepsilon = \frac{\delta^7\chi}{1536n}.$$

Condition (C3) is now satisfied, because the population size λ is required to fulfil

$$\frac{2}{a}\ln\left(\frac{16m}{ac\varepsilon z_*}\right) \leq \frac{4(1-\delta)}{\delta^2 e^{\chi}}\ln\left(\frac{24576mn}{\delta^7\chi}\right) \leq \lambda.$$

All conditions are satisfied, and the theorem follows. □

Conclusions

The artificial fitness levels method was first described by Wegener [75]. The original method was designed for the achievement of upper bounds on the runtime of stochastic search heuristics using only one individual such as the (1+1) EA. Since then, several extensions of the method have been devised for the analysis of more sophisticated algorithms. Sudholt introduced the method presented in section "AFL: Lower Bounds" for the obtainment of lower bounds on the runtime [71]. In an early study, Witt was the first to use a potential function that generalizes the fitness level argument of [75] to analyze the (μ+1) EA [77]. The resulting method is introduced in section "AFL: Upper Bounds" (Theorem 6). His analysis achieved tight upper bounds on the runtime of the (μ+1) EA on LEADINGONES and ONEMAX by waiting

for a sufficient amount of individuals of the population to *take over* a given fitness level A_i before calculating the probability to reach a level of higher fitness. Chen et al. extended the analysis to offspring populations by analyzing the $(N+N)$ EA, also taking into account the take-over process [3]. Corus and Oliveto introduced the method (Theorem 8) for the analysis of the $(\mu+1)$ GA using populations and crossover by coupling each fitness level with a Markov chain to analyze the diversity of the population on each level [5]. They subsequently extended the Markov chain to contain $\mu/2$ states plus an absorbing state for each fitness level to consider the exact amount of diversity present in the population on each level before improving [6]. This extension allows to show that the $(\mu+1)$ GA is faster than any unbiased mutation-only randomized search heuristic, as well as the utility of populations since the provided upper bounds on the expected runtime decrease with the population size and are indeed lower than the lower bound for the (2+1) GA provided by [66]. Lehre introduced a general fitness level method for arbitrary population-based EAs with non-elitist selection mechanisms and unary variation operators [46]. This technique was later generalized further into the level-based method presented in section "Level-Based Analysis of Non-elitist Populations" [8]. The method allows the analysis of sophisticated non-elitist heuristics such as generational genetic algorithms equipped with mutation, crossover, and stochastic selection mechanisms, for classical, noisy, and uncertain optimization [15] as well as estimation of distribution algorithms [16]. Recently, it has been successfully applied to the analysis of competitive coevolutionary algorithms [2, 47].

Drift Analysis

Drift analysis is a very flexible and powerful tool that is widely used in the analysis of stochastic search algorithms. The high-level idea is to predict the long-term behavior of a stochastic process by measuring the expected progress toward a target in a single step. Naturally, a measure of progress needs to be introduced, which is generally called a *distance function*. Given a random variable X_k representing the current state of the process at step k, over a finite set of states S, a distance function $d : S \to \mathbb{R}_0^+$ is defined such that $d(X_k) = 0$ if and only if X_k is a target point (e.g., the global optimum). Drift analysis aims at deriving the expected time to reach the target by analyzing the decrease in distance in each step, i.e., $d(X_{k+1}) - d(X_k)$. The expected value of this decrease in distance $\Delta_k = \mathbb{E}[d(X_{k+1}) - d(X_k) \mid X_k]$ is called the *drift*. See Fig. 9 for an illustration. If the initial distance from the target is $d(X_0)$ and a bound on the drift Δ (i.e., the expected improvement in each step) is known, then bounds on the expected runtime to reach the target may be derived.

Additive Drift Theorem

The additive drift theorem allows to derive both upper and lower bounds on the runtime of stochastic search algorithms. Consider a distance function $Y_k = d(X_k)$

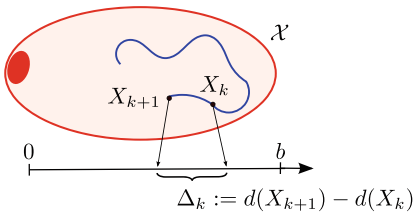

Fig. 9 An illustration of the drift Δ at time step k of a process represented by the random variable X and a distance function d

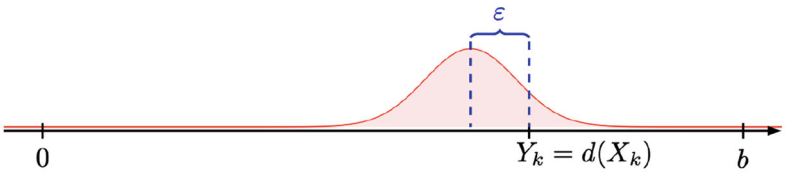

Fig. 10 An illustration of the condition of the additive drift theorem. If the expected distance to the optimum decreases of *at least* ε at each step (i.e., condition C1+), then an upper bound on the runtime is achieved. If the distance decreases of *at most* ε at each step (i.e., condition C1−), then a lower bound on the runtime is obtained

indicating the current distance, at time k, of the stochastic process from the optimum. The theorem simply states that if at each time step k, the drift is *at least* some value $-\varepsilon$ (i.e., the process has moved closer to the target), then the expected number of steps to reach the target is *at most* Y_0/ε. Conversely, if the drift in each step is *at most* some value $-\varepsilon$, then the expected number of steps to reach the target is *at least* Y_0/ε (Fig. 10).

Theorem 15 (Additive Drift Theorem). *Given a stochastic process* $X_1, X_2, \ldots$ *over an interval* $[0, b] \subset \mathbb{R}$ *and a distance function* $d : S \to \mathbb{R}_0^+$ *such that* $d(X_k) = 0$ *if and only if* X *contains the target. Let* $Y_k = d(X_k)$ *for all* k*, define* $T := \min\{k \geq 0 \mid Y_k = 0\}$*, and assume* $\mathbb{E}[T] < \infty$.

Verify the following conditions:

(C1+) $\forall k \quad \mathbb{E}[Y_{k+1} - Y_k \mid Y_k > 0] \leq -\varepsilon$
(C1−) $\forall k \quad \mathbb{E}[Y_{k+1} - Y_k \mid Y_k > 0] \geq -\varepsilon$

Then:

1. *If (C1+) holds for an* $\varepsilon > 0$*, then* $\mathbb{E}[T \mid Y_0] \leq b/\varepsilon$.
2. *If (C1−) holds for an* $\varepsilon > 0$*, then* $\mathbb{E}[T \mid Y_0] \geq Y_0/\varepsilon$.

An example application of the additive drift theorem follows concerning the (1+1) EA for plateau blocks of functions of unitation of length m positioned such that $k > n/2 + \varepsilon n$.

Theorem 16. *The expected runtime of the (1+1)-EA for a* plateau block *of length* m *ending at position* $k > n/2 + \varepsilon n$ *is* $\Theta(m)$.

Proof. The additive drift theorem will be applied to derive both upper and lower bounds on the expected runtime. The starting point is a bitstring X_0 with $m + k$ zeroes, and the target point is a bitstring X_t with k zeroes. Choose to use the natural distance function $Y_t = d(X_t) := n - |X_t|$ that counts the number of zeroes in the bitstring. Subtract k from the distance such that target points with k zeroes have distance 0 and the initial point has distance m. As long as points on the plateau are generated, they will be accepted because all plateau points have equal fitness. Given that each bit flips with probability $1/n$, and at each step the current search point has Y_t zeroes and $n - Y_t$ ones, the drift is

$$\Delta_t := \mathbb{E}\left[Y_t - Y_{t+1} \mid Y_t > 0\right] = \frac{Y_t}{n} - \frac{n - Y_t}{n} = \frac{2 \cdot Y_t}{n} - 1.$$

A lower bound on the drift is obtained by considering that as long as the end of the plateau has not been reached, there are always at least k zeroes that may be flipped (i.e., $Y_t \geq k$). Accordingly for an upper bound, at most $m + k$ zeroes may be available to be flipped (i.e., $Y_t \leq m + k$). Hence,

$$\frac{2k}{n} - 1 \leq \Delta_t \leq \frac{2(m+k)}{n} - 1.$$

Then by additive drift analysis (Theorem 15),

$$\mathbb{E}\left[T \mid Y_0\right] \leq \frac{m}{(2k)/n - 1} = \frac{mn}{2k - n} = O(m)$$

and

$$\mathbb{E}\left[T \mid Y_0\right] \geq \frac{m}{2(m+k)/n - 1} = \frac{mn}{2(m+k) - n} = \Omega(m),$$

where the last equalities hold as long as $k > n/2 + \varepsilon n$. □

Note again that if the plateau block is followed by a gap block, then an upper bound on the expected time to optimize both blocks is achieved by multiplying the upper bounds obtained for each block. This is necessary because points in the gap will not be accepted by the (1+1) EA.

Multiplicative Drift Theorem

In the additive drift theorem, the worst-case decrease in distance is considered. If the expected decrease in distance changes considerably in different areas of the search space, then the estimate on the drift may be too pessimistic for the obtainment of tight bounds on the expected runtime.

Drift analysis of the (1+1) EA for the classical ONEMAX function will serve as an example of this problem. Since the global optimum is the all-ones bitstring

and the fitness increases with the number of ones, a natural distance function is $Y_t = d(X_t) = n - \textsc{Onemax}(X_t)$, which simply counts the number of zeroes in the current search point. Then the distance will be zero once the optimum is found. Points with less one-bits than the current search point will not be accepted by the algorithm because of their lower fitness. So the drift is always positive, i.e., $\Delta_t \geq 0$, and the amount of progress is the expected number of ones gained in each step. In order to find an upper bound on the runtime, a lower bound on the drift is needed (i.e., the worst-case improvement). Such worst case occurs when the current search point is optimal except for one 0-bit. In this case, the maximum decrease in distance that may be achieved in a step is $Y_t - Y_{t+1} = 1$, and to achieve such progress, it is necessary that the algorithm flips the zero into a one and leaves the other bits unchanged. Hence, the drift is

$$\Delta_t \geq 1 \cdot \frac{1}{n}\left(1 - \frac{1}{n}\right)^{n-1} \geq \frac{1}{en} := \varepsilon.$$

Since the expected initial distance is $\mathbb{E}[Y_0] = n/2$ due to random initialization, the drift theorem yields

$$\mathbb{E}[T \mid Y_0] \leq \frac{\mathbb{E}[Y_0]}{\varepsilon} = \frac{n/2}{1/(en)} = e/2 \cdot n^2 = O(n^2).$$

In section "Artificial Fitness Levels (AFL)," it was proven that the runtime of the (1+1) EA for ONEMAX is $\Theta(n \log n)$; hence, a bound of $O(n^2)$ is not tight. The reason is that on functions such as ONEMAX the amount of progress made by the algorithm depends crucially on the distance from the optimum. For ONEMAX in particular, larger progress per step is achieved when the current search point has many zeroes that may be flipped. As the algorithm approaches the optimal solution, the amount of expected progress in each step becomes smaller because search points have increasingly more one-bits than zero-bits in the bitstring. In such cases, a distance function that takes into account these properties of the objective function needs to be used. For ONEMAX, a correct bound is achieved by using a distance function that is logarithmic in the number of zeroes i, i.e., $Y_t = d(X_t) := \ln(i+1)$, where a 1 is added to i in the argument of the logarithm such that the global optimum has distance zero (i.e., $\ln(1) = 0$). With such distance measure, the decrease in distance when flipping a zero and leaving the rest of the bitstring unchanged is

$$\ln(i+1) - \ln(i) = \ln\left(1 + \frac{1}{i}\right) \geq \frac{1}{2i},$$

where the last inequality holds for all $i \geq 1$. Since it is sufficient to flip a zero and leave everything else unchanged to obtain an improvement, the drift is

$$\Delta_t \geq \frac{i}{en} \cdot \frac{1}{2i} = \frac{1}{2en} := \varepsilon.$$

Given that the maximum possible distance is $Y_0 \geq \ln(n+1)$, the drift theorem yields

$$\mathbb{E}[T] \leq \frac{Y_0}{1/(2en)} = 2en \cdot \ln(n+1) = O(n \log n).$$

The multiplicative drift theorem was introduced as a handy tool to deal with situations as the one described above where the amount of progress depends on the distance from the target.

Theorem 17 (Multiplicative Drift Theorem [24]). *Let $\{X_t\}_{t \in \mathbb{N}_0}$ be random variables describing a Markov process over a finite state space $S \subseteq \mathbb{R}$. Let T be the random variable that denotes the earliest point in time $t \in \mathbb{N}_0$ such that $X_t = 0$. If there exist $\delta, c_{\min}, c_{\max} > 0$ such that for all $t < T$:*

1. $\mathbb{E}[X_t - X_{t+1} \mid X_t] \geq \delta X_t$ *and*
2. $c_{\min} \leq X_t \leq c_{\max}$

then

$$\mathbb{E}[T] \leq \frac{2}{\delta} \cdot \ln\left(1 + \frac{c_{\max}}{c_{\min}}\right).$$

The following derivation of an upper bound on the runtime of the (1+1) EA for linear blocks illustrates the multiplicative drift theorem.

Theorem 18. *The expected time for the (1+1)-EA to optimize a linear unitation block of length m ending at position k is $O(n \log((m+k)/k))$.*

Proof. Let X_t be the number of zero-bits in the bitstring at time step t, representing the distance from the end of the linear block. By remembering that increases in distance are not accepted due to elitism, the expected decrease in distance at time step can be bounded by

$$\mathbb{E}[X_{t+1}|X_t] \leq X_t - 1 \cdot \frac{X_t}{en} = X_t\left(1 - \frac{1}{en}\right)$$

simply by considering that if a zero-bit is flipped and nothing else, then the distance decreases by 1. Then the drift is

$$\mathbb{E}[X_t - X_{t+1}|X_t] \geq X_t - X_t\left(1 - \frac{1}{en}\right) = \frac{1}{en}X_t := \delta X_t.$$

By fixing $k = c_{\min} \leq X_t \leq c_{\max} = m + k$, the multiplicative drift theorem yields

$$\mathbb{E}[T] \leq \frac{2}{\delta} \cdot \ln\left(1 + \frac{c_{\max}}{c_{\min}}\right) = 2en \ln(1 + (m+k)/k) = O(n \log((m+k)/k)).$$

□

By fixing $1 = c_{\min} \leq X_t \leq c_{\max} = n$, an $O(n \log n)$ bound on the expected runtime of the (1+1) EA for ONEMAX is achieved.

Variable Drift Theorem

The multiplicative drift theorem is applicable when the drift of a stochastic process is linear with respect to the current position. However, in some stochastic processes, the drift is nonlinear in the current position, i.e.,

$$\mathbb{E}[X_t - X_{t+1} \mid X_t \geq x_{\min}] \geq h(X_t) \tag{3}$$

for some function h. The following variable drift theorem provides bounds on the expectation and the tails of the hitting time distribution of such processes, given some assumptions about the function h.

Theorem 19 (Corollary 1 in [48]). *Let $(X_t)_{t\geq 0}$ be a stochastic process over some state space $S \subseteq \{0\} \cup [x_{\min}, x_{\max}]$, where $x_{\min} \geq 0$. Let $h\colon [x_{\min}, x_{\max}] \to \mathbb{R}^+$ be a differentiable function. Then the following statements hold for the first hitting time $T := \min\{t \mid X_t = 0\}$:*

(i) If $\mathbb{E}[X_t - X_{t+1} \mid X_t \geq x_{\min}] \geq h(X_t)$ and $h'(x) \geq 0$, then

$$\mathbb{E}[T \mid X_0] \leq \frac{x_{\min}}{h(x_{\min})} + \int_{x_{\min}}^{X_0} \frac{1}{h(y)}\,\mathrm{d}y.$$

(ii) If $\mathbb{E}[X_t - X_{t+1} \mid X_t \geq x_{\min}] \leq h(X_t)$ and $h'(x) \leq 0$, then

$$\mathbb{E}[T \mid X_0] \geq \frac{x_{\min}}{h(x_{\min})} + \int_{x_{\min}}^{X_0} \frac{1}{h(y)}\,\mathrm{d}y.$$

(iii) If $\mathbb{E}[X_t - X_{t+1} \mid X_t \geq x_{\min}] \geq h(X_t)$ and $h'(x) \geq \lambda$ for some $\lambda > 0$, then

$$\Pr(T \geq t \mid X_0) < \exp\left(-\lambda\left(t - \frac{x_{\min}}{h(x_{\min})} - \int_{x_{\min}}^{X_0} \frac{1}{h(y)}\,\mathrm{d}y\right)\right).$$

(iv) If $\mathbb{E}[X_t - X_{t+1} \mid X_t \geq x_{\min}] \leq h(X_t)$ and $h'(x) \leq -\lambda$ for some $\lambda > 0$, then

$$\Pr(T < t \mid X_0 > 0) < \frac{e^{\lambda t} - e^{\lambda}}{e^{\lambda} - 1} \exp\left(-\frac{\lambda x_{\min}}{h(x_{\min})} - \int_{x_{\min}}^{X_0} \frac{\lambda}{h(y)}\,\mathrm{d}y\right).$$

To illustrate the variable drift theorem, an upper bound on the optimization time of the (1+1) EA on the class of linear functions with bounded coefficients will be derived. More formally, this class of functions contains any function of the form

$$f(x) := \sum_{i=1}^{n} w_i x_i,$$

with bounded, positive coefficients $w_1, \ldots, w_n \in (w_{\min}, w_{\max})$, where $0 < w_{\min} < w_{\max}$.

The drift function h in this example turns out to be linear; hence, the multiplicative drift theorem could have been applied instead.

Theorem 20. *The expected optimization time of the (1+1) EA on linear functions is less than* $t(n) := en(\ln(n) + \ln(w_{\max}/w_{\min}) + 1)$*, and the probability that the optimization time exceeds* $t(n) + ren$ *for any* $r \geq 0$ *is no more than* e^{-r}.

Proof. Define the distance X_t at time k to be the function value that "remains" at time k, i.e.,

$$X_t := \left(\sum_{i=1}^{n} w_i\right) - \left(\sum_{i=1}^{n} w_i x_i^{(t)}\right) = \sum_{i=1}^{n} w_i \left(1 - x_i^{(t)}\right),$$

where $x_i^{(t)}$ is the i-th bit in the current search point at time t. For any $i \in [n]$, assume that the mutation operator flipped only bit position i, and no other bit positions, an event denoted by the symbol $\mathcal{E}_i$. If $x_i^{(t)} = 0$, then bit position i flipped from 0 to 1 and the distance reduced by w_i. Otherwise, if $x_i^{(t)} = 1$, then bit position i flipped from 1 to 0, the new search point was not accepted, and the distance reduced by 0. Hence, the distance always reduces by $w_i(1 - x_i^{(t)})$ when event $\mathcal{E}_i$ occurs. Using the law of total probability, and noting that the distance can never increase, one obtains

$$\begin{aligned}\mathbb{E}[X_t - X_{t+1} \mid X_t = r] &\geq \sum_{i=1}^{n} \Pr(\mathcal{E}_i \mid X_t = r)\, \mathbb{E}[X_t - X_{t+1} \mid \mathcal{E}_i \wedge X_t = r] \\ &\geq \left(\frac{1}{n}\right)\left(1 - \frac{1}{n}\right)^{n-1} \sum_{i=1}^{n} w_i \left(1 - x_i^{(t)}\right) \geq \frac{r}{en}.\end{aligned}$$

Therefore, $\mathbb{E}[X_t - X_{t+1} \mid X_t] \geq h(X_t)$ for the function $h(x) = x/en$, which has derivative $h'(x) = 1/en$. By Theorem 19 part (i), it follows that

$$\begin{aligned}\mathbb{E}[T \mid X_0] &\leq \frac{x_{\min}}{h(x_{\min})} + \int_{x_{\min}}^{X_0} \frac{1}{h(y)}\,\mathrm{d}y \\ &= \frac{w_{\min}}{h(w_{\min})} + \int_{w_{\min}}^{nw_{\max}} \frac{en}{y}\,\mathrm{d}y \\ &= en + en(\ln(nw_{\max}) - \ln(w_{\min})) \\ &= en(\ln(n) + \ln(w_{\max}/w_{\min}) + 1) =: t(n).\end{aligned}$$

Furthermore, Theorem 19 part (iii) with $\lambda := 1/en$ gives for any $r \geq 0$

$$\Pr(T \geq t(n) + enr) \leq e^{-r}.$$

□

Negative-Drift Theorem

The drift theorems presented in previous subsections are designed to prove polynomial bounds on the runtime of stochastic search algorithms. For this, a positive drift toward the optimum is required. On the other hand, a negative drift indicates that the stochastic process moves away from the optimum in expectation at each step. In such a case, it is unlikely that the algorithm is efficient for the function it is attempting to optimize. Rather, an exponential lower bound on the runtime could probably be proved. The negative-drift theorem is the standard technique used for the purpose.

Apart from a negative drift, the theorem also requires a second condition showing that large jumps are unlikely. The intuitive reason for this second condition is that if large jumps were possible, then the algorithm could maybe be able to jump to the optimum even if in expectation it is drifting away. For technical reasons also, large jumps heading away from the optimum need to be excluded (see [63]) (Fig. 11).

Theorem 21 (Negative-Drift Theorem). *Let X_t, $t \geq 0$, be the random variables describing a Markov process over the state space S and denote the increase in distance in one step $D_t(i) := (X_{t+1} - X_t | X_t = i)$ for $i \in S$ and $t \geq 0$. Suppose there exists an interval $[a, b]$ of the state space and three constants $\delta, \varepsilon, r > 0$ such that for all $t \geq 0$ the following conditions hold:*

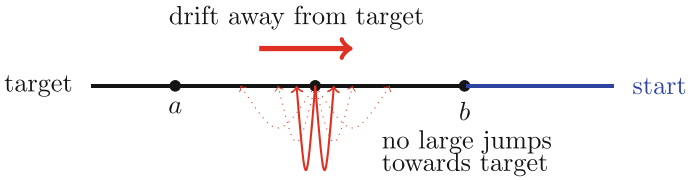

Fig. 11 An illustration of the two conditions of the negative-drift theorem

1. $\Delta_t(i) = \mathbb{E}[D_t(i)] \geq \varepsilon$ *for* $a < i < b$
2. $\Pr(|D_t(i)|) = j) \leq \frac{1}{(1+\delta)^{j-r}}$ *for* $i > a$ *and* $j \geq 1$

Then there exists a constant c^* *such that for* $T := \min\{t \geq 0 : X_t \leq a | X_0 \geq b\}$ *it holds* $Pr(T \leq 2^{c^*(b-a)}) = 2^{-\Omega(b-a)}$.

The following theorem is an example application showing exponential runtime of the (1+1) EA for the NEEDLE function.

Theorem 22. *Let* $\eta > 0$ *be constant. Then there is a constant* $c > 0$ *such that with probability* $1 - 2^{-\Omega(n)}$ *the (1+1) EA on* NEEDLE *creates only search points with at most* $n/2 + \eta n$ *ones in* 2^{cn} *steps.*

Proof. Apply the negative-drift theorem and set the interval $[a, b]$ as $a := n/2 - 2\gamma n$ zeroes and $b := n/2 - \gamma n$ zeroes, with γ a positive constant. By Chernoff bounds, the probability that the initial random search point has less than $n/2 - \gamma n$ zeroes is $e^{-\Omega(n)}$, implying that the algorithm starts outside the interval $[a, b]$ as desired. The remainder of the proof shows that the two conditions of the drift theorem hold.

Since the interval is a plateau, all created points have the same fitness and are accepted. Given that the current search point has i zeroes and that each bit is flipped with probability $1/n$, the drift is

$$\Delta_t(i) = \frac{n-i}{n} - \frac{i}{n} = \frac{n-2i}{n} \geq 2\gamma := \varepsilon,$$

where the last inequality is achieved because in the interval there are always at least b zeroes, i.e., $i \geq n/2 - \gamma n$. Concerning the second condition for standard bit mutation, the probability of flipping j bits decreases exponentially with the number of bits j

$$\Pr(|\Delta_t(i)| \geq j) \leq \binom{n}{j}\left(\frac{1}{n}\right)^j \leq \left(\frac{n^j}{j!}\right)^j \leq \frac{1}{j!} \leq \left(\frac{1}{2}\right)^{j-1}$$

and the condition holds for $\delta = r = 1$. By the negative-drift theorem, the optimum is found within $2^{c*(b-a)} = 2^{cn}$ steps with probability at most $2^{-\Omega(b-a)} = 2^{-\Omega(n)}$. □

The proof can be generalized to plateau blocks of functions of unitation positioned such that $k + m < (1/2 - \varepsilon)n$.

Theorem 23. *The time for the (1+1) EA to optimize a* plateau block *of length m at position such that* $k + m < (1/2 - \varepsilon)n$ *is at least* $2^{\Omega(m)}$ *with probability at least* $1 - 2^{-\Omega(m)}$.

Proof. The proof follows the same arguments as the proof of Theorem 22 by setting $b := m + k$ zeroes and $a := k$ zeroes. □

Conclusions

Drift analysis dates back to 1892 when it was applied for the analysis of stability equilibria in ordinary differential equations [56]. The first use of drift techniques for the runtime analysis of stochastic search heuristics was performed by Sasaki and Hajek to analyze simulated annealing on instances of the maximum matching problem [70]. Drift analysis was applied in a considerable number of applications in evolutionary computation after He and Yao introduced the additive drift technique to the field [38]. Several extensions for the analysis of more sophisticated algorithms and processes have been since devised. The multiplicative drift method introduced in section "Multiplicative Drift Theorem" is due to Doerr et al. [25]. An improved version introduced by Doerr and Goldberg allows to derive bounds also on the probability to deviate from the expected runtime [22]. Witt subsequently introduced a multiplicative drift theorem to achieve lower bounds on the runtime [78]. While the multiplicative drift theorem may only be used when the drift is linear, a variable drift theorem was introduced to deal with cases where the expected progress is nonlinear [42] with respect to the current position. A version for lower bounds has also been derived [26]. A general variable drift theorem with tail bounds was introduced in [48]. This theorem subsumes most existing drift theorems, and a special case of this theorem was given in section "Variable Drift Theorem" (see Theorem 19).

Oliveto and Witt proposed the negative-drift theorem presented in section "Negative-Drift Theorem" to derive exponential lower bounds on the runtime of randomized search heuristics [62]. This theorem was the main tool used in the first analysis of the standard *simple genetic algorithm (SGA)* [64,65]. Finally, Lehre extended the negative-drift theorem to allow a systematic analysis of population-based heuristics using non-elitist selection mechanisms [45]. For an extensive treatment of drift analysis, we refer the reader to the book chapter by Lengler [49].

Final Overview

This chapter has presented the most commonly used techniques for the time complexity analysis of stochastic search heuristics. Example applications have been shown concerning simple evolutionary algorithms on classical test problems. The same techniques have allowed the obtainment of time complexity results on more sophisticated function classes, such as standard combinatorial optimization problems. The reader is referred to [61] for an overview of such advanced results concerning evolutionary algorithms and ant colony optimization and to [60] for an overview of the results in terms of parameterized complexity. Several other techniques have been used to analyze stochastic search heuristics, such as typical runs, family trees, martingales, probability generating functions, and branching

processes. For an introduction to these tools for the analysis of evolutionary algorithms, the reader is referred to the monograph by Jansen [40] which covers a more extensive set of techniques than is possible in this book chapter. Considerable progress has been made in the analysis of populations and diversity which are at the heart of evolutionary computation. We refer to Sudholt's book chapter for an overview of the theory of the mechanisms used to artificially enforce a diverse population [72]. Corus et al. have recently shown how it is possible to set the selective pressure of population-based steady-state algorithms to obtain an appropriate balance between exploration and exploitation far beyond the limits that were previously thought possible, without the need of any artificial diversity enforcing mechanism [11].

Several other aspects of stochastic search optimization have been investigated theoretically, such as simulated annealing, evolution strategies for continuous optimization, particle swarm optimization (▸ Chap. 28, "Particle Swarm Optimization"), memetic algorithms (▸ Chap. 27, "Memetic Algorithms"), and multi-objective optimization techniques (▸ Chap. 10, "Multiobjective Optimization"). These topics are overviewed in [1]. Significant results have been achieved in areas covered in the recent book collection edited by Doerr and Neumann [23]. Among these, certainly worth mentioning are the considerable advances in black-box optimization [20], which may be regarded as a complementary line of research to runtime analysis. Rather than determining the time required by a given heuristic for a problem class, black-box optimization focuses on determining the best possible performance achievable by any search heuristic for that class of problems. A variation to classical runtime analysis is to determine the expected solution quality achieved by a stochastic search heuristic if it is only allowed a predefined budget [41]. Fixed budget computation analyses are driven by the consideration that in practical applications only a predefined amount of resources are available and the hope is to use such resources at best to achieve solutions of the highest quality. Other areas covered within the book collection that have witnessed considerable progress are the theory of estimation of distribution algorithms [43], artificial immune systems [80], and genetic programming [51], for which the very first results are available regarding the time and space complexity for evolving functions with proper input/output behavior [29, 50], as well as an emerging theory for geometric semantic genetic programming [7]. An area that has recently witnessed strong momentum is the theory of parameter control and automated algorithm design (i.e., hyper-heuristics) [21, 28, 44, 52–54, 57, 67, 68], while results have also started emerging regarding the analysis of automated algorithm configurators [35–37] and evolutionary neural architecture search [32, 55].

Abstract

This chapter provides an introductory overview of city logistics systems, highlighting the specific characteristics that make them different from general logistics problems. It analyzes the types of decisions involved in managing city logistics applications, from strategic, tactical, and operational, and identifies the key models to address them. This analysis identifies types of problems, location, location routing, and variants of routing problems with time windows, all those with ad hoc formulations, derived from the constraints imposed by policy and operational regulations, technological conditions, or other specificities of urban scenarios, which result in variants of the classical models that, for its size and complexity, become a fertile field for metaheuristic approaches to define algorithms to solve the problems. Some of the more relevant cases are studied in this chapter, and guidelines for further and deeper insights on other cases are provided to the reader through a rich set of bibliographical references.

City logistics · Decision support systems · Location models · Metaheuristics · Vehicle routing with time windows

Introductory Remarks on City Logistics: The Nature of the Problem

City logistics systems exhibit intrinsic characteristics that differentiate them from the general logistics systems, as part of the supply chain, in terms of the specificities of the scenarios where they occur (urban and large metropolitan areas), as well as for the economic relevance that they have as part of the freight distribution system. This section is aimed at explaining and highlighting these two crucial aspects.

Logistics and City Logistics

Logistics, as defined by the Council of Logistics Management CLM [13], is "that part of the supply chain process that plans, implements, and controls the efficient, effective flow and storage of goods, services, and related information from the point of origin to the point of consumption in order to meet customers' requirements." However, when logistics activities take place in urban areas, they show unique characteristics making them different from the general logistics activities. Thus, in order to differentiate the two phenomena and to highlight the special characteristics, the transport in urban areas, and specifically the freight flows associated with the supply of city centers with goods, is usually referred to as "city logistics," "urban freight distribution," or "last mile logistics."

Taniguchi et al. [51] define city logistics as "the process of totally optimizing the logistics and transport activities by private companies in urban areas while considering the traffic environment, traffic congestion and energy consumption within the framework of a market economy." This definition can be updated by adding to the concept of the energy consumption the contemporary concerns on the environmental impacts such as emissions, urban noise, vibration, etc., generated by logistic vehicles in urban areas. These impacts affect not only the economy but also the quality of life of the city residents.

An analysis of city logistics activities, and how they are performed, results with an immediate identification of their specific intrinsic characteristics. It allows for establishing substantial differences between logistics and city logistics justifying the entity of city logistics as an individual field with proper identity. Some of the main city logistics characteristics include:

- Spatial restrictions:
  - Urban microstructure determined by the urban network (e.g., one-way streets, dead-end streets, etc.) causes the paths between customers, or between the depot and the customers, to differ depending on the order of the visits.
  - Limited vehicle access. Most cities mandate limited access for some areas of the city for specific types of vehicles during specific time windows.
  - Small-quantity deliveries.
  - High density of delivery points.
- Traffic infrastructure: traffic schemes banning specific turnings, traffic lights and their associated traffic control plans, etc.
- Environmental concerns and sensitivities:
  - Growing role of small specialized urban vehicles (i.e., environmentally friendly vehicles commonly referred to as green vehicles) as a consequence of sustainable urban policies implying energy savings, reduction of emissions, noise, etc.
  - Low automation and critical human role when manual deliveries are necessary.
  - High operational and environmental costs, as a consequence of the human involvement among other reasons.

The Relevance of City Logistics

Urban logistics operations consist of the set of activities related with the distribution of goods and provision of services within an urban area. There is a wide range of examples of urban logistics that includes parcel delivery, material collection, goods storage, waste collection, home delivery services, or electrical appliance reparation services, among others. Current urban activities are far away from what they were a couple of decades ago. New challenges have emerged, new technologies have been developed, and urban population dynamics have changed.

The road system is the main transportation modality in most countries. In Europe, 68% of goods transportation is made by roads (BESTUFS report [6]). Countries with less developed rail networks tend to have higher road utilization. Moreover, a high proportion of all goods are delivered within the cities. Cities as London and Dublin estimate this proportion in slightly more than 40% (BESTUFS report [6]), while almost 70% of the deliveries are concentrated in Tokyo (Taniguchi et al., [51]). In summary, road transportation is the **main** freight transportation mode, and **high proportion** of the **total** goods transportation happens in **cities**.

The significant impact of commercial vehicles in daily traffic is evident. According to the BESTUFS report [6], about a fifth of a city's traffic flow is made up of commercial trucks. In London, freight transport accounts for 20–26% of the total traffic, while in Italy this proportion is estimated to be 18%. In the same study, it is reported that urban freight in French cities represents between 13% and 20% of the total traffic. Overall, the BESTUFS [6] estimates that between 15% and 20% of the average flow in cities during rush hours correspond to logistics fleets (i.e., light goods vehicles, heavy goods vehicles, etc.). Consequently, logistics fleets are a net contributor to traffic congestion in urban and metropolitan areas and have a relevant impact on energy consumption and on the quality of life in cities.

Although urban freight distribution represents a small fraction of the total transportation length, the Council of Supply Chain Management Professionals, Goodman [29] estimates that the last mile cost accounts for about 28% of the total transportation cost. In a study made by the European Logistics Association and AT Kearney [21], it is shown that transportation activities account for approximately 43% of the total logistics costs. Assuming that the cost of delivering within urban areas (i.e., the last mile cost) is 28%, we can then estimate that the cost of urban freight activities represents about 12% of the total logistics costs.

A Systems Approach to City Logistics

The complexity of city logistics systems should be addresses from a systemic perspective accounting for all of its components and, what is more important, their interactions determining the dynamics of the system and the way it behaves. Namely, it should be addressed in terms of the conditions, operational but also technological, which are imposed by the relationships among stakeholders, which are synthetically described in this section.

Any systemic approach to city logistics must look at the system as a whole, identify its components, and account for their mutual interactions. For example, consider the impacts that city logistics activities have on traffic congestion, and at the same time, consider how in return the city logistics activities are impacted by traffic congestion and operational constraints of the urban areas.

Thus, the *city logistics models must account for the two-way interaction*. They should include the effects of the city logistics deliveries and commercial activities on urban traffic congestion, and conversely they should include operational constraints in routing and logistics optimization models considering time-varying

traffic congestion allowing defining how city logistics activities are impacted by traffic congestion.

Notwithstanding, a systemic approach should neither forget that urban freight distribution is mainly a private sector activity, designed to maximize the profits, which takes place in a public scenario under rules and constraints determined by public authorities. In the words of Boudoin et al. [10], "today, the city as a geographic and economical space is the centre of attention of decision makers of the private and public sectors, considering that the performance of the logistics system depends also greatly on the decisions taken by these two categories of actors. The urban logistics spaces are in the core of the goods distribution device, as they are interfaces between interurban and urban, private and public, producer and consumer." A systemic approach must also take into account that city logistics is a scenario with various stakeholders with possibly different and conflicting interests.

Public stakeholders will usually be interested in achieving social, economic, environmental, or energetic objectives, while private stakeholders, namely, private shippers and freight carriers, aim to reduce their freight costs and to optimize their traffic flows in accordance with their specific needs, which are not conforming to the objectives of an overall optimization. Therefore, a systemic approach to city logistics must:

1. Be supported by a holistic view in modeling approaches integrating urban and logistic planning which will allow innovative approaches to urban logistics solution.
2. Suitable to be applied in practice in terms of a framework enabling the understanding between stakeholders, fostering new ways of stakeholder collaboration, and providing policy frameworks allowing sustainable business models.
3. Become operational in terms of decision support tools to efficiently implement the desirable policies.

In other words, the conceptual approach to such systemic view must be able to appropriately account for the roles of the main stakeholders and the relationships between them as highlighted in the conceptual diagram in Fig. 1.

Freight operators supply their services under supply conditions and contracts with customers imposing constraints on:

- Fleet routing and scheduling.
- Service times and delivery conditions that could be determined by the characteristics of the delivery (i.e., loading and unloading) point.
- Service time windows imposed either by the customer requirements or by the regulatory conditions determined by local authorities.

The supply regulations established by the local government strongly determine the way in which logistics fleets operate. The restrictions to access inner city, namely, in cities with historical centers, reinforced in most cases by access control systems, usually impose time constraints that determine the routings and scheduling,

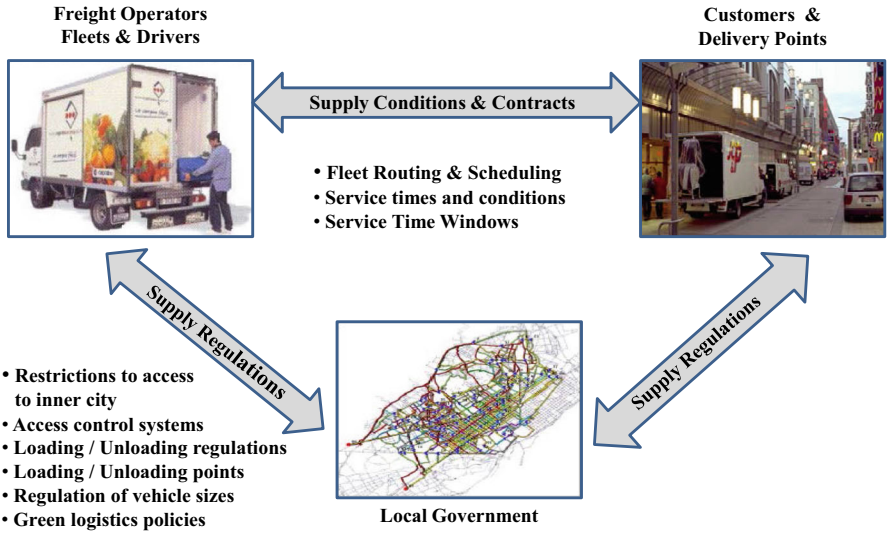

Fig. 1 Stakeholders' interaction in city logistics operations

which can also be affected by the existence, or not, of loading/unloading points and regulations on their use. Furthermore, the regulations on vehicle sizes authorized to operate in urban areas, or green logistics policies imposing thresholds on the acceptable levels of emissions, could determine the fleet compositions.

Organizational Aspects and Decision-Making in City Logistics

The proposed systemic view must be translated in terms of a model, suitably representing the system, which, further than providing a deep understanding on how the system works, should provide support to any type of operational decisions on the system. Two key aspects in this process are, respectively, identify and understand the main logistics operations and identify and distinguish the decision levels in the management of the city logistics system. This view is neatly aligned with the key approach of Operations Research: acquire enough knowledge about a system to understand how the system works, and formulate the system's knowledge in terms of modeling hypothesis that can be subsequently translated in terms of a formal model (usually a mathematical model) which can be used to make decisions about the system. Therefore, understanding the nature of the decisions in city logistics, which of them depend on the nature of the system, and which are conditioned by the relationships among stakeholders is part of such knowledge acquisition to build models of city logistics. Decision levels for fleet management applications (Goel [28]) are primarily:

- **Strategic:**
  - Decisions that usually concern a large part of the organization, have major financial impact, and may have long-term effects: typically concern the design of the transportation system.
  - The **size and mix** of vehicle fleet and equipment.
  - The **type and mix** of transportation services offered.
  - The territory coverage including **terminal location**.
  - Strategic alliances and cooperation, including the integration of information systems.
- **Tactical:**
  - Concerns short- or medium-term activities: typically involve decisions about how to effectively and efficiently use the existing infrastructure and how to organize operations according to strategic objectives.
  - Equipment acquisition and replacement.
  - Capacity adjustments in response to demand forecasts.
  - Static pricing and pricing policies for contract and spot pricing.
  - Acquisition of regularly requested services, including pricing and provisional routing.
  - Long-term driver to vehicle assignments.
  - Cost and performance analysis.
- **Operational:**
  - Commercial vehicle operations underlay a variety of external influences which cannot be foreseen: real-time management decisions have to be made to appropriately react on discrepancies between planned and actual state of the transportation system.
  - Load acceptance.
  - Real-time dispatching considering the actual state of transportation system.
  - Instructing drivers about their tasks.
  - Monitoring the transportation processes, including tracking and tracing and arrival time estimations.
  - Incident management.
  - Observing the state of order processing.
- **Real Time:**
  - Concerns all activities needed to monitor, control, and plan transportation processes.
  - The required information that dispatchers must collect to manage the fleet include vehicle positions and traffic conditions.
  - The decisions that dispatchers must make to manage the fleet include diversion of vehicles from current route to new destinations and insertion of customers into predefined routes.
  - The most challenging task is the generation of dynamic schedules.
  - Determination of plans indicating which vehicle should visit, pick up, deliver, or service a customer and at what time.

As a consequence of the fact that the stakeholders can play different roles in the city logistics scenarios, they can adopt various organizational forms. These organizational forms can be individual with no self-coordination, individual but with different degrees of coordination in which the private stakeholders are the main actors, or super-coordinated where public organizations play the main role currently referred to as goods distribution centers. Each scenario implies different levels of decision from the long-term strategic decisions on the locations of warehouses or distribution centers to the operational decisions concerning fleets and routing and scheduling of fleet vehicles. Moreover, the real-time decisions on rerouting and rescheduling vehicles as far as traffic and operational conditions change become each time more relevant due to technological evolution. Efficiency in these scenarios may be achieved through better fleet management practices, rationalization of distribution activities, traffic control, freight consolidation/coordination, and deployment of intermediate facilities [36].

This last measure plays a fundamental role in most of the city logistics projects based on distribution system, where transportation to and from an urban area is performed through platforms. These platforms are called city distribution centers (CDC), goods distribution centers, or city terminals (CT) [42]. They are located far from city limits. Freights, directed to a city and arriving by different transportation modes and vehicles, are consolidated at platforms on trucks in charge of final distribution. According to Boccia et al. [8], "these platforms have had a great impact on effectiveness of freight distribution in urban areas, but their use is showing some deficiencies because of two main reasons: their position (often far from final customers) and the constrained structure of urban areas."

To overcome the limits of such single-echelon system, distribution systems have been proposed, where another intermediate level of facilities is added between platforms and final customers. These facilities, referred to as satellites or transit points (Fig. 2), perform no storage activities and are devoted to transfer and consolidate freights coming from platforms on trucks into smaller vehicles, more suitable for distribution in city centers (Crainic et al. [16, 17]). This two-echelon system could determine an increase of costs due to additional operations at satellites. However, these costs should be compensated by freight consolidation, decrement of empty trips, economy of scale, reduction of traffic congestion, and environmental safety.

The model simultaneously determines how many depots (CT or CDC) should be open, their locations at the first echelon, how many vehicles (urban vehicles) are needed to supply the satellites, how many satellites should be open at the second echelon, which vehicles (city freighters) should operate from which open satellites, and which customers each vehicle should service.

Most of these decisions must be supported appropriately and that implies the use of suitable models (Giani et al. [24]). Location models (Daskin and Owen [19]) become the key components of strategic decision-making concerning decisions on warehouse or CT locations. Vehicle routing models are at the core of operational and real-time fleet management decisions and processes. Therefore, they deserve a special attention and become the main operational tools to achieve the objectives of

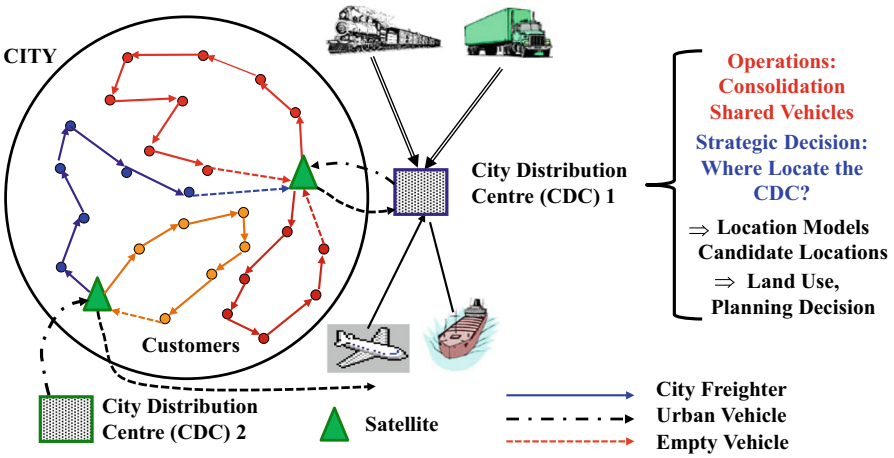

Fig. 2 Two-echelon freight distribution systems and implied decisions

private stakeholders, shippers, and freight carriers. Routing problems in urban areas have specific characteristics that differentiate them from generic routing problems. Bodin et al. [9] have coined the term "street routing" to highlight these differences.

Fleet Management and ICT Applications

We have already highlighted the key role of decision-making in city logistics, and the role of models to support strategic decisions has been highlighted in the previous section. However, the tactical and operational decisions should not be forgotten, as they usually determine the quality of the service, which is highly appreciated by customers. Operational decisions in urban areas are changing very fast due to the impacts of the new telecommunication technologies. Further than enabling faster and more flexible operational modes, the new telecommunication technologies induce deep sociological changes in customers' uses, which in turn foster a quick evolution of management policies. The implications of the latter will be discussed in this section.

The growing importance of the real-time fleet management applications is mainly due to the recent significant evolution of pervasive automatic vehicle location (AVL) technologies (Goel [28]*). Fleet management in urban areas has to explicitly account for the dynamics of traffic conditions leading to congestions and variability in travel times severely affecting the distribution of goods and the provision of services.* An efficient management should be based on decisions accounting for all factors conditioning the problem: customers' demands and service conditions (i.e., time windows, service times, and others), fleet operational conditions (e.g., positions, states and availabilities of vehicles, etc.), and traffic conditions.

Instead of making decisions based on trial and error and operator's experience, a sounder procedure would be to base the decisions on the information provided by a decision support system (DSS). Regan et al. [47, 48] provide a conceptual framework for the evaluation of real-time fleet management systems which considers dynamic rerouting and scheduling decisions implied by operations with real-time information as new orders or updated traffic conditions. The recent advances in information and communications technologies (ICT) have prompted the research on dynamic routing and scheduling problems. At present, easy and fast acquisition and processing of the real-time information is feasible and affordable. The information, which becomes the input to dynamic models, captures the dynamic nature of the addressed problems allowing for more efficient dynamic fleet management decisions.

Barceló et al. [4, 5] propose and computationally explore a methodological proposal for a decision support system to assist in the decision-making concerning the real-time management of a city logistics fleet in dynamic environments when real-time information is available. Figure 3 depicts the architecture of such a DSS based on a dynamic router and scheduler. The feasibility of the proposed solutions depends on:

- The availability of the real-time information, which we assume will be provided by ICT applications, combined with the knowledge of the scheduled plan with the current fleet and customer status.

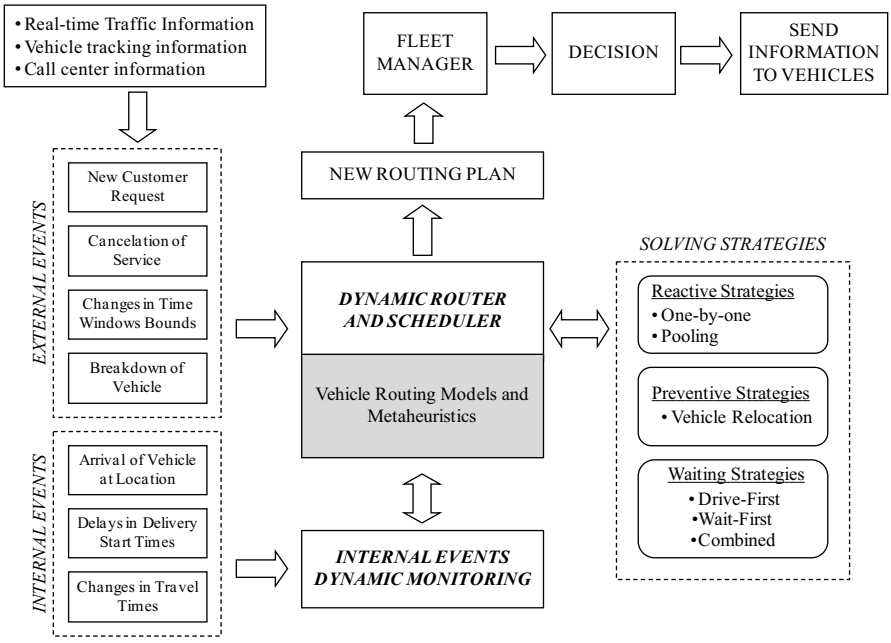

Fig. 3 Logical architecture of a decision support system for real-time fleet management based on a dynamic router and scheduler

- The quality of the vehicle routing models and algorithms to efficiently tackle the available information to provided solutions.

Unlike the classic approach, where routes are planned with the known demand and they are unlikely to be changed throughout the planning period, the real-time fleet management approach assumes that real-time information is constantly revealed to the fleet manager who has to decide whether the current routing plan should be modified or not. The process assumes partial knowledge of the demand. At the beginning of the considered time period (i.e., one work day), an initial schedule for the available fleet to serve the known demand is proposed. This initial operational plan can be modified later on, when the operations are ongoing and new real-time information is available. The new information can concern new demands, unsatisfied demands, changes in the routes due to traffic conditions, changes in the fleet availability (i.e., vehicle breakdowns), etc. It constitutes an input to a dynamic router and scheduler (DRS) which provides a proposal of a new dynamic operational plan prepared on the basis of real-time information.

Figure 4 depicts an example of how the conceptual process described in Fig. 3 can be handled by a dynamic routing and scheduling system. The routes, initially assigned to a set of five vehicles, are identified with various colors. The arrows indicate the order in which customers are to be served according to the initial schedule. We assume that vehicles can be tracked in real time. At time t, after the fleet has started to perform its initial operational plan, a new customer calls requiring a service which has not been scheduled. If real-time information, such as positions

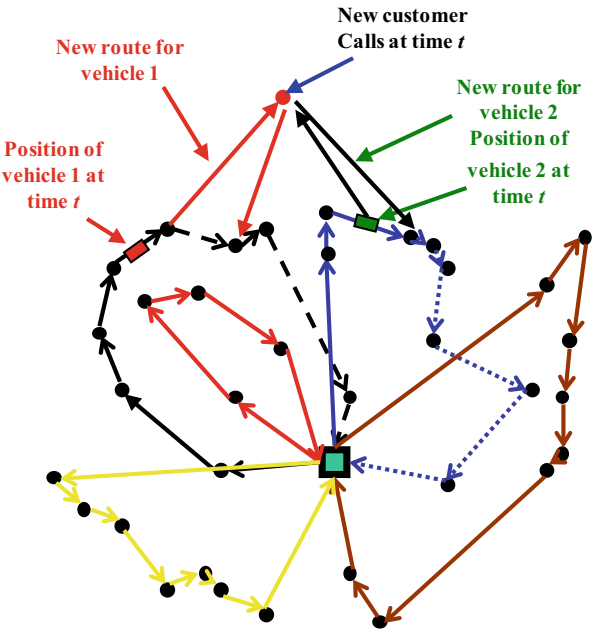

Fig. 4 Dynamic vehicle rerouting in a real-time fleet management system

and states of the vehicles and current and forecasted traffic conditions, is available to the fleet manager, he or she can use it to make a better decision on which vehicle to assign to the new customer and whether the new assignment results in a direct diversion from a route (vehicle 2) or a later scheduling (vehicle 1).

Vehicle routing problem (VRP) techniques constitute a fundament for the transportation, distribution, and city logistics systems modeling. The static version of the VRP has been widely studied in the literature. Among others, an extensive survey on VRP was provided by Fisher [22] and by Toth and Vigo [54]. The static approaches reckon with all the required information to be known a priori and constant throughout the time. However, in most of the real-life cases, a large part of the data is revealed to the decision-maker when the operations are already in progress. Thus, the dynamic VRP assumes partial knowledge of the demand and that new real-time information is revealed to the fleet manager throughout the operational period. A comprehensive review of the dynamic VRP can be found in Ghiani et al. [24]. Psaraftis [45, 46] and Powell et al. [44] contrast the two variants of the problem and clearly distinguish the dynamic VRP from its static version.

A wide variety of vehicle routing problems with time windows (VRPTW) becomes the engine of real-time decision-making processes to address situations where real-time information is revealed to the fleet manager, and he or she has to make decisions in order to modify an initial routing plan with respect to the new needs (Barceló and Orozco [1]). Real-time routing problems are mainly driven by events which are the cause of such modifications. Events take place in time, and their nature may differ according to the type of service provided by a motor carrier. The most common type of event is the arrival of a new order. When a new order is received from a customer, the fleet manager must decide which vehicle to assign to the new customer and what is the new schedule that this vehicle must follow.

A standard practice of introducing the dynamism into the definition of a routing problem is to determine specific features as *time-dependency*. The VRP with time-dependent travel times acknowledges the influence of traffic conditions on the routing planning. An introduction to the problem and a made heuristic development is provided in Malandraki and Daskin [37]. Further algorithm developments for the static VRP with time-dependent travel times can be found in Ichoua et al. [32], Fleishman et al. [23], and Tang [50]. The dynamic VRP with time-dependent information has also been addressed by Chen et al. [12] and Potvin et al. [43].

Thomas and White [53] addressed the problem by assuming that stochastic information was represented by the time of arrival of a new request. The objective of their approach was to find the best policy for selecting the next node to visit that minimizes the total travel time. They called this problem the *anticipatory routing problem* as vehicles anticipate the arrival of a new customer by changing their path if the request is received while they are in transit. The authors assumed that a new service may be delivered only if the reward or benefit is sufficiently high. The problem was modeled as a finite-horizon Markov decision process, and the authors used standard stochastic dynamic programming methods to solve each one of the proposed instances. Thomas [52] extended the results by incorporating waiting strategies with the objective of maximizing the expected number of new customers served. They also modeled the problem using a finite-horizon Markov

decision process. The authors proposed heuristic algorithms for real-time decision-making.

In the approach proposed by Barcelo et al. [2, 3], time-dependent information is generated by means of traffic simulation of a real-world urban network, in order to emulate the role of a real-time traffic information system providing reliable real-time information on traffic conditions and short-term forecasts.

In order to test the management strategies and algorithms assuming the availability of the real-time information, the dynamic traffic simulation model emulates the current travel times estimated as a function of the prevailing traffic conditions and the short-term forecast of the expected evolution of travel times that an advanced traffic information system would provide. This is a basis for making more realistic decisions on the feasibility of providing the requested services within the specified time windows. Furthermore, simulation can also emulate real-time vehicle tracking giving access to positions and availabilities of the fleet vehicles, which is the information required by a DRS.

This example was inspired by the modeling framework proposed by Taniguchi et al. [51], including models needed by the authorities to support long-term planning decisions accounting for the already mentioned interactions between city logistics activities and urban congestion.

Strategic Decisions in City Logistics

The current evolution of city logistics systems has raised the interest in the variants of location models to support the concerned strategic decisions. In many cases they are induced by regulations imposing conditions on the location of the CTs or CDCs and restrictions on the vehicle types allowed to operate in the inner city, leading to organizational restructuring of the services from intermediate satellites. The potential scenarios illustrated in Fig. 2 can be generically addressed by two types of location models, described in this section, depending on whether the routings of the service vehicles are explicitly included in the model or not.

Two-Echelon Single-Source Location Problems

The increasing importance of the e-commerce results with interesting organizational decisions. For example, more and more people purchase products online, but are not usually at home at daytime and cannot accept the deliveries, return the unaccepted deliveries, or deliver the parcels to be sent to other customers. As a consequence, there are required alternative solutions for home deliveries.

An example of such alternative solution was described in BESTUFS II [7]: the Packstations used by Deutsche Post and DHL in Germany. Similar solutions were also deployed in other countries. Usually, they are locker facilities installed in specific locations, which provide automated booths, or locker boxes for self-service collection and delivery of parcels.

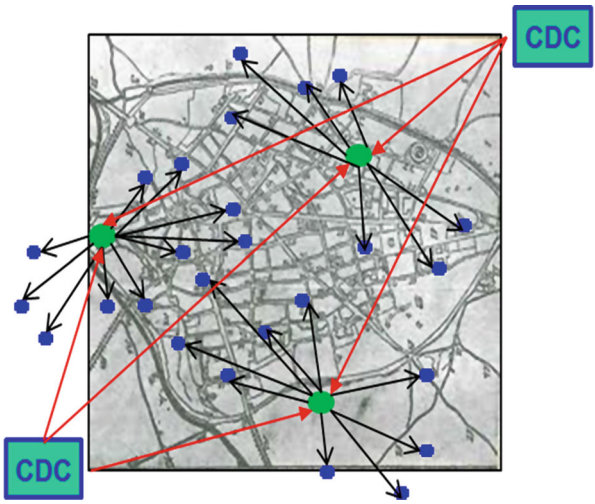

Fig. 5 Two-echelon single-source location problem

In this case, the logistics system can be considered as a particular case of a *two-echelon single-source location problem*, in which special fleet of vehicles service the satellite-automated booths (marked in green in Fig. 5); the special fleet can consist of urban vehicles, such as vans or trucks, fulfilling specific urban regulations regarding sizes and technologies, for example, special vehicles with less than 3.5 tonnes weight, with electrical engines, or propelled by biofuel or low emission fuels. Customers (marked in blue in Fig. 5) travel to the automated locker boxes for service.

In the pilots reported in BESTUFS II [7] the locker boxes have been installed in public spaces (e.g., main station, market place, petrol stations, etc.), and also at parking places of big companies. However, the search for systematic, general solutions can be formulated in terms of two-echelon single-source models. This is the problem arising in a two-stage distribution process, with deliveries being made from first-echelon facilities (e.g., city terminals) to second-echelon facilities (e.g., satellites) and from there to customers. The two-echelon, single-source, and capacitated facility location problem can be considered as an extension of the single-source capacitated facility location problem, dealing with the problem of simultaneously locating facilities in the first and second echelons where:

- Each facility in the second echelon has limited capacity and can be supplied by only one facility in the first echelon,
- Each customer is served by only one facility in the second echelon.

The model simultaneously determines how many depots (CTs or CDCs) should be open, what are their locations at the first echelon, how many vehicles (urban vehicles) are needed to supply the satellites, how many satellites should be open at the second echelon, which vehicles (city freighters) should operate from which open satellites, and which customers each vehicle should service.

Notation:

$I = \{1, 2, \ldots, m\}$: Set of potential facilities (satellites)
$J = \{1, 2, \ldots, n\}$: Set of customers
$K = \{1, 2, \ldots, nn\}$: Set of potential depots (CDCs)
a_j: demand of customer j, $\forall j \in J$
b_i: capacity of facility (satellite) i, $\forall i \in I$
f_{ik}: cost of assigning facility i to depot k, $\forall i \in I, \forall k \in K$
c_{ijk}: cost of facility i from depot k servicing customer j, $\forall i \in I, \forall j \in J, \forall k \in K$
g_k: cost of setting a depot at location k, $\forall k \in K$

Decision variables:

$$Y_{ik} = \begin{cases} 1 & if\ facility\ i\ is\ open\ and\ served\ from\ depot\ k, \forall i \in I, \forall k \in K \\ 0 & otherwise \end{cases}$$

$$X_{ijk} = \begin{cases} 1 & if\ facility\ i\ served\ by\ depot\ k\ services\ customer\ j, \forall i \in I, \\ & \forall j \in J, \forall k \in K \\ 0 & otherwise \end{cases}$$

$$Z_k = \begin{cases} 1 & if\ a\ depot\ is\ set\ a\ location\ k, \forall k \in K \\ 0 & otherwise \end{cases}$$

The model:

$$p : \text{Min} \sum_{i \in I} \sum_{k \in K} \sum_{j \in J} c_{ijk} x_{ijk} + \sum_{i \in I} \sum_{k \in K} f_{ik}\ \ y_{ik} + \sum_{k \in k} g_k z_k \tag{1}$$

subject to

$$\sum_{j \in J} a_j x_{ijk} \leq b_i \quad \forall i \in I, \forall k \in K \tag{2}$$

$$\sum_{i \in I} \sum_{k \in K} x_{ijk} = 1 \quad \forall j \in J \tag{3}$$

$$\sum_{k \in k} y_{ik} \leq 1 \ \ \forall i \in I \tag{4}$$

$$x_{ijk} \leq y_{ik} \ \ \forall i \in I, \forall j \in J, k \in K \tag{5}$$

$$y_{ik} \leq Z_k \quad \forall i \in I, k \in K \tag{6}$$

$$x_{ijk}, y_{ik}, z_k \in \{0, 1\} \quad \forall i \in I, \forall j \in J, k \in K \tag{7}$$

The objective function (1) includes the total cost of assigning customers to facilities, the cost of establishing facilities, and the cost of opening depots. The

side constraint (2) ensures that the customer demand serviced by a facility does not exceed its capacity. The Eq. (3) ensures that each customer is assigned to exactly one facility. Each facility can be serviced by only one depot, as defined by constraint (4). The inequality (5) states that the assignments are made only to open facilities (i.e., customers are allocated only to open facilities). Lastly, the formulation (6) ensures that facilities are allocated only to open depots.

Tragantalerngsak et al. [55] propose a variety of Lagrangian heuristics for this problem. Taking into account the computational results achieved, one of the most performing Lagrangian decompositions analyzed is based on the possibility of strengthening the resulting subproblems as a consequence of the observation that at least one depot must be open. Therefore, without any loss of generality, there can be used the constraint:

$$\sum_{k \in K} z_k \geq 1 \tag{8}$$

Also, there may be included a constraint which forces to open sufficient facilities to supply all customer demands:

$$\sum_{i \in I} \sum_{k \in K} y_{ik} b_i \geq \sum_{j \in J} a_j \tag{9}$$

This will improve the lower bound provided by the relaxation.

By relaxing the constraints (3) and (6), with Lagrangian multipliers λ and ω, respectively, the problem can be separated into the two following Lagrangian subproblems LRxy and LRz:

$$LR_z : \min \sum_{k \in K} \left(g_k - \sum_{i \in I} \omega_{ik} \right) z_k \tag{10}$$

subject to

$$\sum_{k \in K} z_k \geq 1 \tag{11}$$

$$z_k \in \{0, 1\} \quad \forall k \in K \tag{12}$$

and

$$LR_{xy} : \min \sum_{i \in I} \sum_{k \in K} \sum_{j \in J} \left(c_{ijk} - \lambda_j \right) x_{ijk} + \sum_{i \in I} \sum_{k \in K} \left(f_{ik} + \omega_{ik} \right) \tag{13}$$

subject to

$$\sum_{j \in J} a_j x_{ijk} \leq b_i \quad \forall i \in I, \forall k \in K \tag{14}$$

$$\sum_{k \in K} y_{ik} \leq 1 \forall i \in I \tag{15}$$

$$\sum_{i \in I} \sum_{k \in K} b_i y_{ik} \geq \sum_{j \in J} a_j \tag{16}$$

$$x_{ijk} \leq y_{ik} \quad \forall i \in I, \forall j \in J, k \in K \tag{17}$$

$$x_{ijk}, y_{ik} \in \{0, 1\} \quad \forall i \in I, \forall j \in J, k \in K \tag{18}$$

Let $g1_k = g_k - \sum_{i \in I} \omega_{ik}$; then problem LR_{xy} can be solved by inspection:

$$z_k = \begin{cases} 1 \text{ if } g1_k \leq 0 \\ 0 \text{ Otherwise} \end{cases} \tag{19}$$

In the case where all $g1_k > 0$, set $z_{k'} = 1$, where $g1_{k'} = \min_k \{g1_k\}$ and $z_k = 0$, $k \neq k'$.

The problem can be reformulated as

$$\min \sum_{i \in I} \sum_{k \in K} v_{ik} y_{ik} \tag{20}$$

subject to

$$\sum_{k \in K} y_{ik} \leq 1 \quad \forall i \in I \tag{21}$$

$$\sum_{i \in I} \sum_{k \in K} b_i y_{ik} \geq \sum_{j \in J} a_j \tag{22}$$

$$y_{ik} \in \{0, 1\} \quad \forall i \in I, k \in K \tag{23}$$

where $v_i k$ is the optimal solution of

$$\min \sum_{j \in J} \left(c_{ijk} - \lambda_j\right) x_{ijk} + (f_{ik} + \omega_{ik}) \tag{24}$$

subject to

$$\sum_{j \in J} a_j x_{ijk} \leq b_i \quad \forall i \in I, \forall k \in K \tag{25}$$

$$x_{ijk} \in \{0, 1\} \quad \forall i \in I, \forall j \in J, k \in K \tag{26}$$

The problem of finding v_{ik} is now a 0-1 *knapsack problem* involving all facilities, but the fact that each facility can be served only from one depot enables to rewrite the problem as follows:

$$\text{Let } v_i = \min_k \{v_i k\} \tag{27}$$

Solve

$$\min \sum_{i \in I} v_i u_i \tag{28}$$

subject to

$$\sum_{i \in I} b_i u_i \geq \sum_{j \in J} a_j \tag{29}$$

$$u_i \in \{0, 1\} \quad \forall i \in I \tag{30}$$

This is a 0-1 knapsack problem with n variables. The lower bound for problem P is then given by $LBD = v(LR_{xy}) + v(LR_z)$. The upper bound UBD can be found from the solution of the problem LR_z as follows:

Let z_k^* be the solution to LR_z and $\tilde{K} = \left\{k | z_k^* = 1\right\}$. Solve LR_{xy} again but over the depots in $\tilde{K}$. The solution from this restricted set is then used to find a feasible solution. Let $\mathbf{u}_*$ be the solution to this problem, and denote $\tilde{I} = \left\{i | u_i^* = 1\right\}$.

Then

$$y_{ik}^* = \begin{cases} 1 \text{ if } i \in \tilde{I} \text{ and } k \in \tilde{K} \\ 0 \text{ otherwise} \end{cases} \tag{31}$$

The corresponding solution $\boldsymbol{x}_*$ is obtained as the solution giving the v_{ik} coefficients if $i \in \tilde{I}$, $k \in \tilde{K}$, $y_{ik}^* = 1$. Otherwise, $x_{ijk}^* = 0$.

Using these solutions no capacity constraints are violated, but there may be some customers j that were assigned to multiple open facilities or not assigned to any facilities. A *generalized assignment problem* is constructed from these customers, open facilities, and the remaining capacity of open facilities. The solution to these problems reassigns these customers and provides the expected upper bound.

Once the lower bound *LBD* and upper bound *UBD* of the optimal objective function have been calculated, the Lagrangian multipliers λ and ω are updated until a convergence criterion is met.

Two-Echelon Location Routing

There are more variants of the location problems arising from a combination of organizational decisions and urban regulations on the characteristics and conditions of the logistics fleets, as discussed in section "Organizational Aspects and Decision-Making in City Logistics" and illustrated in Fig. 2. A more appealing version of the addressed location problem is the *two-echelon location routing*. In this case, in the first echelon, city freighters service satellites from city distribution centers. In the second echelon, special small urban vehicles serve customers from satellites in downtown regulated zones.

A special case of the two-echelon location routing, also prompted by the growth of e-commerce in urban areas, is the one depicted in Fig. 6. Here, the services to the satellites from the CDCs are provided by special fleets during the night. During the day, special city freighters (e.g., electrical vehicles, tricycles, etc.) serve the customers from the satellites.

Nagy and Salgy [38] elaborated a rather complete state-of-the-art report on this problem. They proposed a classification scheme and analyzed a number of variants as well as the exact and heuristic algorithmic approaches. Drexl and Scheinder [20] updated this state-of-the-art survey, providing an excellent panoramic overview of the current approaches. Metaheuristics dominate the panorama since they look more appropriate to deal with real instances of the problem. Perhaps one of the most appealing is that of Nguyen et al. [39] based on a GRASP approach combined with learning processes and path relinking. Another interesting heuristic, an approach to a relevant variant of the problem based on a Tabu Search accounting for time

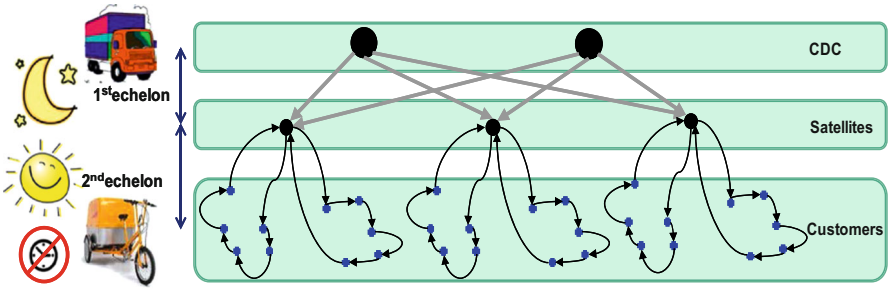

Fig. 6 An example of two-echelon location routing accounting for special urban regulations

dependencies, can be found in Nguyen et al. [40]. The interested reader is directed to these references given that space limitations do not allow including them in this chapter.

Operational Decisions: Routing Problems

According to Taniguchi et al. [51], vehicle routing and scheduling models provide the core techniques for modeling city logistics operations. Once the facilities, or the city logistics centers, have been located, the next step is to decide on the efficient use of the fleet of vehicles that must service the customers or make a number of stops to pick up and/or deliver passengers or products. Vehicle routing problems constitute a whole world given the many operational variants using them. The book of Toth and Vigo [54] provides a comprehensive and exhaustive overview of routing problems. To illustrate their role in city logistics, we have selected the relevant case of pickup and delivery models with time dependencies, which play a key role in courier services, e-commerce, and other related applications.

Pickup and Delivery Vehicle Routing Problem with Time Windows

Pickup and delivery vehicle routing problem with time windows (PDVRPTW) is a suitable approach for modeling routes and service schedules for optimizing the performance of freight companies in the city logistics context (e.g., the couriers). It is also a good example to demonstrate the operational decisions in the routing problems.

In this problem, each individual request includes pickup and a corresponding delivery of specific demand. The relationships between customers are defined by pairing (also known as coupling) and precedence constraints. The first constraint links two particular customers in a pickup-delivery pair, while the second one specifies that each pickup must be performed before the corresponding delivery.

Therefore, the main objective of the PDVRPTW is to determine, for the smallest number of vehicles from a fleet, a set of routes with a corresponding schedule, to serve a collection of customers with determined pickup and delivery requests, in such a way that the total cost of all the trips is minimal and all side constraints are satisfied. In other words, it consists of determining a set of vehicle routes with assigned schedules such that:

- Each route starts and ends at a depot (a vehicle leaves and returns empty to the depot),
- Each customer is visited exactly once by exactly one vehicle,
- The capacity of each vehicle is never exceeded,

- A pair of associated pickup-delivery customers is served by the same vehicle (pairing constraint),
- Cargo sender (pickup) is always visited before its recipient (delivery) (precedence constraint),
- Service takes place within customers' time window intervals (time windows constraint),
- The entire routing cost is minimized.

In order to describe mathematically the demonstrated PDVRPTW, we define for each vehicle k a complete graph $G_k \subseteq G$, where $G_k = (N_k, A_k)$. The set N_k contains the nodes representing the depot and the customers, which will be visited by the vehicle k. The set $A_k = \{(i, j): i, j \in N_k, i \neq j\}$ comprises all the feasible arcs between them. Thus, the problem formulation takes the form

$$\min \sum_{k \in K} \sum_{(i,j) \in A_k} c_{ijk} x_{ijk} \tag{32}$$

subject to

$$\sum_{k \in K} \sum_{j \in N_k \cup \{n+1\}} x_{ijk} = 1 \qquad \forall i \in N^+, \tag{33}$$

$$\sum_{i \in N_k{}^+} \sum_{j \in N_k} x_{ijk} - \sum_{j \in N_k} \sum_{i \in N_k{}^-} x_{jik} = 0 \qquad \forall k \in K, \tag{34}$$

$$\sum_{i} \sum_{j \neq i} x_{jik} \leq \mid S \mid -1 \qquad \forall S \subseteq N : \mid S \mid \geq 2, \forall k \in K \tag{35}$$

$$\sum_{j \in N_k^+ \cup \{n+1\}} x_{0jk} = 1 \qquad \forall k \in K, \tag{36}$$

$$\sum_{i \in N_k \cup \{0\}} x_{ijk} - \sum_{i \in N_k \cup \{n+1\}} x_{jik} = 0 \qquad \forall k \in K, \quad j \in N_k, \tag{37}$$

$$\sum_{i \in N_k^- \cup \{0\}} x_{i,n+1,k} = 1 \qquad \forall k \in K, \tag{38}$$

$$x_{ijk} \left(z_{ik} + s_i + c_{ijk} - z_{jk} \right) \leq 0 \qquad \forall k \in K, \quad (i, j) \in A_k, \tag{39}$$

$$e_i \leq z_{ik} \leq l_i \qquad \forall k \in K, \quad i \in N_k \cup \{0\}, \tag{40}$$

$$z_{i,k} + c_{i,p(i),k} - z_{p(i),k} \leq 0 \qquad \forall k \in K, i \in N_k^+ \tag{41}$$

$$x_{ijk}\left(q_{ik} + d_j - q_{jk}\right) = 0 \qquad \forall k \in K, (i, j) \in A_k, \tag{42}$$

$$d_i \leq q_{i,k} \leq Q \qquad \forall k \in K, i \in N_k^+ \tag{43}$$

$$0 \leq q_{p(i),k} \leq Q - d_i \qquad \forall k \in K, i \in N_k^+ \tag{44}$$

$$q0k = 0 \qquad \forall k \in K, \tag{45}$$

$$x_{ijk} \in \{0, 1\} \qquad \forall k \in K, (i, j) \in A_k, \tag{46}$$

where

N:	set of customers, where $N = N^+ \cup N^-$, $\lvert N^+\rvert = \lvert N^-\rvert$,
N^+:	set of all customers that notify pickup request,
$N-$:	set of all customers that notify delivery request,
c_{ijk}:	nonnegative cost of a direct travel between nodes i and j performed by vehicle k, assuming that $c_{ijk} = c_{jik} \forall i, j \in V$,
i:	customer, where $i \in N_k^+$,
$p(i)$:	pair partner of customer i, where $p(i) \in N_k^-$,
$_{di}$:	customer's demand that will be picked up/delivered at $i/p(i)$, respectively, where $d_i = d_{p(i)}$,
$_{qik}$:	vehicle's k capacity occupancy after visiting customer i,
$_{ai}$:	arrival time at customer i,
$_{wi}$:	waiting time at the customer i, where $w_i = max\{0, e_i - a_i\}$,
$_{zik}$:	start of service at customer i by vehicle k, where $z_i = a_i + w_i$.

The nonlinear formulation of the objective function (32) minimizes the total travel cost of the solution that assures its feasibility with respect to the specified constraints. Equation (33) assigns each customer to exactly one route, while formulation (34) is a pairing constraint, which ensures that the visit of each pickup-delivery pair of customers (i^+, $p(i^+)$) is performed by the same vehicle k. The inequality (35) eliminates the possibility of construction of potential sub-tours. The three following constraints secure the commodity flow. Equality (36) defines the depot as every route's source and states that the first visited customer is the one with a pickup request. Likewise, formulation (38) determines the depot as every route's sink, and the last visited customer is the one that demands a delivery service. The degree constraint (37) specifies that the vehicle may visit each customer only once. The schedule concordance is maintained by Eqs. (39) and (40) according to which, in case that a vehicle arrives to a customer early, it is permitted to wait and start the service within the time window interval only. The precedence constraint (41) assures that for each pair of customers the pickup i is always visited before its delivery partner $p(i)$. The next three restrictions express the dependencies between

the customers' demands and the vehicles' restrained current and total capacities. Equation (42) indicates that after visiting the customer j, the current occupancy of the carriage loading space of the vehicle k is equal to the sum of the load carried after visiting the preceding customer i and the demand collected at customer j. According to inequality (43), the dimension of current occupancy of the total capacity of the vehicle k after visiting a pickup customer i shall be neither smaller than its demand d_i nor bigger than the entire vehicle's capacity. Similarly, following formulation (44), the current capacity of the vehicle k after visiting a delivery customer $p(i)$ shall never be smaller than zero and bigger than the difference between the total vehicle capacity and the size of its delivery request $d_{p(i)}$. The capacity constraint that considers the depot (45) states that the vehicle does not provide it with any service. The last formulation (46) expresses the binary and nonnegative nature of the problem-involved variable.

The exact algorithms are able to solve to optimality only the VRP problems with small number of customers (Cordeau et al. [15]). The heuristics do not guarantee optimality, but since they are capable of providing, for large-sized problems, a feasible solution in a relatively short amount of time, they strongly dominate among all the methods. What is more, the heuristics are proven to be quite flexible in adaptation to different VRP problem variations, which is of special importance when considering the real-world applications.

Tabu Search (TS) has been applied by many researchers to solve VRP. It is known to be a very effective method providing good, near-optimal solutions to the difficult combinatorial problems. The TS term was firstly introduced by Glover [27], and the concepts on which TS is based on had been previously analyzed by the same author Glover [26]. The main intention for TS creation was the necessity to overcome the barriers, stopping the local search heuristics from reaching better solutions than the local optima and explore intelligently a wider space of the possible outcomes. In this context, TS might be seen as extension of the local search methods or as a combination of them and the specific memory structures. The adaptive memory is the main component of this approach. It permits to flexibly and efficiently search the neighborhood of the solution.

The input to TS constitutes an initial solution created beforehand by a different algorithm (Fig. 7). An initial solution construction heuristic determines tours according to certain, previously established rules, but does not have to improve them. Its characteristic feature is that a route is built successively and the parts already constructed remain unchanged throughout the process of the execution of the algorithm.

Sweep algorithm is a good example of a VRP initial solution construction heuristic. It was introduced by Gillett and Miller [25]. However, its beginnings might be noticed in earlier published work of other authors, e.g., Wren [57] and Wren and Holliday [58]. The name of the algorithm describes its basic idea very well. A route is created in the process of gradually adding customers to a route. The selection of customers to add resembles the process of sweeping by a virtual ray that takes its beginning in the depot. When the route length, capacity, or the other previously set constraints are met, the route is closed, and the construction of a new

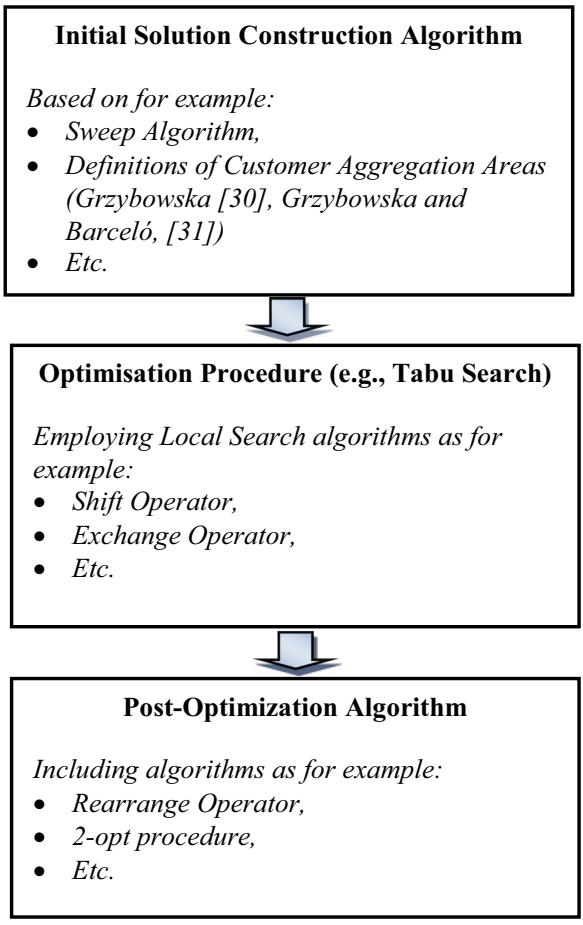

Fig. 7 Composite approach to solve a VRP

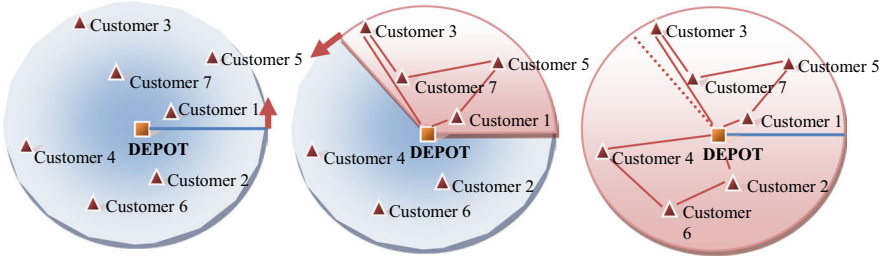

Fig. 8 Sweep algorithm

route is started. The whole procedure repeats until all the customers are "swept" in the routes. A graphic representation of the sweep algorithm is provided in Fig. 8.

The solution provided by the classic sweep algorithm for PDVRPTW most likely will violate precedence and pairing constraints. The initial solution does not have to be feasible since it will be improved later on by TS in the optimization step.

However, a feasible initial solution for PDVRPTW can be provided by a modified sweep algorithm accounting for side constraints. As a result, when a customer is met by the sweeping ray, it is added to the currently built route together with its corresponding partner, respecting the precedence constraint. The details on sweep algorithm adapted to provide initial solution for PDVRPTW are presented in Algorithm 1.

Algorithm 1: Sweep Algorithm for PDVRPTW

1. Let L be the list of all the customers $L = N \backslash \{0\}$
2. Sort all the customers by increasing angle $\angle A0S$, where S is the current customer, 0 is the depot, and A according to the chosen variant is either randomly chosen or fixed reference point.
3. Divide L into k sub-lists such that each sub-list l satisfies:

$$\angle A0S \in \left(\frac{2l-2-k}{k}\pi, \frac{2l-k}{k}\pi \right], \forall l \in K = \{1, \ldots, k\}$$

4. Sort all the customers in each sub-list l in decreasing order according to the travel cost between the depot and the customer.
5. **If** the sub-list l is not empty, **then** select the first customer, search for its partner, **and** insert both customers in a route in the least cost incrementing position. Respect the precedence constraint.
6. Delete the inserted customers from the sub-lists and go to step 5.
7. Repeat steps 5 and 6 for all the sub-lists.

Unified Tabu Search heuristic proposed by Cordeau et al. [14] can be used to optimize the initial solution. Originally, it was designed to solve a VRPTW. However, it can be adjusted to solve PDVRPTW. The main change regards the fact that each modification of a route concerns a pickup-delivery pair of customers instead of an individual customer. This affects the architecture and functioning of TS structures (e.g., adaptive memory). In addition, the local search algorithms used in TS need to consider the constraints of pairing and precedence.

TS starts with establishing the initial solution as best ($s_* = s_{\text{ini}}$). In each iteration, the employed local search algorithm defines a *neighborhood* $N(s_*)$ of the current best solution s_* by performing a collection of a priori designed *moves* modifying the original solution. The new solution s that upgrades the original solution, and characterizes with the best result of the objective function, is set as the best ($s_* = s$). This repetitive routine (i.e., *intensification phase*) lasts until no further improvement can be found, which is interpreted as reaching the optimum. It uses the information stored in the short-term memory (i.e., *"recency" memory*) recording a number of consecutive iterations in which certain components of the best solution have been present. The short-time memory eliminates the possibility of cycling by prohibiting the moves leading back to the already known results, during certain number of iterations. The moves are labeled as *tabu* and placed at the last position in the *tabu list*—a short-term memory structure of length defined by a parameter called *tabu*

tenure. The value of the tabu tenure might be fixed or regularly updated according to the preestablished rules, e.g., recurrently reinitialized at random from the interval limited by specific minimal and maximal value (Taillard [49]). The higher the value of the tabu tenure, the larger the search space to explore is.

The consequent choice of the next best solution is determined by the current neighborhood and defines the general direction of the search. The lack of broader perspective in most of the cases leads to finding a solution, which represents a local optimum instead of a global. It is also due to the decision on when to finish the whole procedure improvement (i.e., *stopping criterion*), which might be determined by a designated time limit for the complete performance or by a previously established number of repetitions, which do not bring any further improvement. In order to overcome this handicap, TS stops the local search algorithm and redirects the search in order to explore intelligently a wider space of the possible solutions (i.e., *diversification phase*). This includes permitting operations, which result in deterioration of the currently best solution. This phase requires access to the information accumulated during the whole search process and stored in the long-term memory structure (i.e., *frequency memory*). The success of the complete method depends on the balance established between these two phases, which complement each other instead of competing.

The functioning of the algorithm based on tabu bans is very efficient. However, oftentimes it may result in losing improvement opportunities by not accepting highly attractive moves, if they are prohibited. In such cases, the *aspiration criteria* should be activated. It is an algorithmic mechanism, which consists in canceling the tabu restrictions and permitting the move, if it results in construction of the new solution with the best yet value of the objective function. The implementation of TS is presented by Algorithm 2.

Algorithm 2: Tabu Search

1. Let η be the maximal number of permitted TS iterations.
2. Let α and β be the parameters of preestablished value equal to one.
3. Let Δ be the value of the objective function.
4. Let s be the initial solution.
5. Let s^* be the best solution and $s* = s$
6. Let $c(s^*)$ be the cost of the best solution.
7. **If** the solution s is feasible, **then** set $c(s^*) = c(s)$; **else** set $c(s^*) = \infty$
8. Let $B(s)$ be adaptive memory structure, whose arguments are initially set equal to zero.
9. **For** all the iterations $\kappa < \eta$, execute local search operator and create neighborhood $N(s)$
10. Select a solution from the neighborhood that minimizes the Δ function.
11. **If** solution s is feasible **and** $c(s) < c(s*)$, **then** set $s^* = s$ **and** $c(s^*) = c(s)$
12. Update $B(s)$ according to the performed move.
13. Update α and β

To defineSearch the neighborhood of a current solution, TS uses a local search algorithm. Local search algorithms are commonly used as intermediate routines performed during the main search process of more complex heuristics. However, they constitute individual algorithms. Some of them are referred to as *operators* with specified features (e.g., *shift operator*, *exchange operator*, *rearrange operator*, etc.), while the others possess their own denomination (e.g., the local optimization methods involving neighborhoods, which apply to the original solution a number of modifications equal to k, are known as the *k-opt* heuristics).

Shift operator is aPickup-Delivery Customer Pair Shift Operator good example of a local search algorithm in TS. Its objective is to remove a customer from its original route and feasibly insert it in another route of the current solution, in such a way that its total cost is minimized. When solving PDVRPTW the shift move includes a pickup-delivery customer pair instead of an individual customer. During the entire search process, all the pickup-delivery pairs are successively moved, and all the possible reinsertion locations in the existing routes are checked. Only the moves which are in accordance with all the side constraints shall be accepted. Algorithm 3 presents the functioning of shift operator in TS for solving PDVRPTW.

Algorithm 3: Pickup-Delivery Customer Pair Shift Operator

Let s be the current solution containing a set of routes R
Calculate $c(s)$, $q(s)$, and $w(s)$
Let $s^* = s$ be the best solution with cost $c(s^*) = c(s)$
Let $f(s^*) = \infty$ be the value of the objective function of the best solution s^*
Let $\Delta^* = \infty$ be the best value of the objective function
Let $B(s)$ be the empty adaptive memory matrix
For each route $r_1 \in R$ **and for** each route $r_2 \in R$, **such that** $r_1 \neq r_2$
For each pickup-delivery customer pair $m \in r_1$
Remove pair m from route r_1
Set bool TABU = FALSE
If the value of the tabu status in $B(s)$ for r_2 **and** pair m is $\neq 0$, **then** TABU = TRUE
Find the best insertion of pair m in r_2 and obtain new solution s'
Calculate $c(s')$, $q(s')$, and $w(s')$
Let $f(s')$ be the value of the objective function of the new solution s'
Let $p(s')$ be the value of the penalty function of the new solution s'
Let $\Delta = 0$ be the value of the objective function
If $f(s') < f(s^*)$, **then** $\Delta = f(s')$; **else** $\Delta = f(s') + p(s')$
Check the feasibility of solution s'
Set bool AspirationCriteria = FALSE
If $c(s') < c(s^*)$ **and** solution s' is feasible, **then** AspirationCriteria = TRUE
If $\Delta < \Delta^*$ **and** (Tabu = TRUE **or** AspirationCriteria = TRUE), **then** $\Delta^* = \Delta$ **and** the best move was found

The algorithm uses the values of violations of the constraints for the calculation of the objective function, as well as for determining the rate of the penalties, which

need to be imposed for not complying with initial restrictions. These values are calculated according to the following formulas:

$$\Delta = f(s) + p(s) \tag{47}$$

$$f(s) = c(s) + \alpha \cdot q(s) + \beta \cdot w(s) \tag{48}$$

$$p(s) = \lambda \cdot c(s) \cdot \sqrt{n \cdot k} \cdot \varphi(s) \tag{49}$$

$$\varphi(s) = \sum_{(m,r) \in B(s)} \rho_{m,r} \tag{50}$$

where

Δ: objective function,
$f(s)$: cost evaluating function for the solution s,
$p(s)$: penalties evaluating function for the solution s,
$c(s)$: cost of solution s,
$q(s)$: vehicle capacity constraint violation function for solution s,
w(s): time windows constraint violation function for solution s,
α: parameter related to the violation of the vehicle capacity constraint,
β: parameter related to the violation of the time windows constraint,
λ: scaling factor,
n: total number of customers,
k: total number of vehicles
φ(s): parameter controlling the addition frequency,
$B(s)$: adaptive memory matrix,
$\rho_{m,r}$: number of times the pickup-delivery customer pair m has been introduced into route r.

It is a usual practice to complement the TS heuristic with a *post-optimization* step. Its objective is to further improve the solution provided by TS. It is important to note that the final result has to be obligatorily feasible. Local search heuristics are often used for post-optimization purposes and *2-opt heuristic* is a good example. The 2-opt procedure is the most common representative of the family of *k-opt heuristics*. It has been introduced by Croes [18] for solving a Travelling Salesman Problem. The main idea of the 2-opt method is valid for the other k-opt heuristics. In the main, it consists of removing two nonconsecutive arcs connecting the route in a whole and substituting them by another two arcs reconnecting the circuit in such a way that a new solution which fulfills the predefined objectives is obtained. This move is commonly called a *swap* since it consists of swapping two customers in the original sequence. The swap can be performed in accordance with one of the following strategies: (i) search until the first possible improvement is found, and perform the swap, and (ii) search through the entire tour and all possible improvements, and perform only the swap resulting in the best improvement. A graphic representation of 2-opt procedure is provided in Fig. 9.

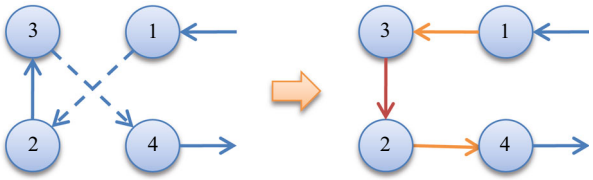

Fig. 9 2-opt algorithm

As in the case of the previously presented algorithms, the classic formulation of the 2-opt algorithm needs to be adapted to solve the PDVRPTW. The final solution needs to be strictly feasible; thus all the side constraints, including pairing and precedence, need to be respected. The PDVRPTW adapted 2-opt algorithm is presented2-opt Algorithm by Algorithm 4.

Algorithm 4: 2-opt Algorithm Adapted to PDVRPTW

1. Let R be the set of routes defining the current solution s
2. **For** each route $r \in R$
3. Let $r*$ be the best route and $r^* = r$
4. Calculate $c(s^*)$, $q(s*)$, and $w(s*)$
5. **While** best move is not found
6. Let $pos(i)$ be the position of customer i in the sequence of customers of route r
7. Let $pos(j)$ be the position of customer j in the sequence of customers of route r
8. **For** each customer i and j in route r **such that** $pos(j) = pos(i) + 2$
9. Create new empty route r'
10. **For** each customer h in route r
11. **If** $pos\ (h) \leq pos$(i) **or if** $pos(h) \geq pos(j + 1)$, **then** append customer h to r'; **else** append customer h at position $pos(i) + pos(i) - pos(h) + 1$ to r'
12. Calculate $c(s')$, $q(s')$, and $w(s')$ and check the feasibility of route r'
13. **If** $c(r') < c(r*)$ **and** route r' is feasible, **then** $c(s^*) = c(s')$ **and** the best move was found

Real-Time Management

Under this category we cluster what are considered the most relevant city logistics services made available by the pervasive penetration of the ICT technologies. These technologies made it possible for the demand to occur anywhere and at any time. This entails a request for the system to provide the capability of suitably responding to the demand in real time, and in a way that at the time satisfies the quality requirements of the customers, and also provides the most suitable benefit to the company. This section describes the main characteristics

highlighting the dynamic aspects of the problem, which must be addressed by efficient computational time-dependent versions of the ad hoc algorithms. This is an area of applications characterized by the synergies between technologies, decision-making, and sophisticated routing algorithms. The domain of application, however, has recently been expanded to account also for emerging versions of public transport services, special cases of demand-responsive transport services, which can be formally formulated in similar terms (just replacing freight or parcels by persons). This application will be considered in section "Extensions".

Let us suppose that an initial operational plan has been defined with k routes and that there is an *advanced traffic information system* providing real-time information that allows us to calculate current travel times for every pair of clients. Since most of real-world fleets are usually equipped with *automatic vehicle location* (AVL) technologies, it also assumed that the fleet manager is capable of knowing the exact location of the vehicles at every time and has a two-way communication with the fleet.

In our proposed *rerouting algorithm* (RRA), we compute the feasibility of the remaining services while we keep track of the current state and location of the vehicles. In order to simplify the tracking process, we consider two approaches: either to compute feasibility once a vehicle finishes a service and informs about its current situation to the fleet manager or in a periodical manner after updating the fleet's situation. In the first approach, the trigger for the computations is only the departure of the vehicle, but there might be risks when vehicles take longer times to complete the service. The second approach is computationally more intensive, but it may prevent future failures in the service when unexpected service times are present.

In the case of the vehicle routing with time windows, there are two critical factors that define the feasibility of a route: capacity and time windows. Assuming that no variations in demand are expected (e.g., more units to pick up), capacity can be neglected as the corresponding route (static or dynamic) is built taking into account this constraint. In such case, time windows constraints become more critical as there are many uncontrollable parameters (e.g., unexpected traffic conditions, delayed service, etc.) that may affect the feasibility of a service and, therefore, the performance of the route.

Figure 10 describes the full dynamic monitoring process. On one hand, we have the advanced traffic information system which provides current and forecasted travel times of the road network to the fleet manager. On the other hand, we have the fleet management center that is able to communicate with the vehicles and receive their position along with other data such as current available capacity and status.

These two sources are inputs to a dynamic tracking system which through a desired strategy (periodic, after service or both) computes the current feasibility of the routing plan. If an unfeasible service is detected, the RRA is triggered to find a feasible current plan. If a customer cannot be allocated to a vehicle that is on the road, the RRA tries to assign an idle vehicle housed at the depot. If no vehicles are available, a penalty is applied.

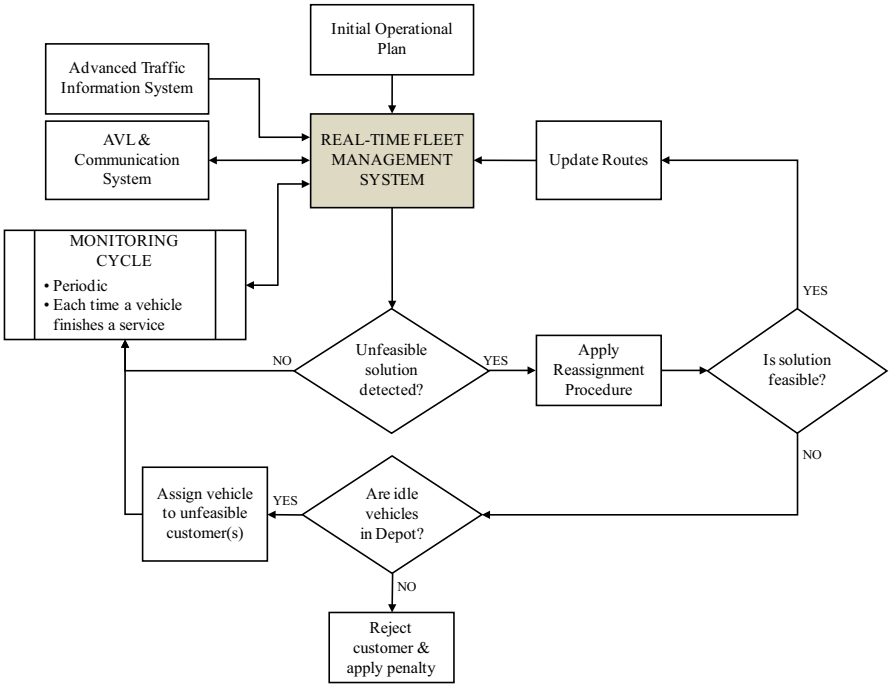

Fig. 10 Rerouting algorithm through dynamic tracking of the fleet

Computation of Feasibility

Computing the current feasibility of a route depends on the state of the vehicle at the time of evaluation. If a vehicle is traveling to the next scheduled customer or departing from a customer's location after service, the feasibility of the route is obtained by computing the expected arrival times to the next customers on the route. If at the time of evaluation, a vehicle has already started a service or waiting to start it, we must first estimate the departure time from the current location and then the arrival times in the rest of the route.

Under our approach, we assume that drivers send messages to the fleet management center when they arrive to and start or end a service with a customer. Therefore, at the time of evaluation, if a vehicle providing service has not finished under the estimated time lapse, the algorithm assumes that the remaining service time is the expected time used in the computation of the route. That is, if a service is assumed to take 10 min and, at the time of evaluation, the vehicle has 14 min without sending the end-of-service signal, the algorithm assumes, in a preventive way, that the vehicle needs another 10 min to complete the service.

Formally, the feasibility conditions can be computed as follows. Let $\hat{a}_i$ be the estimated arrival time of a vehicle at customer i, E_i the lower bound of the time

window of customer i, e_i the estimated service start time at customer i, S_i the estimated service time at customer i, and $T_{ij}(t)$ the travel time between customer i and j when vehicle departs at time t. Let V_k be a dummy node in the network representing vehicle k which route is given by $\{1, 2, \ldots, i, i+1, \ldots, n-1, n\}$.

If at time t_e, the vehicle has just finished a service at customer i or it is traveling to customer $i+1$, the estimated arrival and service start times at the next scheduled customers can be computed as follows:

$$\hat{a}_i = \begin{cases} t_e + T_{V_k,h}(t_e) & \text{if } h = i+1 \\ e_{h-1} + S_{h-1} + T_{h-1,h}(e_{h-1} + S_{h-1}) & \text{if } h = i+2, i+3, \ldots, n \end{cases} \tag{51}$$

$$e_h = \max\left\{E_h, \hat{a}_h\right\}, \quad \text{for } h = i+1, i+2, \ldots, n \tag{52}$$

On the other hand, if at time t_e, the vehicle is waiting to start service or providing service to customer i, we first compute d_i, the expected departure time from customer i. Let a_i be the real arrival time of a vehicle at customer i's location. Therefore, d_i is computed as follows:

$$d_i = \begin{cases} t_e + S_i & \text{if } \max\{\mathrm{E_i}, a_i\} + S_i < t_e \\ \max\{E_i, a_i\} + S_i & \text{otherwise} \end{cases} \tag{53}$$

In this case, the expected arrival times in subsequent customers $h = i+1, i+2, \ldots, n$ are given by:

$$\hat{a}_h = \begin{cases} d_i + T_{i,i+1}(d_i) & \text{if } h = i+1 \\ e_{h-1} + S_{h-1} + T_{h-1,h}(e_{h-1} + S_{h-1}) & \text{if } h = i+2, i+3, \ldots, n \end{cases} \tag{54}$$

where e_h is computed as in (2). The service at customer h becomes then *unfeasible* if $\hat{a}_h > L_h$, where L_h is the upper bound of the required time window in customer h. Figure 11 depicts a situation when one of the services becomes unfeasible.

The proposed RRA consists of computing feasibility conditions every time a vehicle has finished a service and is ready to depart from its current location. If one or more customers are detected to be in an unfeasible sequence, they are withdrawn and reinserted in the route using a greedy *dynamic insertion* heuristic (DINS). A re-optimization procedure is then applied using a *Tabu Search*-based metaheuristic (DTS). The greedy insertion heuristic is described in the following subsection.

If DINS algorithm does not find a feasible assignment to the vehicles on route, it allocates the withdrawn order to an idle vehicle in the depot. If no vehicles are available, the algorithm rejects the customer. The pseudo-code of the RRA is the following:

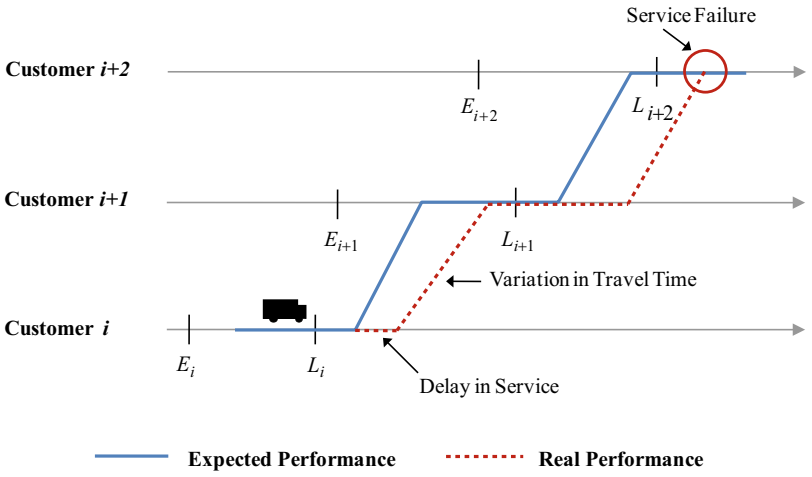

Fig. 11 Example of service failure due to delays [41]

Algorithm 5: Rerouting Algorithm

After a vehicle k finishes a service:

1. Compute feasibility conditions for all unvisited customers in the route of vehicle k
2. Let U_k be the set of unvisited customers which are now unfeasible in current scheduling
3. **If** $U_k = \varnothing$, **then** STOP; **else** continue to step 4
4. **For** each customer $u \in U_k$, withdraw u from route applying operator DELETE(u)
5. **For** each customer $u \in U_k$, reinsert u in current routes applying DINS algorithm
6. **If** reinsertion is not possible for a customer, **then** create new route with available vehicle (if any)
7. Apply DTS algorithm to re-optimize routes.

The RRA assumes that all customers that are found to be unfeasible have the same importance, ranking, or priority. Therefore, if there is more than one unfeasible customer, step 5 selects randomly, with equal probability, the next customer to be inserted in the routes.

Heuristic Approach

The RRA is a two-phase methodology that first identifies customers that are likely to be not serviced on time and then reassigns them in order to optimize the service level of the fleet. After the identification of customers, the algorithm withdraws those customers from the routes and uses them to build a set of customers U_k to be reassigned. The reassignment algorithm works by first inserting customers in U_k with a greedy insertion heuristic, and then, routes are re-optimized using a Tabu Search metaheuristic.

Dynamic Insertion Heuristic (DINS)

The heuristic used in the DRS is derived from the basic insertion heuristic proposed in Campbell and Savelsbergh [11], where every unrouted customer is evaluated at every insertion point. The evaluation of this movement consists in checking the feasibility and profitability of every insertion, which is the negative of the amount of additional travel time added to the route. The customer with a feasible insertion having the maximum profitability is then selected and inserted in the route. We have adapted this heuristic by introducing some new elements to reflect the dynamics of the operations of a fleet in an urban environment.

The objective of DINS heuristic is to insert a new client into the current routing plan once the vehicles have started the services. The general idea of the algorithm is simple. When a new client arrives to the system, the algorithm checks the current state of the vehicles. Then, routes with insufficient time to visit the new client within their schedule are rejected. Finally, the algorithm searches for the least cost feasible insertion in the candidate routes. If no feasible insertion is possible and there are idle vehicles at the depot, a new route is created including the new customer.

We assume that there are n routed customers in R different routes at the beginning of the time planning horizon. We also suppose that there is a single depot with a homogeneous fleet of vehicles with capacity Q. We define the following notation:

$T_{i,j}(t)$: travel time between customers i and j when vehicle departs at time t,
V_r: vehicle assigned to route r, $r = 1, 2, .., R$,
q_r: total demand assigned to route r,
d_i: demand of customer i,
E_i: time window lower bound of customer i,
L_i: time window upper bound of customer i,
e_i: earliest service start time at customer i,
l_i: latest service start time at customer i,
S_i: service time at customer i.

The time window of a customer i is denoted by (E_i, L_i). The values e_i and l_i refer to the earliest and latest time a service can take place at customer i, and they must

satisfy the following condition: $E_i \leq e_i \leq l_i \leq L_i$. If we wish to insert customer w at time instant $t > 0$, the vehicles of the fleet may have one of the following three states:

1. The vehicle is in service at some customer i (SER).
2. The vehicle is moving to the next planned customer on the route or waiting at the customer location to start service within the time window (MOV).
3. The vehicle is idle at the depot, without a previously assigned route (IDL).

The state of a vehicle will let us know when a vehicle should be diverted from its current route, be assigned to a new one if it is idle, or keep the planned trip. Whenever a new customer arrives, the status of each vehicle must be known to compute travel times from their current positions to the new customer.

The first iteration of the algorithm consists of rejecting those routes that are definitely infeasible. To do this, it is necessary to compute the total available time of the routes, i.e., the sum of the available time (if any) of a vehicle on the assigned route. We define the available time of a vehicle as those periods of time where (i) a vehicle is waiting to provide service to a customer or (ii) a vehicle has finished the scheduled route and is returning to the depot. This is, in fact, the maximum slack time a vehicle has available to travel and service customer w.

The calculation of the available route time can be done by estimating the arrival times at each of the scheduled customer locations that has not been served at the time of insertion of the customer w. The arrival time a_i at customer i is computed from the current position of the vehicle, and we assume that the vehicle will start service as soon as it arrives, if the customer's time window is already open; otherwise, the vehicle waits. The calculation of arrival times can be made as follows.

If, at instant t, the vehicle is moving toward the next customer i, then the estimated arrival time is given by $a_i = t + T_{Vr,i}(t)$. The arrival times at subsequent customers on the route are computed as follows:

$$a_i = \max\{E_{i-1}, a_{i-1}\} + S_{i-1} + T_{i-1,i}\,(\max\{E_{i-1}, a_{i-1}\} + S_{i-1}) \tag{55}$$

Hence, the available time of a vehicle in route r at some node i (including the depot) is the difference between the associated lower limit of the time window and the arrival time of the vehicle to that location. That is, $W_i^r = \max\{E_i - a_i, 0\}$. Therefore, the total available time of a route r is given by $AT_{v_r} = \sum_i W_i^r$.

From each route, we choose the unvisited node that is the closest to the new client. If the travel time from that node to the new customer is greater than the total available time AT_{Vr}, then we reject the route. If every route is rejected, a new route must be created for this new customer. The routes obtained, as a result of this previous iteration, are *possibly feasible* in the sense that vehicles serving those routes have enough time to travel to the new customer. This is a necessary

condition, but not sufficient, because we have to check for time windows feasibility. The second major iteration of the algorithm consists, therefore, in checking the feasibility and profitability of an insertion in every arc of the possible feasible routes. The feasible insertion with the highest profitability is then selected, and the corresponding route must be updated.

Feasibility In order to evaluate the feasibility of the insertion of customer w between nodes i and $i+1$, we must compute e_w and l_w, the expected earliest and latest service start times, respectively. The earliest service start time at the inserted customer w is given by:

$$e_w = \begin{cases} \max\left\{E_w, t + T_{V_r,w}(t)\right\} & \text{if } V_r = i \\ \max\left\{E_w, e_i + S_i + T_{i,w}(e_i + S_i)\right\} & \text{otherwise} \end{cases} \tag{56}$$

The latest service start time is calculated through a backward procedure starting with the depot (the last node to be visited by the vehicle) as follows:

$$l_w = \min\left\{L_w, \tilde{t}_w - S_w\right\} \tag{57}$$

where $\tilde{t}_i = \arg\max_t \left\{t + T_{i,i+1}(t) - l_{i+1}\right\}, \ \forall t \leq l_{i+1} - T_{i,i+1}(t)$ is the latest possible departure time that allows the vehicle to arrive to the next scheduled customer $i+1$ at time l_{i+1}. If $e_w \leq l_w$ and $D_w < Q - q_r$, the insertion is feasible.

Profitability The profit of an insertion is defined as the negative of the additional travel time incurred from inserting a customer in a route. If customer w is to be inserted between nodes i and $i+1$, the profitability of this insertion is given by:

$$\begin{aligned} \text{Profit} = \big\lfloor T_{i,w}(\max\{E_i, a_i\} + S_i) + T_{w,i+1}(\max\{E_w, a_w\} + S_w) \\ - T_{i,i+1}(\max\{E_i, a_i\} + S_i) \big\rfloor \end{aligned} \tag{58}$$

If no insertion is possible and there are available vehicles at the depot, then a new route that includes customer w is created. If the whole fleet of vehicles is already occupied, then the call is rejected, and a penalty may be applied. Given a customer w to be inserted at time t into a set R of routes, the pseudo-code of the DINS heuristic is as follows:

The solution obtained by DINS heuristic can be further optimized by applying DTS.

Algorithm 6: DINS Heuristic

1. **For** each route r in R **do**:
Compute available time AT_{Vr}
Find travel time from w to closest neighbor
If available time is not enough, **then** reject route r
Else, add route r to R', the set of possible feasible routes
2. **For** each route r in R' **do**:
Check the status of the vehicle and set its position as the starting node of the route.
For each arc $(i, i+1)$ of the remaining route sequence **do**:
If insertion of w is feasible and profit is improved **then**:
Store current profit and insertion places
3. **If** insertion is possible **then:**
Insert w in least cost arc and update selected route.
4. **Else,** create a new route with an available idle vehicle (if any).

Dynamic Tabu Search (DTS)

DTS constitutes an adaption of the *Unified Tabu Search* (UTS) heuristic proposed by Cordeau et al. [14]. The modifications of the original method were made in order to include the dynamic aspects of the addressed problem. One of the most important modifications regards the engagement of the operators, which perform the local search only on the unvisited customers of the scheduled routes.

Similarly as UTS, DTS is an iterative process searching for the best solution s^*. In each iteration, the algorithm searches for the best non-tabu solution s' in the neighborhood space $N(s)$ of current solution s, which minimizes the value of the cost function $f_D(s)$ or satisfies the aspiration criteria. The solutions found in the search process are evaluated by the cost function:

$$\mathrm{f_D}(s) = c_D(s) + \alpha q(s) + \beta d_D(s) + \gamma w_D(s) \tag{59}$$

where

$c_D(s)$: estimated total travel time of the routes for the pending scheduled customers,
$q(s)$: total violation of the vehicles' capacity,
$d_D(s)$: total violation of the routes duration,
w_D(s): total violation of the time windows constraint of the customers to be visited.

The adaptive memory matrix $B(s)$ denotes the attribute set of a solution s and is defined as follows: $B(s) = \{(i, k)$, where customer i (or a pair of customers in the case of PDVRPTW) is visited by vehicle $k\}$.

The penalty function $p(s)$ was added to the objective function in order to diversify the search of the solutions toward new or not thoroughly explored areas. For each solution s' such that $f_D(s') \geq f_D(s)$, the penalty is calculated as follows:

$$\mathrm{p}\left(s'\right) = \lambda c_D\left(s'\right)\sqrt{n_u m} \sum_{(i,k)\in B(s')} \rho \tag{60}$$

where

n_u: number of customers that have not been visited (or pairs of customers in the case of PDVRPTW),
m: current number of routes,
λ: positive value parameter to control the intensity of diversification,
ρ_{ik}: addition frequency parameter equal to the number of times the attribute (i, k) has been added to a solution.

The value of the addition frequency parameter, which controls the intensity of diversification, is updated regularly and at the end of each iteration of DTS.

The aspiration criteria defined for the DTS accepts a solution if its cost improves the best solution found so far. Also, in order to achieve quick online solutions, we added a stopping criterion which takes into account the rate of improvement in the search process. When the κ number of iterations has been reached without observing an improvement larger than ε, then the search process is stopped.

Similarly as in UTS (Cordeau et al. [14]), in DTS we employ a relaxation mechanism facilitating the exploration of the solution space. The mechanism is particularly useful in the cases when tight constraints are defined (e.g., hard time windows, pairing, and precedence constraints). The relaxation is achieved by dynamically adjusting the values of the parameters: α, β, and γ. When the solution s' is feasible, the value of the best feasible solution is updated, and the current values of the three parameters are reduced by dividing them by the factor $(1 + \delta)$. In the contrary case, the current values of the parameters are increased by multiplying them by the same factor. δ is a parameter of fixed value.

DTS was designed in a way, so that it becomes a flexible framework in which various local search operators can be embedded. As a result, depending on the addressed problem, a different operator can be enabled. Algorithm 7 provides a general description of the DTS. The reader interested in details is directed to Barceló et al. [4, 5].

Algorithm 7: Dynamic Tabu Search

1. **If** solution s is feasible **then**:
2. Set $s^* = s, \alpha = 1, \beta = 1, \gamma = 1$
3. Set $c(s^*) = c(s)$ **else** set $c(s^*) = \infty$
4. **For** $i = 1, \ldots, \eta$ **do**:
5. Select solution $s' \in N(s)$ that minimizes the objective function $\Delta = f(s') + p(s')$ such that s' is not tabu **or** satisfies aspiration criteria
6. **If** s' is feasible **and** $c(s') < c(s^*)$, **then** set $s^* = s$' **and** $c(s^*) = c(s')$
7. **If** $q(s') = 0$, **then** $\alpha = \alpha/(1+\delta)$, **else** $\alpha = \alpha(1+\delta)$
8. **If** $\mathrm{d}(s') = 0$, **then** $\beta = \beta/(1+\delta)$, **else** $\beta = \beta(1+\delta)$
9. **If** $\mathrm{w}(s') = 0$, **then** $\gamma = \gamma/(1+\delta)$, **else** $\gamma = \gamma(1+\delta)$
10. Set $s = s$'
11. Update α, β and γ
12. **If** number of iterations without improvement $= \kappa$, **and** last improvement $< \varepsilon$, **then** STOP

Extensions

The variants of pickup and delivery problems with time windows and time-dependent link travel times discussed in section "Operational Decisions: Routing Problems", as core components of the real-time fleet management applications analyzed in section "Real-Time Management" (as we have already mentioned), provide another area of application in urban scenarios which can be considered advanced implementations of demand-responsive transport systems. Examples of such could be the special shared taxi services provided by Uber [56] or Kutsuplus, uber-like minibus demand-responsive transit system experimented in Helsinki KUTSUPLUS [33].

A summary description of the Real-Time Multiple Passenger Ridesharing system and how it works could be the following. A customer asks for a service at a given time; the service could consist of either picking up a passenger (or various passengers) or a parcel, at a given location pickup location, at a given time (or within a time window) and delivering the passenger(s) or the parcel, at a delivery location at a given time (or within a time window). The service vehicles already in operation follow routes individually calculated depending on the customers' initial and final positions, the current traffic conditions, and the defined passengers' time windows.

Figure 12 illustrates conceptually how the demand-responsive mobility services work. Let's assume a fleet consisting of two vehicles V1 and V2, both with initially

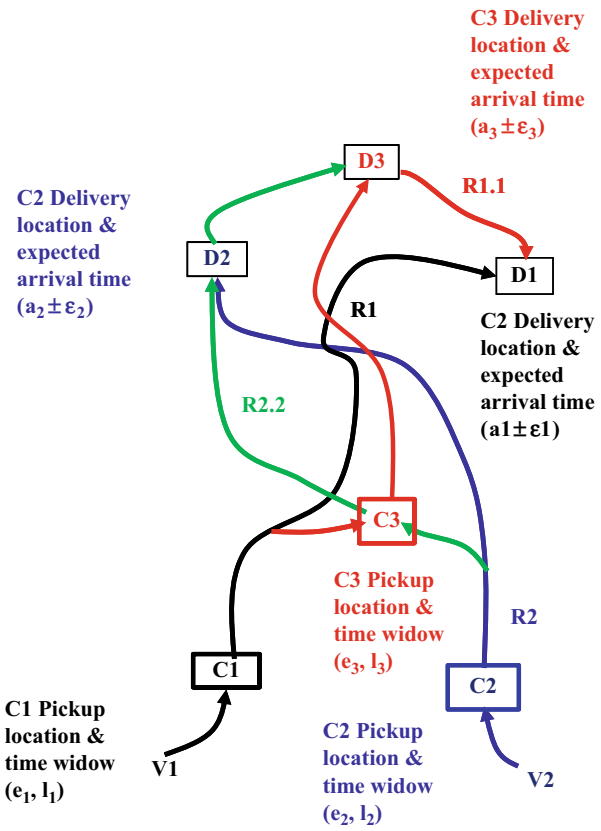

Fig. 12 Example of demand-responsive mobility services

assigned plans which have been previously optimized. At a given time a customer C1 calls the system for a service, the customer's location is automatically recorded by the system. The customer tells the system which is his/her time expectancy of pickup, in other words the time window (e_1, l_1) of his/her waiting time expectancy (e.g., e_1 could be the time at which the call is made, and l_1 the latest time he/she expects to be picked up). The customer also informs the system of his/her destination that is delivery point, D1, and likely the time at which he/she would approximately like to arrive at the destination, let's say $(a_1 \pm \varepsilon_1)$, where ε_1 represents an acceptable slack time.

The system, which is aware of locations and status of each vehicle in the fleet (e.g., fleet vehicles are GPS tracked, and the ICT functions inform the system on the current level of occupancy of the vehicle, i.e., the number of passengers, their destinations, and time constraints), as well as the current network conditions (e.g., a real-time traffic information system keeps the decision support system updated about travel times, congestions, incidents, and so on), determines which of the vehicles is the most appropriate to provide the service to customer C1 both in

terms of quality of the service and profitability. Let's assume that on the basis of the available information, the dispatching system assigns the service to vehicle V1 and the route R1 to pick up the customer and take him or her to his/her destination.

In a similar way, let's assume that customer C2, who is located at C2, has to be picked up within the time window (e_2, l_2) and wants to travel to destination D2. He or she expects to arrive around $(a_2 \pm \varepsilon_2)$ and is assigned to vehicle V2 that will follow route R2 to pick him/her up and travel to the destination D2.

The critical situation showing how the performance of the entire system depends on the quality of the decision support system that manages the fleet, and dispatches the services, arises when some time later, let's say at time t, a new customer C3, at location C3, asks for a pickup service within the time window (e_3, l_3) to travel to destination D3 where he/she expects to arrive around $(a_3 \pm \varepsilon_3)$.

In order to provide the new customer the requested service, the system faces many alternatives. First, it can open a new route assigning one of the empty vehicles of the fleet to the new client, but this action may imply a high cost. A better alternative would be to assign one of the en route vehicles that are closer to the client, if the time constraints of the customers that are already being served allow this. In this example, both proposed solutions accept a diversion policy, so, either of the vehicles could divert from their original routes to serve the new client and return to their originally assigned schedules.

One of the alternatives is to assign the new customer service to the vehicle V1, which exchanges its route R1 for the new route R1.1 (described in the figure with red arrows). This vehicle picks up customer C3 within the accepted time window, and then it drives to the D3 destination to deliver the customer. After this, vehicle V1 follows its new route and delivers customer C1 at the corresponding destination D1 taking into account the time constraints of all the served customers. The second possibility is that the new service of customer C3 is assigned to vehicle V2, which diverts its route to pick up the customer by following route R2.2 (described in the figure with green arrows). In this case, the vehicle delivers customer C2 at its destination D2 first, and then, it goes to the destination D3 of customer C3. Also in this case, we need to take into account the time constraints with respect to all involved customers. The decision will be made accounting for criteria that, while ensuring the quality of the service provided to the customers, achieve the maximum system profitability.

The management of the system is based on a decision support system similar to the one described in section "Real-Time Management". It allows making decisions on which vehicle to assign to each new coming customer. The dynamic rerouting is a particular case of the pickup and delivery problem with time windows, with time-dependent travel times, similar to the one described in section "Operational Decisions: Routing Problems".

Linares et al. [34, 35] provide details on a simulation study on the performance of these types of systems as a function of the expected demand for service relative to the total demand of conventional car trips in the selected urban scenario, the size of fleet providing the service (i.e., 500, 750, 1000 . . . vehicles), and the capacity of the fleet vehicles, six or eight passengers.

Concluding Remarks

The main objective of this chapter is to introduce the main characteristics of city logistics problems that make them a special category—clearly differentiated from the general logistics problems. The analysis of these characteristics and their peculiarities regarding the type of decisions to make (i.e., strategic, tactic, and operational) allows to identify various classes of problems (i.e., location, location routing, routing with time windows, etc.) each one becoming a fertile domain for heuristics, given the complexity and size of the problem to solve in real life. A selected set of examples of such heuristics has been described in this chapter, with special attention paid to those particularly relevant to urban scenarios due to the imposed constraints such as the regulatory policies imposed by the authorities, time constraints imposed by the conditions of servicing customer in these scenarios, and the time dependencies implied by the variability of travel times in urban congestion. For the interested reader the chapter is complemented with a wide set of references.

Abstract

Cutting and Packing (C&P) problems arise in many industrial and logistic applications, whenever a set of small items, with different shapes, has to be assigned to large objects with specific shapes so as to optimize some objective function. Besides some characteristics common to combinatorial optimization problems, the distinctive feature of this field is the existence of a geometric subproblem, to ensure that the items do not overlap and are completely contained in the large objects. The geometric tools required to deal with this subproblem depend on the shapes (rectangles, circles, irregular) and on the specific conditions of the problem being solved. In this chapter, after an introduction that describes and classifies Cutting and Packing problems, we review the basic strategies that have appeared in the literature for designing constructive algorithms, local search procedures, and metaheuristics for problems with regular and irregular shapes.

Keywords

Cutting stock · Bin packing · Strip packing · Container loading nesting

Introduction

Cutting and Packing (C&P) problems are hard combinatorial optimization problems (almost all are NP-hard) that arise in the context of several real-world applications, both in industry and in services, whenever one or more large objects or container's space has to be divided into smaller items, so that waste is minimized. These problems include cutting paper rolls into narrower rolls in the paper industry, cutting large boards of wood into smaller rectangular panels in the furniture industry, or cutting the irregularly shaped components of garment from fabric rolls, but they include also packing boxes into containers or loading items on pallets in logistics applications. All the problems have in common the existence of a geometric subproblem, originated by the natural item non-overlapping constraints.

In the literature, these problems have received an increasing amount of attention. In the 1960s, the seminal papers were published, and the number of publications has exponentially grown since then. As combinatorial optimization problems, C&P problems may be solved using all the optimization approaches and techniques available nowadays: linear programming techniques, branch and bound search algorithms, constraint logic programming, dedicated heuristics, metaheuristics, mathheuristics etc. Unfortunately, due to their combinatorial nature, exact techniques are not capable of efficiently tackling these problems for large instances; therefore, heuristic approaches must be used.

The remaining of this chapter is organized as follows. In the next section, C&P problems will be formally defined and categorized, according to their objective, and to their quantitative and geometric parameters. Then, in the following two sections, heuristic approaches for rectangular problems and irregular problems, both two-

and three-dimensional, are presented, ranging from simple constructive heuristics to mathematical programming model-based heuristics and including metaheuristics.

Cutting and Packing Problems

A carpenter wants to build a wardrobe for which he/she needs to cut a set of rectangular items in the quantities and with the dimensions presented in Table 1. To cut these items, the carpenter has at his/her workshop two large wood panels of 3 by 2 m and three other large wood panels of 2.5 by 2.5 m. How should the carpenter cut the small items from the available large panels to minimize the waste (the trim of the cutting process)?

This toy example allows us to introduce the main concepts of Cutting and Packing problems. In general, in Cutting and Packing problems, "small" items have to be assigned to "large" objects under both geometric constraints (assuring that the items do not overlap and are contained inside the objects) and quantitative constraints (e.g., at least a given quantity of each item type has to be cut). The objective of the problem may be either related to the minimization of the value of the large objects that are used or to the maximization of the value of the small items that are cut. The solution to the problem is one or more cutting patterns describing the geometric disposition of the small items in/on the large objects (Fig. 1). It should be emphasized that, in general, to describe the solution of a Cutting and Packing problem is not enough to say which small items are cut from which large objects (the assignment part of the problem). Part of the solution is describing how the small items are arranged on the large objects (the geometric problem).

These problems can be categorized according to a typology proposed by Wäscher et al. [105]. This typology takes into account the problem objective, the number of objects and items, and the geometry of the items. The different types of Cutting and Packing problems will be described by closely following the Wäscher et al. typology.

Dimensionality

Cutting and Packing problems are usually classified according to their dimensionality as one-, two-, and three-dimensional problems. This classification is directly

Table 1 Example of a two-dimensional rectangular cutting problem

Item type	Quantity	Length (m)	Width (m)
1	2	2.00	0.50
2	2	1.80	1.00
3	3	1.90	0.65
4	2	2.10	0.55
5	6	0.65	0.23

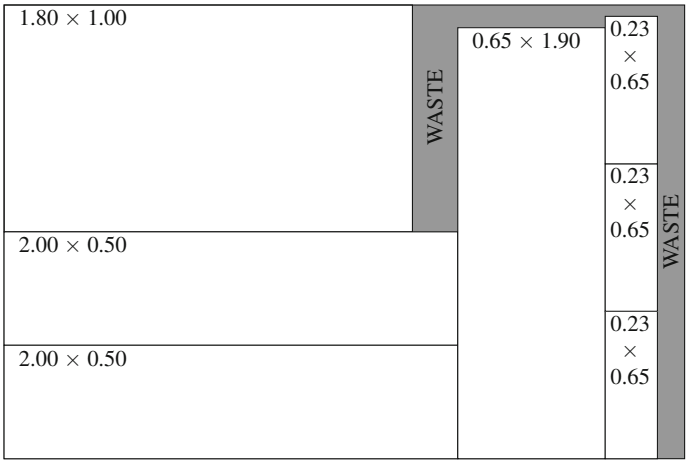

Fig. 1 A two-dimensional cutting pattern example

related to the number of physical dimensions relevant for the problem. If it is true that our world and all the objects in it are three-dimensional, when planning how to cut narrower paper rolls from a wider roll, only one dimension is relevant as the other two are kept equal in small items and large objects, i.e., the problem is one-dimensional (1D). Applying the same reasoning to the initial carpenter problem, it is the length and the width of the large objects that must be cut in order to match the length and the width of the small items, not changing the thickness of the wood boards; this is therefore a two-dimensional problem (2D). When packing parallelepiped boxes inside a truck or a container, the three dimensions are relevant for the problem, and it is therefore a three-dimensional problem (3D). Although four- and even higher-dimensional problems are theoretically possible, very few relevant practical applications have been described until now (Christensen et al. [35]), and therefore, they will be disregarded in this text. In Fig. 2, examples of 1D, 2D, and 3D problems arising in the paper, garment, furniture, and logistics industries are shown.

Geometry

The second most distinctive characteristic of the Cutting and Packing problems is the geometry associated with the dimensions that are relevant for the problem. In 1D problems, the geometric problem is trivial as, once the assignment problem is solved and it is known which small items are cut from each large object, the cutting order is not relevant as any sequence is feasible. Two- and three-dimensional problems are classified as rectangular, circular, or irregular problems. This division is related with the type of geometric tools needed to handle the geometric constraints of the problem. Geometric feasibility is guaranteed if the small items do not overlap each

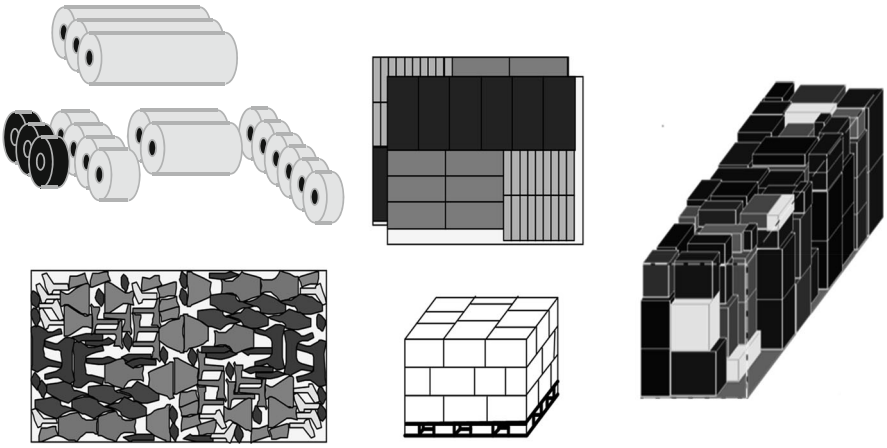

Fig. 2 Examples of one-, two-, and three-dimensional Cutting and Packing problems

other and are completely contained inside the large object. For the sake of simplicity, in the following only two dimensions will be considered, but the same reasoning and concepts hold for three-dimensional problems.

When dealing with rectangular shapes, analyzing if they do not overlap each other is just a question of coordinate comparison. Let rectangle i, with dimensions (l_i, w_i), have its left lower corner placed on coordinates (x_i, y_i) of the Cartesian plane, and let rectangle j, with dimensions (l_j, w_j), have its left lower corner placed on coordinates (x_j, y_j) of the Cartesian plane. Rectangle j does not overlap rectangle i if it is either above, below, or to the left or right of rectangle j, i.e.,

$$x_j + l_j \leq x_i \quad \vee \quad x_j \geq x_i + l_i \quad \vee \quad y_j \geq y_i + w_i \quad \vee \quad y_j + w_j \leq y_i$$

The containment conditions of rectangle i inside the larger rectangle (L, W) (assuming that its left lower corner is placed on coordinates $(0, 0)$) are:

$$x_i \geq 0 \quad \wedge \quad x_i + l_i \leq L \quad \wedge \quad y_i \geq 0 \quad \wedge \quad y_i + w_i \leq W$$

In circular Cutting and Packing problems, small items have circular shapes and the large object can be either another (larger) circle or a rectangle. The condition for the items not to overlap is now based on the computation of the distance between the centers of the circles. Let circle i, with radius r_i, have its center placed on coordinates (x_i, y_i) of the Cartesian plane, and let circle j, with radius r_j, have its center placed on coordinates (x_j, y_j) of the Cartesian plane. Circle j does not overlap circle i if the distance between the two centers is greater than or equal to the sum of their radii, i.e.,

$$\sqrt{(x_i - x_j)^2 + (y_i - y_j)^2} \geq r_i + r_j$$

It should be noticed that it is not necessary to compute the computationally expensive square root, and this condition can be replaced by the equivalent one having both sides squared.

The containment condition of circle i, with its center placed on coordinates (x_i, y_i), inside the larger circle of radius R and center on coordinates $(0, 0)$ is:

$$\sqrt{x_i^2 + y_i^2} \leq R - r_i$$

If the container is a rectangle (L, W), with its bottom left corner on coordinates $(0, 0)$, the containment conditions are:

$$x_i - r_i \geq 0 \quad \wedge \quad x_i + r_i \leq L \quad \wedge \quad y_i - r_i \geq 0 \quad \wedge \quad y_i + r_i \leq W$$

All shapes other than rectangles and circles are considered irregular and require more complex geometric algorithms to check and enforce geometric feasibility. A complete and thorough tutorial on the geometry of irregular Cutting and Packing problems (aka as nesting problems) can be found in Bennell et al. [20]. As the no-fit polygon is the most widely used geometric tool to analyze if two irregular shapes overlap, it will be described for the simpler case of convex polygons.

Let P_i be a polygon with n_i vertices with coordinates $(a_i^k, b_i^k), k = 1, \ldots, n_i$ relative to an arbitrary reference point. Let P_j be another polygon with n_j vertices with coordinates $(a_j^m, b_j^m), m = 1, \ldots, n_j$ also relative to an arbitrary reference point. Consider that the reference point of polygon P_i is placed on coordinates (x_i, y_i) and that the reference point of polygon P_j is placed on coordinates (x_j, y_j). The direct comparison of the relative positions of two polygons is a complex and computationally heavy task, mainly in the general case when the polygons are non-convex. An alternative is to resort to the concept of no-fit polygon, a new polygon that captures the geometric information of both polygons. In fact, the edges of the no-fit polygon are the edges of the two polygons taken in a special order. With the no-fit polygon, checking the relative position of two polygons is reduced to checking the relative position of one point against the no-fit polygon.

To build the no-fit polygon, consider polygon P_i fixed and polygon P_j sliding around P_i, always in contact but never intersecting P_i. The trace of the reference point of P_j during this movement is the no-fit polygon of P_j in relation to P_i: $NFP_{P_iP_j}$ (Fig. 3). The reference point of $NFP_{P_iP_j}$ is the same as the reference point of P_i. In order to guarantee that all the small items do not overlap, it is necessary to build the no-fit polygons for all pairs of items. They can, however, be built in a preprocessing phase, as they do not depend on the absolute coordinates of the reference point of P_i.

Let $NFP_{P_iP_j}$ be the no-fit polygon of polygon P_j in relation to polygon P_i, with N_{ij} vertices with coordinates $(a_{ij}^k, b_{ij}^k), k = 1, \ldots, N_{ij}$, and with its reference point placed on coordinates (x_i, y_i). Polygon P_j will not intersect polygon P_i if its reference point is on coordinates (x_j, y_j) such that:

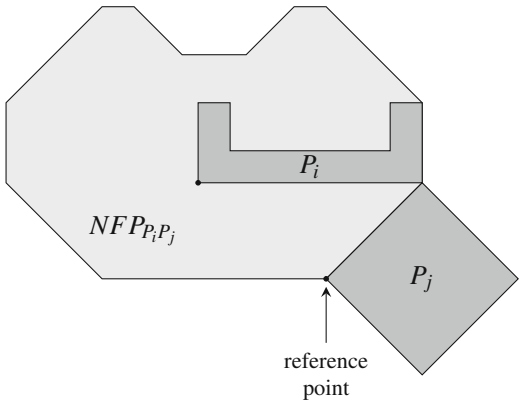

Fig. 3 The no-fit polygon of polygon P_j in relation to polygon P_i

$$\exists k \in \{1, \ldots, N_{ij} - 1\} : y_j \geq \frac{b_{ij}^{k+1} - b_{ij}^{k}}{a_{ij}^{k+1} - a_{ij}^{k}}(x_j - a_{ij}^{k}) + b_{ij}^{k}$$

i.e., the comparison of the coordinates of one point against one polygon.

Note that the direction of the inequality in the aforementioned expressions (" $\geq$" or " $\leq$") depends on the orientation chosen for the polygons, i.e., if vertex $k + 1$ is on the left-hand side or on the right-hand side of the line defined by the vertices $k - 1$ and k.

Problem Types

From the non-geometric point of view, Cutting and Packing problems can be formally defined as follows:

> A set of small items of m distinct types, with distinct geometries and values v_i, $i = 1, \ldots, m$, have to be assigned in a minimum amount of d_i^L and a maximum amount of d_i^U units, to a set of n distinct types of large objects, with distinct geometries and values V_j, $j = 1, \ldots, n$ available in a limited amount of D_j units.

The objective of the problem may be either *output maximization* or *input minimization*. If there are more small items to cut/pack[1] than space available in the large objects, the goal is to select the subset of small items to pack so that the value extracted from the large objects (the value of the small items effectively packed) is maximized. Therefore, these problems are of *output maximization*, where the *output*, the value v_i of the small items, may be proportional or not to their area/volume. In this situation, as there are more small items to pack than large objects available, the value V_j of the large objects is irrelevant as all the large objects will be used. If there are more large objects available than the ones needed to pack all the small items, the

[1] In what follows, we will use the term *pack* to refer indistinctly to Cutting and Packing processes.

goal is to select the subset of large objects to use so that the value of the used large objects is minimized. Therefore, these problems are of *input minimization*, where the *input*, the value V_j of the large objects, may be proportional or not to their area/volume. In this situation, as there are more large objects available than the ones needed to pack all the small items, the value v_i of the small items is irrelevant as all small items will be packed.

Depending on the values of m, d_i^L, d_i^U, n, and D_j, and on the objective of the problem, we will get the six main Cutting and Packing problem types, according to Wäscher et al.'s typology:

- Identical Item Packing Problem (IIPP)
- Placement Problem (PP)
- Knapsack Problem (KP)
- Cutting Stock Problem (CSP)
- Bin Packing Problem (BPP)
- Open Dimension Problem (ODP)

The first three are *output maximization* problems and the last three are *input minimization* problems.

In the IIPP, the small items are of only one type ($m = 1$), i.e., all the items are geometrically equal, but there is not a maximum demand for the item ($d_i^U = \infty$), i.e., that item should be packed as many times as possible. In the PP, m types of items have to be packed, but there is an upper limit on the number of items of each type to be packed (d_i^U). In the KP, all the small items are geometrically different, and therefore, the number of items is equal to the number of types of items (m) and the upper limit on the number of items to pack of each type is 1 ($d_i^U = 1$).

In what concerns the *input minimization* problems, while in the CSP, there are few types of items (m), with a demand d_i^L greater than or equal to 1, in the BPP, all the small items are different and have a demand of 1 ($d_i^L = 1$). In both cases, the large objects may be all different, i.e., there is only one unit of each large object ($D_j = 1$), the large objects may be of several types n with an availability D_j for each type, or they may be of just one type ($n = 1$) with an infinite availability ($D_j = \infty$). In the ODP, there is an "infinite" availability of the large object due to the open (not limited) dimension of the large object. An example is the rectangular strip packing problem, in which small rectangles have to be packed on a rectangle of "infinite" length, so that the length used is minimized. This happens in the textile industry where items are cut from fabric rolls. In practical applications of ODP, the m types of small items have a demand d_i. The characterization of the six types of problems, based on the values of their parameters, is resumed in Table 2. The symbol "–" stands for "*not relevant for the problem type characterization*."

In *output maximization* problems, in which there is an upper bound on the number of small items of each type to pack (d_i^U), there may also exist a lower bound d_i^L, meaning that it is mandatory to pack at least d_i^L small items of type i.

Table 2 Characterization of the six types of problems based on the values of their parameters

Problem	Objective	m	d_i^L	d_i^U	n	D_j
IIPP	output maximization	1	–	∞	–	–
PP	output maximization	≥ 1	–	≥ 1	–	–
KP	output maximization	≥ 1	–	1	–	–
CSP	input minimization	≥ 1	≥ 1	–	1 ≥ 1	∞ 1
BPP	input minimization	≥ 1	1	–	1 ≥ 1	∞ 1
ODP	input minimization	≥ 1	≥ 1	–	1	1

The six types of problems are represented in Figs. 4 and 5 for the two-dimensional rectangular Cutting and Packing problem. The small items and large objects effectively cut/used in a hypothetical solution are represented in dark gray to highlight the difference between *output maximization* problems where all large objects are used and *input minimization* problems where all small items are pack.

Additional Characteristics and Constraints

Many additional constraints to the cutting/packing patterns arise from the practical applications of these problems. These additional constraints are specific for each dimensionality or kind of geometry; however, two characteristics emerge as common to almost all two- and three-dimensional Cutting and Packing problems: small item orientation and guillotine patterns.

Given the physical characteristics of the raw materials from which the large objects are made, sometimes it is not possible to rotate small items, i.e., they have to be packed with the dimensions and orientation given: length strictly along the length and width strictly along the width. It is the case of wood boards or fabric rolls, for instance. In other cases, there is no problem in rotating the small items when placing them on the large objects, as it happens in the steel industry. Even when small item rotations are allowed, it is usual to differentiate the cases where only 90 and 180 degree rotations are allowed, which lead to orthogonal patterns, from other situations when other rotation angles are also admissible, in what is usually designated as free rotation. In three-dimensional packing problems, as container loading problems, there may be "this-side-up" constraints that restrict the number of feasible orientations in which a box may be loaded in the truck or container.

When dealing with rectangles, guillotine constraints may be imposed to the cutting patterns. A cutting pattern is said to be *guillotinable* if all the small items can be extracted with top-down (right-left) cuts made on the large object. Each cut produces two rectangles that may be the demanded small items or may be bigger rectangles to cut according to the same rule. Guillotine cutting patterns can be classified according to the number of times that the cutting tool has to be turned 90 degrees. If a sequence of horizontal (vertical) cuts, generating strips, followed by a

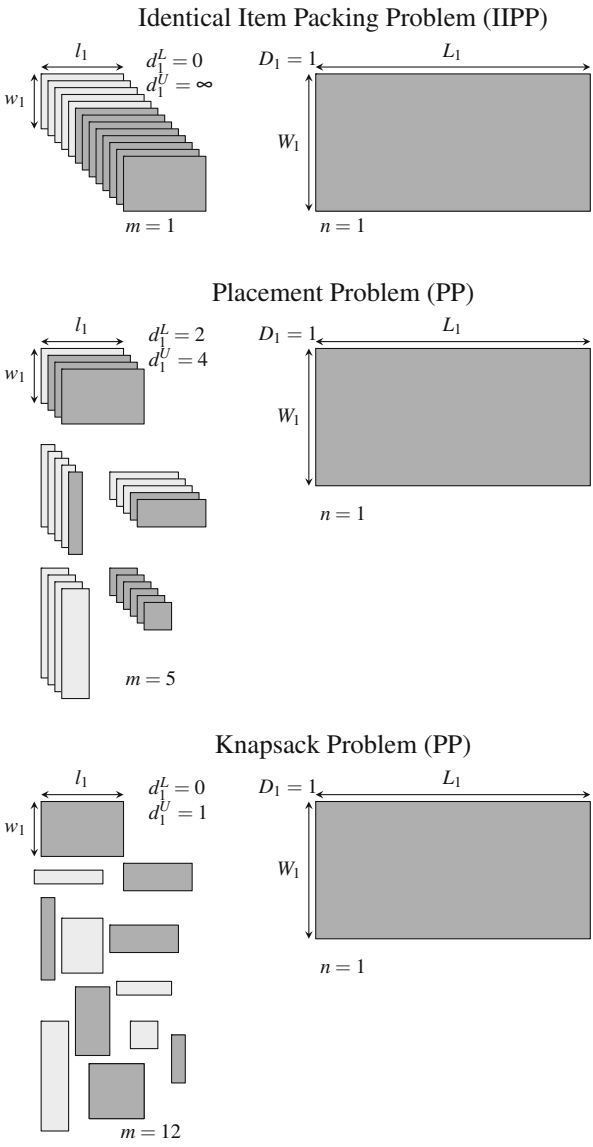

Fig. 4 Illustration of the three types of *output maximization* Cutting and Packing problems for the two-dimensional rectangular form of the problem

sequence of vertical (horizontal) cuts on each strip completely executes the cutting pattern, then this pattern is called a two-stage pattern. If an additional horizontal (vertical) cut is needed to cut the small items, then the pattern is classified as a three-stage pattern. The pattern is said to be n-stage if the cutting tool must be turned n times to complete the pattern. Figure 6 presents two-, three-, and n-stage guillotine cutting patterns and a non-guillotine cutting pattern. These concepts can be extended to three dimensions, when dealing with the cut of parallelepipeds.

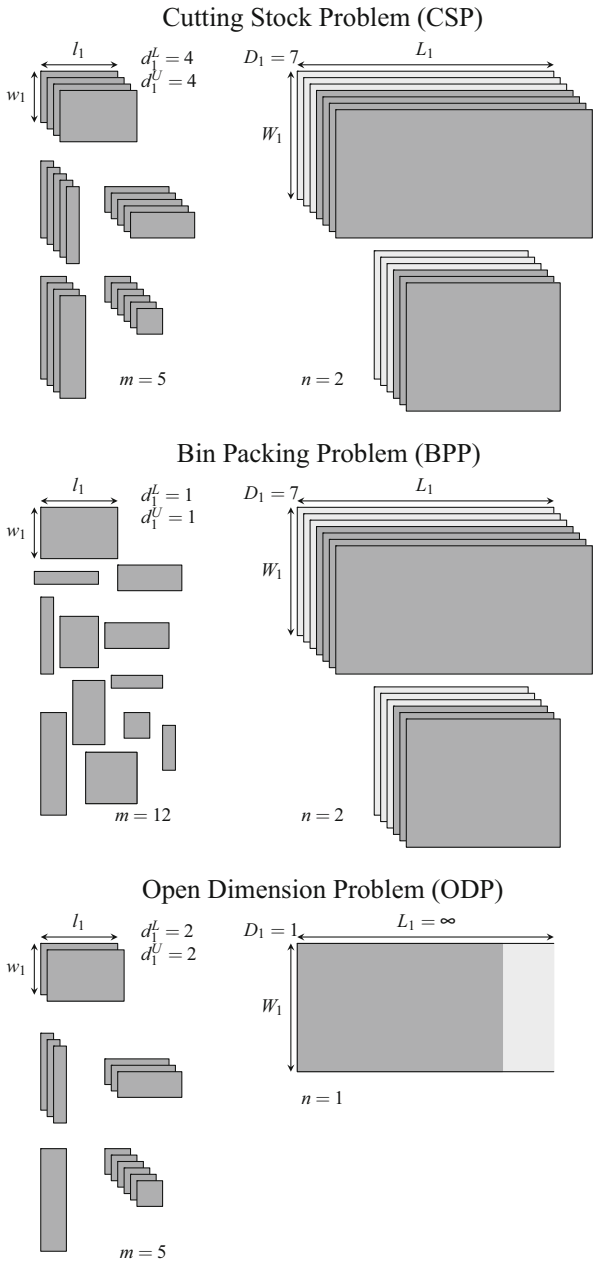

Fig. 5 Illustration of the three types of *input minimization* Cutting and Packing problems for the two-dimensional rectangular form of the problem

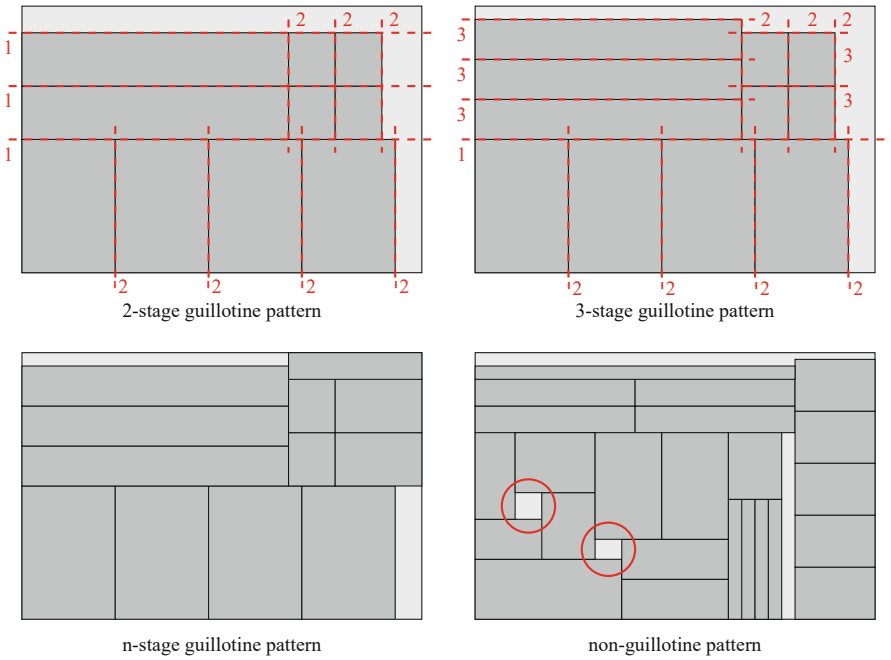

Fig. 6 Two-, three-, and n-stage guillotine cutting patterns and a non-guillotine cutting pattern

Rectangular Problems (2D and 3D)

This section describes the most widely used techniques for developing heuristic algorithms for Cutting and Packing problems involving rectangular items in two and three dimensions. First, constructive procedures will be described, then local search methods, and finally, metaheuristic algorithms successfully used for the basic versions of the problems. The section will conclude with some references to model-based heuristics.

Constructive Heuristics

Most of the heuristic algorithms include some constructive procedure in which a feasible solution is iteratively built by adding at each iteration a subset of items to the existing partial solution. All of these procedures involve two basic steps: selection of the items to be packed and selection of the space in which to pack them. Depending of the order in which these two steps are called, two types of algorithms can be distinguished:

1. *Item-driven algorithms*
   In this type of algorithms, the item to be packed is chosen first and then the best location for packing it is selected. The best-known example of this type is the *Bottom-Left* (*BL*) algorithm, proposed by Baker et al. [16], and then used by many other authors. In the *BL* algorithm, an ordered list of items is given and at each step the first item in the list is taken and placed to the lowest and left-most position in the empty space. In Jakobs's implementation [64], the position is obtained by putting the item at the upper right corner of the space and then shifting it alternately as far as possible to the bottom and then as far as possible to the left, as in Fig. 7a. Liu and Teng [75] developed an improved implementation giving priority to the downward movement, so the item is only shifted to the left when it cannot be shifted downward, as in Fig. 7b. They showed that, unlike Jakobs's method, there is always an ordering of the items that can produce the optimal solution.

   A refinement of the *BL* algorithm is the *Bottom-Left-Fill* (*BLF*) algorithm proposed by Chazelle [31], in which the empty spaces between items already packed are also considered to accommodate the new item. The algorithm has to maintain a list of points in a bottom-left order to indicate where the new item can be placed. These points are checked in order until a feasible position is found. Figure 8 compares *BLF* with *BL* on an example. A new item has to be added to the partial solution and is initially placed at the upper right corner (Fig. 8a). In Fig. 8b, the *BLF* algorithm is used. The figure shows the candidate points and the position selected for the new item. Using the *BL* algorithm the solution in Fig. 8c is obtained. Hopper and Turton [60] showed that the *BLF* heuristic outperforms the *BL* routine by up to 25% with the performance gain being higher for larger problems. However, its complexity is $O(n^3)$, while the complexity of *BL* is just $O(n^2)$.

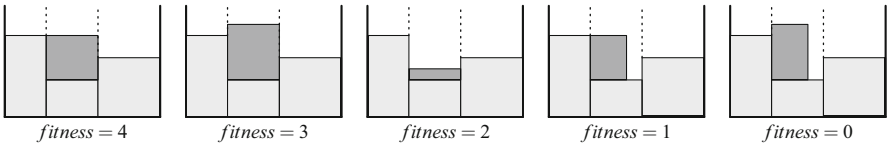

Fig. 9 Scoring rule of Leung et al.

2. *Space-driven algorithms*

In this type of algorithms, a space is selected first from the list of available spaces and then the item or the subset of items that fits best into the space is chosen to be packed.

An example of this type of procedure is the *Best-Fill* (*BF*) algorithm proposed by Burke et al. [26] for the strip packing problem in which, at each step, the lowest space is chosen and then the item that fits best is chosen to occupy it.

A further refinement of the *BF* algorithm is the *Scoring* rule by Leung et al. [69], in which the quality of the fitting is evaluated using a fitness measure that takes into account other factors besides the way in which the base of the item fills the base of the space. Figure 9 shows the empty space selected and the fitness values corresponding to candidate items.

Apart from these simple cases, the algorithms in which the space is chosen first are usually more complex, because they have to decide how to manage the empty spaces and because they usually choose subsets of items to fill the spaces instead of just one item.

Concerning the management of the spaces, there are basically two alternatives: partition the empty space into smaller disjoint spaces or consider non-disjoint maximal spaces [66].

Partitions are very useful when guillotine cuts are considered or in three-dimensional problems when the items have to be fully supported from below by other items or the base of the large object. They are also easier to manage, because every time an item is placed in a space, it produces some new spaces to substitute the previous one, without modifying any other space in the list.

Conversely, maximal spaces are more flexible and can produce solutions that partitions are not able to attain, but they are more difficult to manage. As maximal spaces are not disjoint, putting an item into one space may modify other spaces and the whole list of spaces has to be checked. An example of

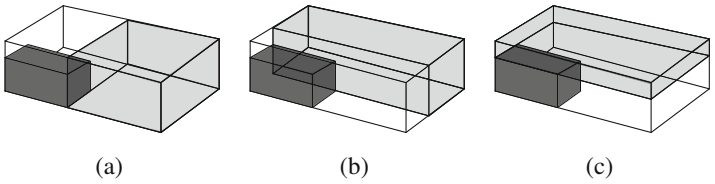

Fig. 10 Space management in 3D: maximal spaces

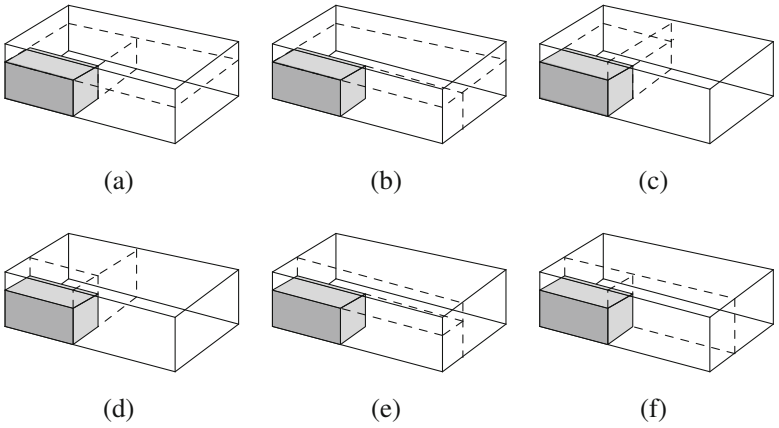

Fig. 11 Space management in 3D: partitions

maximal spaces appears in Fig. 10. Initially the parallelepiped is empty and when an item is packed at its bottom left corner, three maximal spaces are generated. Figure 11 shows an example of partition. In this case, when putting the item at the bottom-left corner of the parallelepiped, a decision has to be taken about the new spaces generated. Six possibilities appear, depending on the horizontal or vertical cuts. Most approaches follow the strategy of generating the largest possible front space, then maximizing the side space, and finally, the top space holds the remaining volume. This strategy aims to produce walls of objects that are transverse to the length of the paralellepiped, while providing full support for the objects. A notable exception is presented in Xiang et al. [109], where priority is given to the size of the top space, resulting in packing patterns based on layers instead of walls.

The other aspect that the algorithms have to decide is if, at each step, just one item is selected to be packed or if a subset of items with a certain structure is selected. In this second case, the items come in *blocks*, that is, arranged in a structure of rows and columns. Blocks have been used by many authors and can be considered the standard way of packing items once the space has been chosen. In most cases, the blocks are *homogeneous*, that is, composed of just one type of item, as in Fig. 12a, but sometimes, in more recent studies (Fanslau and Bortfeldt [47], Zhu et al. [112], Wei and Lim [106]), they are *heterogeneous*, including

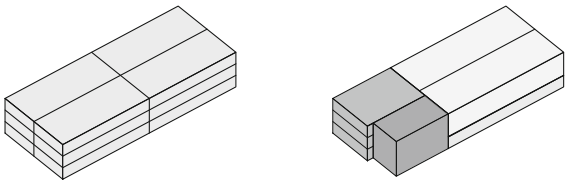

Fig. 12 Homogeneous and heterogeneous blocks

(a) Homogenous block (b) Heterogenous block

items of different types as long as their dimensions do not differ more than a given threshold, as in Fig. 12b.

Finally, there are algorithms that select simultaneously both elements, the item or block to be packed and the space in which to pack it. An example is the procedure proposed by Wu et al. [108] for packing rectangles into a rectangle, in which, following the principle that "Golden are the corners; silvery are the sides; and strawy are the voids," all the unpacked items are evaluated to be placed at each corner of the remaining empty space. The placement algorithm proposed by Wei et al. [107] considers all pairs (p, r) (position-rectangle), selects one of them according to some fitness criteria, and places the rectangle in this position.

Local Search Heuristics

There are several ways to define and explore the neighborhood of a solution. Two main groups of local search procedures can be distinguished: those in which the solution is given by an ordered list of items, that will be decoded into a physical solution by means of an algorithm such as BL or BLF, and those in which the layout of the solution is used to define the neighborhood.

1. *Procedures based on ordered lists of items*
   In Hopper and Turton [60], the problem is represented by a permutation of items, giving the order in which the items are packed. They define two manipulation operations. The first one swaps two randomly selected items in the permutation. The second operator flips the orientation of one randomly selected item. In the translation to the next solution, only one of the operators is applied with a 50% chance. The initial solution is randomly generated.

   Leung et al. [70] apply the scoring algorithm [69] to an ordered list of items. If two items have the same score, the first item on the list is packed first. Therefore, different item sequences can generate different solutions. They exhaustively study the sequences produced by exchanging the positions of every pair of items and keep the best solution found.

   Ceschia and Schaerf [30] deal with a multi-container problem and work with a set of sequences, one for each container. Each element of a sequence is a homogeneous block. A move consists of moving some items of a block to another position of the same or another sequence, keeping or changing their orientation.

An example appears in Fig. 13 [30], involving two containers. Part of the block in position 4 in the first sequence is moved to position 4 in the second sequence.

2. *Procedures based on the layout of the solutions*
   The movements determining the neighborhood of a solution can be defined directly on the layout of the solution, taking into account the position of the items on the large objects. Some examples of these moves can be seen in the following figures. Figure 14 [9] shows a simple move in which an item is selected to change its position on the strip. Once it is selected, it is removed and packed again on an empty space in which the item can fit or not. It is does not fit, as in the example of the figure, the overlapping items are removed and packed again by using a constructive procedure.

   In Fig. 15 [86], a block of items that were left initially unpacked are inserted into a bin. The overlapping items are removed and the new empty spaces are filled again.

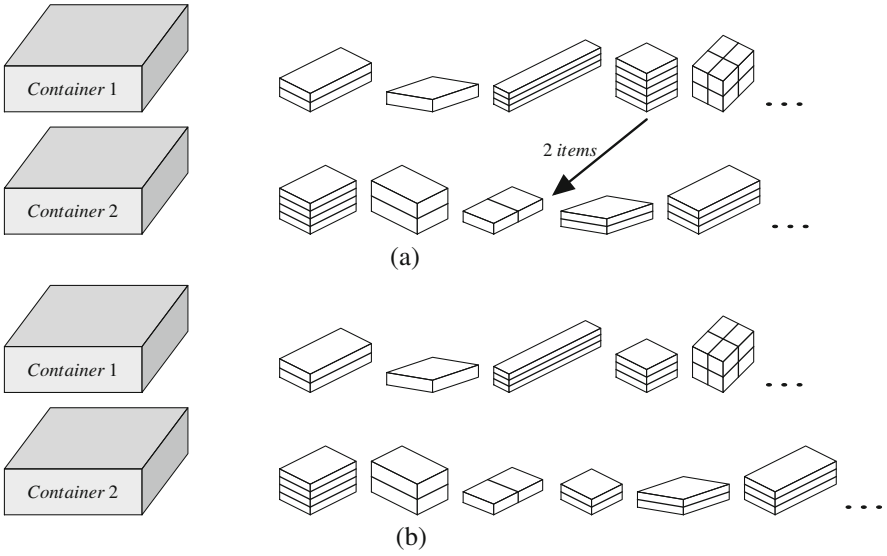

Fig. 13 Ceschia and Schaerf's movement. (**a**) Initial solution. (**b**) New solution

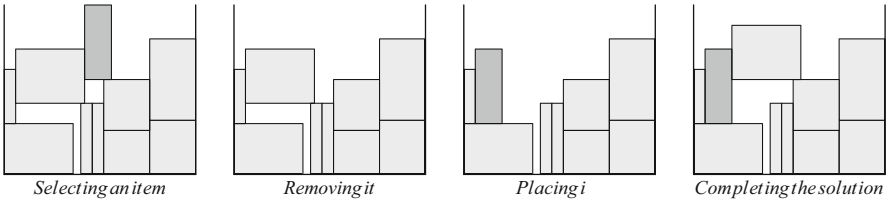

Fig. 14 Changing the position of an item

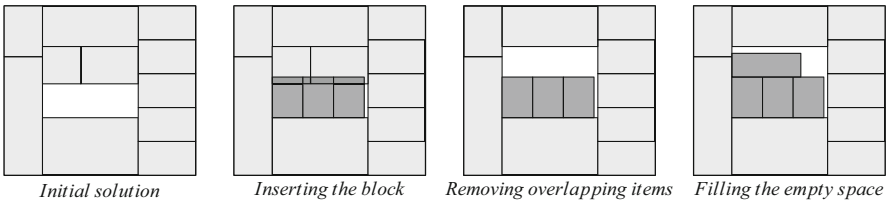

Fig. 15 Inserting a block

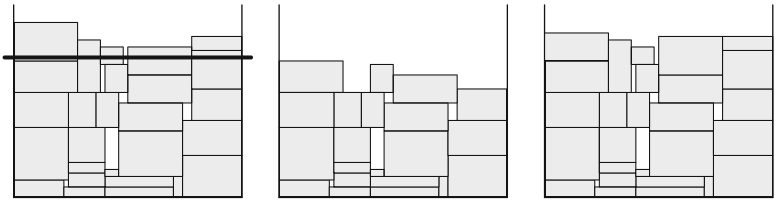

Fig. 16 Removing and filling in a two-dimensional problem

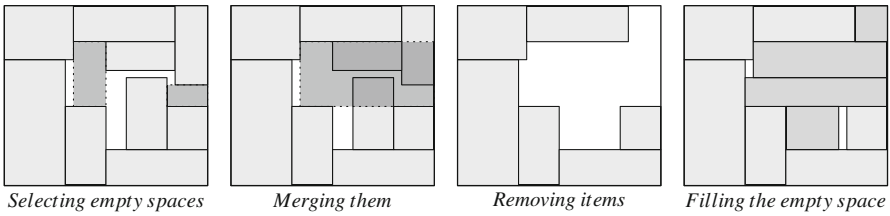

Fig. 17 Merging empty spaces in two and three dimensional problems

A frequently used type of movement consists of removing part of the solution and rebuilding the partial solution in a way that produces a different solution. A two-dimensional example appears in Fig. 16 [9], in which the last part of the solution of a strip packing problem is removed and the strip filled again, using a different procedure. Finally, Fig. 17 [86] shows a more complex move, which can be applied to two- and three-dimensional problems. Two empty spaces are selected and then the smallest rectangle (or parallelepiped in 3D) containing them is determined and the items contained totally or partially in it are removed. The resulting space is filled again, producing a new solution.

Metaheuristics

Multi-start Algorithms

Lesh et al. [67] develop the $Bottom - Left - Descending$ (BLD) algorithm, in, which the known BL algorithm is used four times, ordering the items by decreasing height, width, area, and perimeter. In order to improve BLD, they

develop a stochastic variation, algorithm BLD^*. BLD^* starts with a fixed order (say decreasing height) and generates random permutations from this order. Items are selected in order, one at a time. For each selection, BLD^* goes down the list of remaining items, accepting each item with probability p, until an item is accepted. If the last item is reached and not selected, it restarts at the beginning of the list. After an item is accepted, the process starts again from the beginning of the list. The probability of obtaining some ordering y, starting from some fixed ordering x, is proportional to $(1 - p)^{Ken(x,y)}$, where $Ken(x, y)$ is the Kendall–Tau distance between the two permutations.

Belov et al. [17] propose two iterative heuristics for the strip packing problem. The first one uses a special single-pass heuristic *SubKP* in each iteration. *SubKP* fills the selected empty space by solving a 1D knapsack problem, considering only item widths. At each iteration, the profits of the items change according to a sequential value correction method [82]. The second iterative heuristic, *BS(BLR)* uses at each iteration a single-pass heuristic *Bottom-Left-Right (BLR*), a modification of *BL*, in which the item can be assigned to the left or to the right in the most bottom-left free space large enough for that item. To construct item orderings for *BLR*, a simplified *BubblePermute* [68] procedure is used.

Araujo and Armentano [11] also propose a multi-start random constructive algorithm. At each step of each constructive process, a list of homogeneous blocks are evaluated and ranked. A biased random selection determines the block to pack but, before packing it, another biased random procedure reduces the rows and/or columns of the block. These two randomizing strategies guarantee the diversity of the solutions obtained.

Genetic Algorithms

Most of the genetic algorithms proposed for solving Cutting and Packing problems use a representation in which each solution is given by an ordered list of items and a decoding algorithm translates this list into a physical solution.

Jakobs [64] already used this representation in his genetic algorithm, with an specific crossover operator and a mutation operator that exchanges the position of some elements of the permutation. The solutions are decoded by using the *BL* algorithm.

Hopper and Turton [60] use this representation, with partially matched crossover (PMX) and order-based mutation. They also consider elitism and seed the initial population with a solution obtained by a heuristic placement procedure. As decoding algorithm they use *BL* and *BLF*.

Leung et al. [72] also use as chromosomes ordered list of items, a mutation operator consisting of swapping the positions of two items randomly chosen, and two-point and cycle crossover operators. They also include a simulated-annealing operator to induce competition between parents and children. If the children are better, they are accepted, but if the children are not as good as their parents, they can still be accepted with some probability. This helps to prevent the population from becoming homogeneous too early. The solutions are decoded using a procedure similar to the *BLF*.

Iori et al. [63] also use the ordered list representation. The main difference with respect to standard procedures is that they distinguish between improving and non-improving phases, depending on the number of individuals generated without improving the best solution obtained. The phase influences the fitness evaluation, the elitism strategy, and the use of mutation. Another special feature is the use of local search to improve the individual with the largest fitness. Although they use a more sophisticated decoder, Feng et al. [49] follow a similar idea.

A different approach to genetic algorithms based on list of items is the Biased Random-Key Genetic Algorithm proposed by Gonçalves and Resende [56] for the Bin Packing Problem. If the instance being solved has n items, the chromosome has $2n$ genes, the first n for the sequence of items, and the last n for their orientations. Each individual of the population is a vector of $2n$ random keys. Initially, the values are generated at random in the real interval [0, 1]. At each iteration, some mutants are added, generated in the same way that the elements of the initial population. Also, a small group of elite individuals are taken from the previous generation. The remaining members are obtained by parameterized uniform crossover, combining elite and non-elite individuals. For each component of the vector, the elite individual component is taken with a given probability. Once the individuals are formed, they are decoded, first ordering the items according to the values of their random keys, to produce an item sequence, and then placing the items into the bins using some placement algorithms derived from *BLF*. Figure 18 shows how the part of the chromosome corresponding to the items is sorted to produce an item sequence. A similar approach is used in Zudio et al. [113], but with the addition of using a Variable Neighborhood Descendent algorithm to improve the solutions obtained by crossover.

A completely different structure for a genetic algorithm is proposed by Bortfeldt and Gehring [24] for the container loading problem. Unlike all previous algorithms, they use the layer structure of the solution. Each feasible solution is composed of a set of layers, whose height and width are the same as the container and whose depth

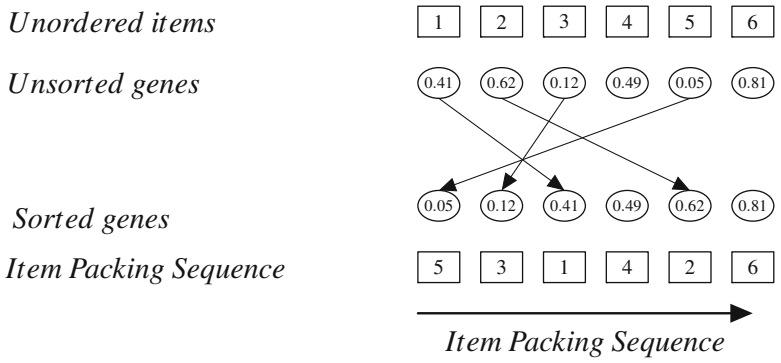

Fig. 18 Decoding of the item sequence in the algorithm of Gonçalves and Resende

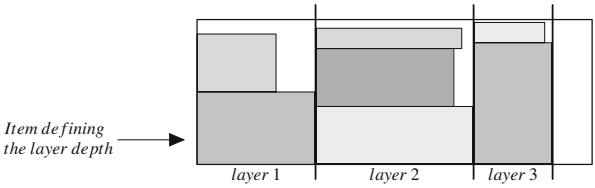

Fig. 19 Layer structure of the Bortfeldt and Gehring's solutions

is defined by one of their items (see Fig. 19). The constructive algorithm builds a solution with this layer structure and the genetic operators build new solutions by combining layers of previous solutions and including new layers for completing solutions when necessary.

Simulated Annealing Algorithms

Hopper and Turton [60] propose a simulated annealing algorithm in which the neighborhood is defined by the set of solutions that can be reached applying two manipulation operations. The first one swaps two randomly selected items in the permutation. The second operator flips the orientation of one randomly selected item.

In Lai and Chan [66], the neighborhood is obtained by swaps of randomly selected pairs of items and the solutions are decoded using an algorithm similar to *BLF*. In Leung et al. [69, 70], simulated annealing is used jointly with a constructive and a local search algorithm to escape from local minima. Neighbors are produced again by swapping pairs of items and the constructive algorithms work as decoders. Ceschia and Schaerf [30] also enhance their local search procedure by adding a simulated annealing phase to escape from local optima. More recently, Rakotonirainy and van Vuuren [91] proposed two simulated annealing procedures. In the first, the list of items is decoded by a constructive heuristic and the moves are made on the list. In the second, moves are made directly on the layout of the solution, removing part of the solution and completing it again.

Burke et al. [27] propose a hybrid procedure in which a solution is generated by a two-step process that first applies the best-fill heuristic to place an initial number of items onto the large object. Then, the remaining unassigned items are placed using the bottom-left-fill heuristic with different input orderings as guided by the simulated annealing search procedure. The locations of the items assigned in the initial best-fit stage of the process remain fixed throughout, whereas the items placed during the second stage will move locations according to the orderings produced by simulated annealing.

Tsao et al. [102] also propose a hybrid procedure in which a genetic crossover operator is used in addition to the traditional swap and insert operators. In the initialization phase, a pool of solutions is generated. During the search procedure, neighbors are generated by randomly selecting two solutions from the pool and applying a crossover operator to them. The usual Simulated Annealing acceptance/rejection rule is then applied.

Tabu Search Algorithms

The basic elements of a tabu search algorithm, apart from a feasible starting solution, are a move defining the neighborhood of the current solution, an evaluation of neighbors, a tabu list, an aspiration criterion, and some intensification and diversification strategies. A good example is *TSpack*, developed by Lodi et al. [77] for Bin Packing Problems. Starting from a solution in which each item is packed into a different bin, a move consists of selecting a target bin to be emptied, selecting an item in it, j, and solving the packing problem composed of a subset of k bins plus item j. Improving moves that reduce the number of bins are accepted, as well as moves maintaining the number of bins but packing j out of the target bin. The number k of bins packed again is a parameter that controls the size of the neighborhood and the search effort. Small values of k correspond to intensification while large values of k correspond to diversification. Nevertheless, when the search stalls without finding an acceptable move and k reaches its maximum value, other more aggressive diversification strategies are used to change the way in which the target bin is selected and to destroy part of the solution and build it again in a way in which the new solution is substantially different. Algorithm *TSpack* has been adapted by Bennell et al. [18] for solving a bin packing problem with due dates.

Alvarez-Valdes et al. [6] developed a tabu search algorithm for a two-dimensional cutting problem with guillotine cuts. The initial solution is built by a greedy constructive algorithm and the neighbors of a solution are defined taking at random one rectangle, considering its adjacent rectangles, one at a time, and emptying the minimum region containing both and respecting the guillotine cut structure. The region is filled again several times by using a GRASP algorithm, producing a set of neighboring solutions. The best non-tabu solution among them is selected. The tabu list keeps the rectangle being emptied and its size varies dynamically after a given number of non-improving moves. Intensification and diversification strategies are defined by modifying the value of the items for the greedy constructive procedure. If items appearing more often in the good solutions are given larger values, the search intensifies around best solutions. If these items receive lower values, they are less attractive to be in the solutions and the search diversifies.

Tabu search algorithms for Identical Item Packing Problems and Cutting Stock Problems are also based on the use of blocks [7, 8, 90]. The moves are defined as block insertion, block reduction, or block expansion. IIPP is an example of flat landscape, with many solutions having the same number of items. In order to distinguish among them and lead the search toward promising regions of the solution space, the original objective function is modified by adding other elements, favoring solutions with good characteristics, such as having the empty spaces as near as possible. Long-term memory is used for intensification and diversification purposes, favoring or penalizing blocks that have appeared often throughout the search.

Tabu search algorithms can also be developed using ordered lists of items, as in Wei et al. [107]. The move is defined as the swap of two items, although only a subset of non-tabu moves are explored at each iteration, because they are

evaluated building the corresponding solutions (or decoding them in the terminology of genetic algorithms).

GRASP Algorithms

GRASP algorithms for Cutting and Packing are based on the constructive procedures and the local search moves described above [2,6,9,38]. If at the improvement phase several moves are defined, the GRASP algorithm can be hybridized with a variable neighborhood descent (VND) procedure that controls the moves at each GRASP iteration. An example can be found in the algorithm by Parreño et al. [86] for the Bin Packing Problem, in which several moves based on removing the last part of the solution are combined with a more aggressive move that empties pairs of bins, as it appears in Fig. 20. Once a solution of N bins has been obtained, the target is set to obtain a solution with $N - 1$ bins. When the constructive procedure fills $N-1$ bins, it stops, leaving some items unpacked. Then, the improving moves try to pack all these items into the $N - 1$ bins. Many of the proposed GRASP algorithms use the reactive GRASP strategy, in which the value for the parameter controlling the randomization procedure adjusts itself using the information of the search.

Alvarez-Valdes et al. [3] solve a two-stage cutting stock problem combining two GRASP algorithms, one based on items and the other based on strips. The solutions obtained by the two GRASP algorithms have different structures and their combination by means of a path relinking procedure leads to very efficient solutions.

Path Relinking Algorithms

Path relinking algorithms have been applied to Cutting and Packing problems in connection with tabu search algorithms, as they were initially designed [6], but also

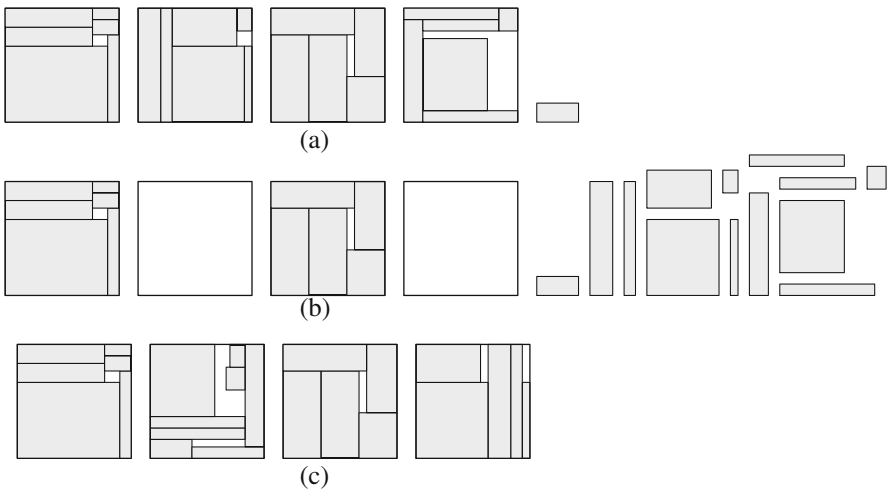

Fig. 20 Improvement move for a Bin Packing Problem. (**a**) Current solution. (**b**) Emptying two bins. (**c**) Pack first the unpacked item and then the removed items

connected to GRASP algorithms, in which a set of elite solutions is kept throughout the search. The work by Alvarez-Valdes et al. [10] on the Multiple Bin-Size Bin Packing Problem combines several variants of path relinking. Figure 21, taken from it, shows the process in which some part of the layout of a guiding solution B is imposed on the initial solution A, producing a new solution that can be considered to lie in the path between them.

Tree Search Algorithms

In tree search algorithms, the solution space is searched using a tree in which each node represents a partial solution, starting from the empty solution at the root node. From each node, branching creates a new level with as many new nodes as possible ways of adding a new element, item, or block, to the partial solution. As this tree would grow exponentially, there are several ways of controlling its growth, limiting the successors of each node to only those most promising, according to a certain criterion, usually the value of the solution obtained by completing the partial solution with a greedy heuristic, as proposed in the Pilot Method by Duin and Voß [42].

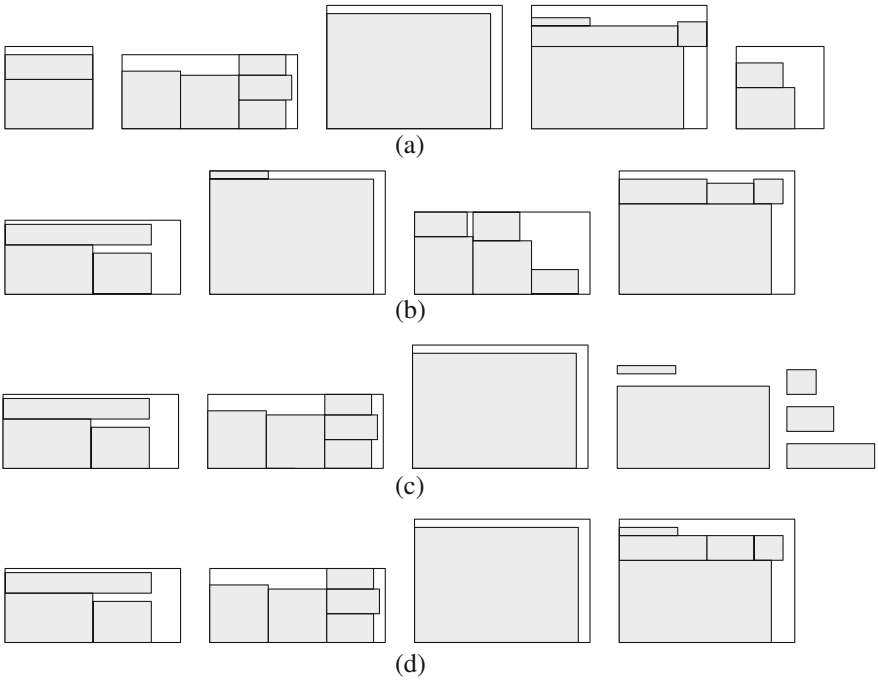

Fig. 21 Path Relinking for a Multiple Bin-Size Bin Packing Problem. (**a**) Initial solution A. (**b**) Guiding solution B. (**c**) Impose on A the first fin of B and remove bins with repeated items. (**d**) New complete solution

When solving a container loading problem, Eley [45] uses a parameter *breadth* to control the number of successors and in his computational study fixes this breadth to 7. Ren et al. [92] follow the same strategy but, at each level, only blocks getting the maximum value in at least one of the five proposed criteria are used to create a new branch. The scheme of Christensen and Rousoe [36] is also similar to Eley's, but they use a dynamic breadth, which adjusts itself dynamically to exhaust the available time while guaranteeing the completion of the tree search.

Pisinger [88] also proposes a tree search for the container loading problem in which the container is first decomposed into a set of layers, whose height and width are the same as the container, and then each layer is decomposed into a set of strips. A partial solution at a node is composed of a set of layers, partially filling the depth of the container. At each branching node, a limited set of layers are considered to be added to the partial solution, according to a ranking rule, and the solution is increased by filling the selected layer with strips. Again, a limited set of strips is considered, and the strips are filled by solving 1D knapsack problems.

Fanslau and Bortfeldt [47] have developed a more complex tree search method. Again, a node of the tree is a partial solution, in this case composed of a set of heterogeneous blocks. A basic search phase transforms a partial solution with i blocks into another with $i + d$ blocks, where d is the depth of the search. The value of an augmented solution is obtained by completing it using a heuristic procedure. Basic searches can be linked to compose more complex search patterns, as shown in Fig. 22, in which, starting from a partial solution with i blocks, a search with depth $d = 3$ is divided into 1 or 2 basic searches. The basic search of depth 3 on the left-hand side produces 8 augmented incomplete solutions (white circles) that are completed to be evaluated (dark circles). The right-hand side shows two linked basic searches. The first one, of depth 2, produces 4 solutions, which are completed. The best complete solution (double dark circle) indicates the incomplete solution from which to start the second basic search of depth 1. The best solution found indicates which block $i + 1$ is added to the partial solution.

Tree search algorithms were used by several teams competing in the ROADEF Challenge 2020, in which a large cutting problem arising in the glass industry had to be solved. Libralesso and Fontan [73] developed a tree search, including simple

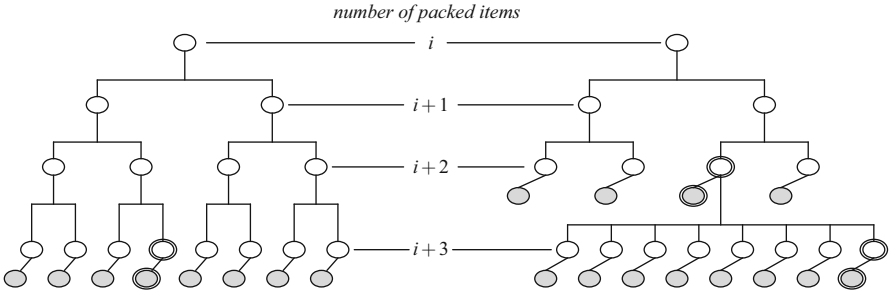

Fig. 22 Tree search structure of Fanslau and Bortfeldt

bounds, dominance, symmetry-breaking rules, and a new evaluation function, and used it in an iterative way in which at each iteration the number of active nodes is increased until optimality is proven or a time limit is reached. Parreño et al. [87] proposed a Beam Search algorithm, combining local and global evaluations of the nodes and a lookahead procedure, and applied a local search to best solution found.

More recently, Arruda et al. [14] have combined and extended the ideas of the BF algorithm and Pilot Method to develop a tree search algorithm in which at each branching level only items fitting into the lowest space of the skyline are considered and evaluated by completing the partial solution with several heuristics.

The OR/AND graph approach developed by Arenales and Morabito [13] for the two-dimensional cutting problem can be also considered as a tree search procedure. At each node of the tree, there is a rectangle obtained by repeatedly cutting the original stock sheet and the cuts that can be applied to this rectangle define the successors of the node.

Also noteworthy are the tree-search approaches of Araya and Riff [12] and Liu et al. [76]. The former avoids exhaustive search of the tree by using a Beam Search algorithm. Several blocks of items with high space utilization are pre-generated and then placed in the empty spaces. Each node of the tree corresponds to a partial solution, defined by the list of maximal empty spaces, the list of items to pack, and a list of blocks. Branching corresponds to packing a block into one of the empty spaces. Liu et al. [76] resort to full tree exploration and, in the initialization phase, build stacks of items instead of general blocks. These stacks are used to build walls along orthogonal slides of the paralellepiped. Branching is done by selecting stacks to build a new wall.

Other Metaheuristic Schemes

Burke et al. [25] propose a Squeaky Wheel Optimization algorithm for the strip packing problem in which at each iteration the ordered list of items is decoded into a feasible solution by means of the Best-Fit algorithm. The items protruding a given height are considered badly placed and their value increases. Therefore, they get better positions in the ordered list and are placed earlier in the next iteration.

Guided Local Search has been used by Faroe et al. [48] for the 3D Bin Packing Problem and by Hifi et al. [59] for the multidimensional knapsack problem. The guided local search moves out of a local maximum/minimum by penalizing particular solution features that it considers should not occur in a near-optimal solution. It defines a modified objective function, augmented with a set of penalty parameters on these features. The usual local search method is then used to improve the augmented objective function. The cycle of local search and penalty parameter update can be repeated as often as required.

Liu et al. [74] use the Particle Swarm Optimization framework to develop an algorithm for the multiobjective bin packing problems. Each particle encodes a packing solution, which includes the number of bins used and the order in which the items are packed into the bin by the *BLF* heuristic. Chen et al. [33] also use particle swarm optimization for solving a two-dimensional cutting problem, using as a decoder a heuristic algorithm, based on the *BL* procedure, but adapted to

the specific problem being solved. A similar idea is used by Koonsintananan and Kimpan [65] for the three-dimensional packing problem.

Zhang et al. [110] take the Variable Neighbourhood Search framework to develop an algorithm for the strip packing problem. Instead of swapping items, as in other proposals, the neighborhoods consist of swapping bloks, sequences of items in the item list. By varying the size of the blocks, a series of increasingly complex neighborhoods are defined.

Capua et al. [29] develop an Iterated Local Search for the bin packing problem with conflicts, focusing on the efficient implementation of exponential-size neighborhoods, Borgulya [23] combines a Estimation of Distribution Algorithm with a genetic algorithm to solve a variable bin-size bin packing algorithm.

Ant Colony Optimization has also been used to solve the tree-dimensional packing problem. In this approach, the solution is coded as the number and type of items to pack, along with the loading sequence (Zhang et al. [111]).

Huang et al. [61] propose a differential evolution algorithm for this problem. Again, the chromosome encodes the item sequence and a bottom-left heuristic decodes the chromosome. A ternary tree is used to store and manage the blanks.

Matheuristics

For one- and multi-dimensional cutting stock problems, Gilmore and Gomory [51–53] proposed in 1961–1965 to solve the following integer program:

$$Min \sum_{q \in Q} c_q x_q$$

$$s.t. \quad \sum_{q \in Q} a_{iq} x_q \geq d_i, \quad i = 1, .., m \tag{1}$$

$$x_q \geq 0 \ \ and \ \ integer, \forall q \in Q \tag{2}$$

where Q is the set of all feasible cutting patterns for all stock sheets S_p, x_q the number of times pattern q is used in the solution, a_{iq} the number of times item i appears in pattern q, d_i the demand of item i and c_q the cost of pattern q.

As the set of patterns Q cannot be completely described except for very small problems, they developed a column generation scheme that can be summarized as follows:

1. Generate an initial set $\widetilde{Q}$ of m cutting patterns, where each pattern contains one type of item.
2. Solve the linear relaxation of the earlier formulated problem considering only the variables corresponding to patterns in $\widetilde{Q}$.
3. For each type of sheet S_p, solve the subproblem:

$$z_p = Max \sum_i \pi_i a_i$$

$$\text{s.t.} \quad \{a_1, \ldots, a_m\} \text{ is a feasible cutting pattern for } S_p$$

where π is the vector of dual prices of the LP solution. If, for some p, $z_p > c_p$, then the column corresponding to that solution is added to $\widetilde{Q}$ and Step 2 is returned to in order to solve the enlarged LP problem. Otherwise, the current solution is rounded to get an integer solution and the process ends.

The question now is how to solve efficiently the subproblem of Step 3. Note that, even if the subproblem is solved by exact methods, the whole procedure is heuristic, due to the rounding step. The quality of the integer solution will depend not only on the algorithm used to solve the subproblem but also on the rounding procedure and on the structure of the demands.

Since the seminal work of Gilmore and Gomory, many authors have used this framework to solve Cutting and Packing problems or at least to have a reference or a starting point for new developments to overcome its limitations and adjust it to other problems. Examples go from Dyckhoff [43], Stadtler [97], and Valerio de Carvalho [104] for 1D problems, to Riehme et al. [93] for 2D cutting problems with extremely varying demands, or to Alvarez-Valdes et al. [5], who develop and compare several procedures to solve the subproblems as well as several rounding procedures.

Matheuristics have been increasingly used in recent years to combine the power of exact methods with the flexibility of heuristics. In this field, there is not a fixed common framework, each author for each problem identifies the part to be solved by a mathematical programming solver and the part to be run by heuristic methods.

Many of the approaches to the cutting problem described earlier would now be called matheuristics. However, matheuristics have also been developed for other types of cutting and packing problems.

Polyakovskiy and M'Hallah [89] develop a two-phase matheuristic for the bin packing problem with due dates. The first phase builds an initial solution using a heuristic that applies an iterative constraint programming-based neighborhood search. The second phase improves the solution by solving approximately a series of assignment low-level mixed integer linear problems.

Birgin et al. [22] address the multi-period two-dimensional non-guillotine cutting stock problem with usable leftovers and propose a forward-looking matheuristic approach. The method solves a sequence of single-period subproblems but the forward-looking approach takes into account the future impact of the decisions of the period, thus allowing the method to suggest the purchase of some extra raw material whose leftovers are expected to be used in future periods, resulting in a lower overall cost.

Grancolas and Pain-Barre [57] propose a metaheuristic approach for the two-dimensional strip packing problem, consisting of two procedures: a local search

algorithm that provides satisfactory placements of the items on the horizontal axis, and an exact procedure that searches the positions of the items on the vertical axis, starting from the most promising ones, and that can be stopped at any time, when the current solution is provably optimal or a given time limit is reached.

Silva et al. [37] addresses the three-dimensional packing problem by decomposing the problem into three phases. In the first phase, walls of items are generated using a constructive heuristic, and in the second phase, a knapsack mathematical programming model is used to select the most promising walls. Finally, in the third phase, a one-dimensional packing problem is solved to place the selected walls in the large parallelepiped.

A decomposition strategy for the same problem is also followed by Toffolo et al. [100]. In this case, in a first phase, stacks of items are built using an exact dynamic programming algorithm, while in a second phase, the two-dimensional problem of packing the stacks of items on the floor of the parallelepiped is solved using a best-fit heuristic.

Irregular Problems

Irregular packing problems are Cutting and Packing problems with convex and non-convex shapes (aka nesting problems). Although different shapes can be considered, from now on, it will be assumed that the small items are described by polygons. In fact, most of the heuristics for these problems assume a polygonal shape for the small items. Moreover, although any type of Cutting and Packing problem, according to Wäscher et al. typology, can deal with irregular shapes, in practice, one can almost only find Placement Problems and Open Dimension Problems. In the former, a large board and a set of irregular items with a maximum demand are given, and the goal is to lay out a subset of items on the board so that the waste is minimized, while in the latter, the large object has fixed width and variable length, big enough to accommodate all the items (in some papers it is described as having infinite length). and the goal is to lay out all the small items so that the length of the board that is effectively used to pack the items is minimized. This is the variant of the problem, usually called irregular strip packing problem. Some papers approach the irregular Bin-Packing Problem [28, 79] and the irregular Cutting-Stock Problem [39, 96], but henceforward, the focus will be on the irregular packing problem with a single rectangular board, either with fixed or variable length, as this corresponds to the majority of the literature in the field.

Constructive Heuristics

Constructive heuristics build a solution for the problem by placing the pieces one by one. Two design decisions have to be made in a constructive heuristic: (1) given a set of pieces to place, in which sequence should the pieces be placed; (2) given a set of

pieces already placed on the board, where to place the next piece. The constructive heuristics vary on the strategies used for these two phases.

The bottom-left placement rule is the basis for most of the constructive heuristics available in the literature. The basic idea of the bottom-left rule is that each piece, in turn, is placed as low in the layout as possible and, for equal height, as much to the left as possible. The name of the rule and the description just made, suppose a vertical strip (width in the horizontal and length in the vertical). However, in irregular packing problems, the board/strip is most commonly represented with the width along the vertical direction and the length (which is aimed to be minimized in irregular strip packing) along the horizontal. Therefore, although the authors in the literature still refer to bottom-left rules, the pieces are actually placed as much to the left as possible (the minimum possible x-coordinate value), and for the same x-position, the lowest y-coordinate value is selected (Fig. 23). The basic implementation of the bottom-left placement rule places the piece on a feasible position of the layout (usually the up-right corner of the board) and starts moving the piece to the left, considering a discrete set of points where pieces can be placed (a grid is defined over the board), and as soon as an overlap with an already placed piece is detected (resorting to one of the geometric representation and manipulation strategies presented in section "Geometry") the movement is backtracked and a vertical move is tried. If successful, the horizontal movement is resumed. This process stops when a piece cannot move horizontally or vertically without overlapping other pieces or crossing the borders of the board (Algorithm 1). In this bottom-left implementation, unused spaces may become holes in the layout, as pieces may block access to those regions to the following pieces.

Art [15] proposed the first heuristic based on a bottom-left rule. On top of the bottom-left rule used to place each piece on the board, a compound rule for sequencing the pieces (selecting the next piece to place) was considered:

Fig. 23 Bottom-left placement rule

Algorithm 1: Bottom-left basic implementation

```
Place the piece on an up-right feasible placement position
while Piece does not overlap other pieces and is completely inside the board do
    Move piece one grid unit left
    if Piece overlaps another piece or is not completely inside the board then
        Move piece one grid unit right
        Move piece one grid unit down
    end if
end while
Move piece one grid unit up
Bottom-left position found
```

- consider the set of pieces that have not yet been placed;
- among these, select the set of pieces that can be placed on an x-coordinate that is within a given tolerance of the minimum x-coordinate where a piece can be placed;
- among these, select the set of pieces with an area within a given tolerance of the maximum area;
- among these, select the set of pieces with a minimum probable waste;
- among these, select the piece that can be placed in the lowest y-coordinate.

This compound rule is rather interesting as it highlights some of the main drawbacks of constructive heuristics.

To avoid the greedy effect of constructive heuristics, the authors try not to have too rigid and fixed rules to select the next piece to place. Whatever the rule we choose, independently of how clever and fit to the problem it is, a greedy choice at the beginning originates, leaving to the end the worst pieces to place, "destroying" solutions that looked promising at the beginning. Art tries to overcome this effect by balancing "doing well now" with "not doing bad in the end." Therefore, he does not commit to the piece that originates the most bottom-left placement but instead considers a set of pieces that are near (doing well now) and then, among these, selects the biggest ones, which are harder to place in the end (not doing badly in the end).

Another drawback of constructive heuristics is, by definition, that they do not backtrack on the decisions made, i.e., once a piece is placed, it is not removed to try another piece. In each step, more than one piece may be tried, and the one considered best is chosen, but in later phases, this step cannot be revisited, and a different decision is made. Backtracking is a characteristic of search heuristics that will be discussed in section "Local Search Heuristics." Art tries to overcome this drawback by attempting to anticipate the final effect of placing a piece through the concept of probable waste, i.e., the space that will become unusable after placing this piece. Figure 24 illustrates the concept. Similar implementations of this bottom-left placement rule were later on used by Oliveira and Ferreira [84] and Jakobs [64] as a block of more complex and sophisticated heuristics.

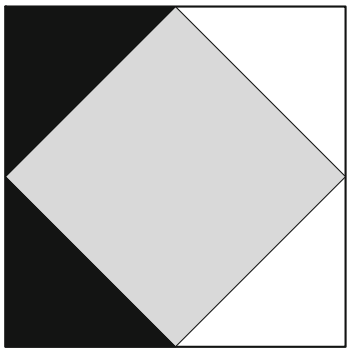

Fig. 24 Probable waste introduced by a piece (dark region on the left), according to Art [15]

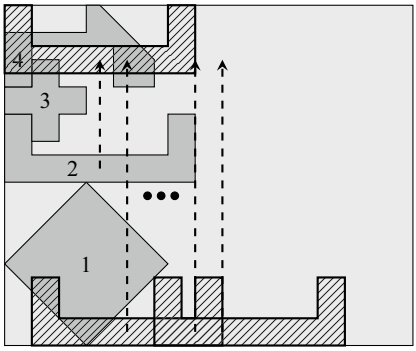

Fig. 25 Bottom-left placement rule, with the piece starting from unfeasible placement positions

Art [15] introduced interesting concepts, but the computational resources available at that time prevented a proper exploration of these ideas (the geometric representation of the pieces had to be very rough), and the bottom-left placement rule was only recovered in the middle of the eighties. Segenreich and Braga [95] propose another bottom-left placement rule. A grid is also defined over the board, and the pieces start from the origin of the coordinates. If the position is unfeasible, the piece is moved one grid unit along the y-axis, and feasibility is rechecked. Once the board's width is reached, the piece is moved one grid unit along the x-axis, the y-coordinate is reset, and the process is repeated until a feasible placement position is found. Given how the piece moves in this search for a feasible position, this is the most bottom-left placement for the piece. To improve the heuristic performance, the initial position for a piece is not always the origin of the coordinates but the position where the last piece of that type was placed, as for sure there is not a most bottom-left position prior to that one (Fig. 25). The most important characteristic of this implementation of the bottom-left placement rule is its hole-filling capacity, i.e., spaces left empty in the middle of the layout can be used to place smaller pieces that are next in the sequence. Dowsland et al. [40] and Takahara et al. [99] also used this bottom-left implementation.

These bottom-left implementations suppose discrete movements of the pieces within the grid. Resorting to the concept of no-fit polygon, Gomes and Oliveira [54]

and Dowsland et al. [41] proposed implementations of the bottom-left placement rules with continuous (real-domain) placement positions. When placing a piece j on the board, Gomes and Oliveira describe the possible placement points by:

- the vertices of the no-fit polygons NFP_{ij} of piece j in relation to pieces $i \in \mathscr{I}$, where $\mathscr{I}$ is the set of pieces that have been already placed;
- the vertices of the rectangle R_j that represents the extreme points where piece j can be placed without crossing the board border;
- the intersections of the edges of all NFP_{ij}, where $i \in \mathscr{I}$;
- the intersections of the R_j edges with the edges of all NFP_{ij}, where $i \in \mathscr{I}$.

Among these, the feasible placement points are on the boundary or outside all the NFP_{ij} and on the boundary or inside R_j, i.e., points, leading to a placement of piece j that does not overlap other already placed pieces and is inside the board (Fig. 26).

Chehrazad et al. [32] introduced a novel placement algorithm to address nesting problems, using a semi-discrete approach to represent both the pieces and the strip. In this method, the pieces and the strip are represented by equidistant vertical line segments. The discretization algorithm uses a sweep-line method and applies minimal extensions to the line segments of a piece to ensure that non-overlapping placement of the segments, representing two pieces, cannot cause overlap of the original pieces. The authors implemented a bottom-left-fill greedy placement procedure, using an optimised ordering of the segments overlap tests. The efficiency of this algorithm stems from its ability to avoid computing intersections between pieces, making it both fast and scalable. Therefore, it can be used as a fundamental component to effectively implement metaheuristics.

A completely different constructive heuristic was proposed in Oliveira et al. [85] and later on improved by Bennell and Song [21] – TOPOS.

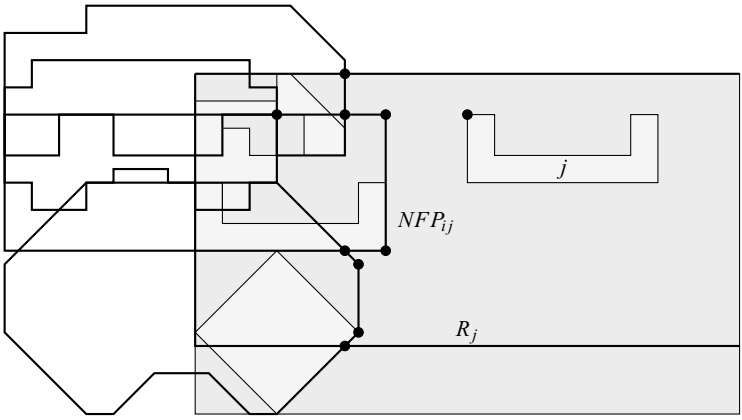

Fig. 26 Bottom-left placement rule, implemented over vertices of the NFP

In TOPOS, as in any other constructive algorithm, pieces are placed one by one on the board, building partial solutions. For each piece, the no-fit polygon of that piece in relation to the external contour of the set of pieces already placed (a partial solution), which form a kind of super-piece, is used to determine feasible placement points on the board. Once the placement point of a piece is determined, the piece is "merged" with the previous partial solution, and the external contour is updated. In the original implementation of Oliveira et al., new pieces could only be placed on the exterior of the partial solution, while in Bennell and Song, pieces may be placed inside the partial solution, i.e., it allows hole-filling. The most distinctive characteristic of TOPOS is that the partial solutions do not have a fixed position on the board. Their placement on the board may change according to the need to have more space below, above, on the left, or on the right of the partial solution to better accommodate new pieces. TOPOS proposed two strategies to answer the two design decisions of a constructive heuristic: where to place a given piece and which should be the next piece to place.

To decide where to place a given piece, three different placement rules are used:

1. minimum area rectangular enclosure – the piece is placed on the point where the area of the rectangle that encloses the piece and the partial solution is minimum;
2. minimum length rectangular enclosure – the piece is placed on the point where the length of the rectangle that encloses the piece and the partial solution is minimum;
3. maximum overlap between the two rectangular enclosures – the piece is placed on the point where the area of the overlap between the piece rectangular enclosure and the partial solution rectangular enclosure is minimum.

The candidates to placement points (the points where the three criteria are evaluated) are the vertices of the no-fit polygon and special points on the edges of the no-fit polygon. On these special points, the criterion that is being used to select the placement point is optimized, when the constraint of belonging to that edge is considered. For example, in Fig. 27, point X corresponds to the point of the edge $\overline{AB}$ where the area of the rectangular enclosure of the two polygons is minimum [85].

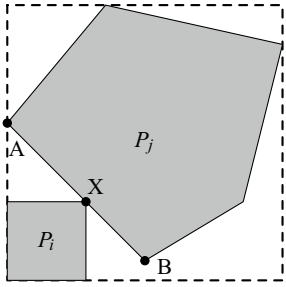

Fig. 27 X is a special point of edge $\overline{AB}$ where the area of the rectangle enclosure of the two polygons is minimum

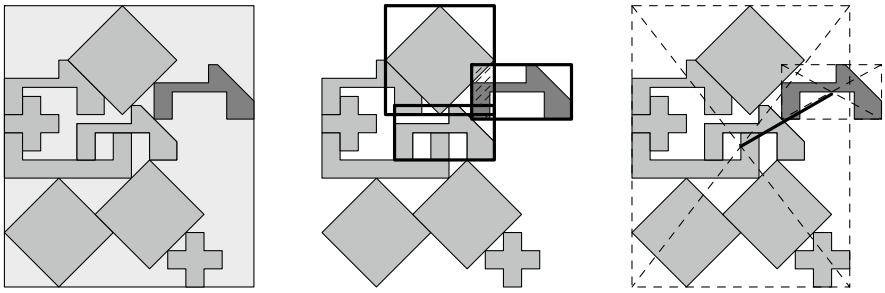

Fig. 28 TOPOS next-piece-to-place selection criteria

Once selected where each potential next-piece-to-place should be effectively placed, the several alternatives are compared using three different criteria, illustrated in Fig. 28:

Waste – The piece adding less waste to the partial solution is chosen.
Overlap – The piece whose rectangular enclosure overlaps more with the rectangular enclosures of the pieces belonging to the current partial solution is chosen.
Distance – The piece that is placed nearest to the geometric center of the partial solution is chosen.

These criteria may be combined or used independently. *Waste* and *Distance* can be used either in absolute value or in relative value, divided respectively by the area of the piece or by the half-perimeter of the rectangular enclosure of the piece. Bennell and Song [21] proposed two additional ways of using these criteria besides the original aggregation by sum: *Vector*, where the number of criteria in which a piece is better than the others is used to decide which is the best piece to place; *Priority*, where the criteria are used in a hierarchical way, with the lower levels being used to solve ties in the upper levels. Finally, in both implementations of TOPOS, all allowed orientations for each piece are tested.

Jostle [40], by Dowsland et al., is also a constructive heuristic where the way the next piece to place is selected is particularly interesting. Starting from a random or any priority-based sequence of the pieces, pieces are placed on the board following a leftmost strategy. The pieces are then sequenced by decreasing order of the x-coordinates of their right-most vertices and placed again on the board, but now according to a right-most strategy. Pieces are reordered by increasing order of the x-coordinates of their left-most vertices, and the process is repeated for a predefined number of iterations or until the solution does not change. This heuristic mimics the process of shaking objects on a tray so that they fit better together.

Local Search Heuristics

Local search heuristics may be divided into two groups: (1) heuristics that search over the actual problem solution space, i.e., complete layouts where all the pieces are laid down on the board; (2) heuristics that search over a solution representation, or codification, which in irregular packing problems is usually the sequence of pieces. The second group requires an additional constructive placement heuristic, or decoder, to transform the sequence into an actual layout (Fig. 29). Neighborhood structures based on swaps (dotted line), inserts (dashed line), or rotations (solid line) are defined over the sequences.

Heuristics Based on Searching Over Sequences

Heuristics based on searching over sequences vary depending on how a sequence is changed into another one (the neighborhood structure) and how the search process is controlled. Gomes and Oliveira [54] proposed a probabilistic 2-exchange heuristic in which neighbor solutions are generated by swapping a pair of pieces in the sequence. Given all pairs of pieces that can be exchanged, three different criteria were explored to decide which should be the next sequence/center of the neighborhood:

- first-better – accepts the first swap that leads to a sequence, which, decoded into a layout, is better than the current solution;
- best-better – accepts the best swap, i.e. the swap, which, decoded into a layout, leads to the best solution among all the swaps;
- random-better – accepts a swap chosen randomly among all the swaps, which, decoded into a layout, lead to better solutions than the current solution.

The search stops when no better solution can be generated from the current sequence.

More sophisticated search control strategies can be developed based on this "search over sequences" paradigm, as will be seen in section "Metaheuristics."

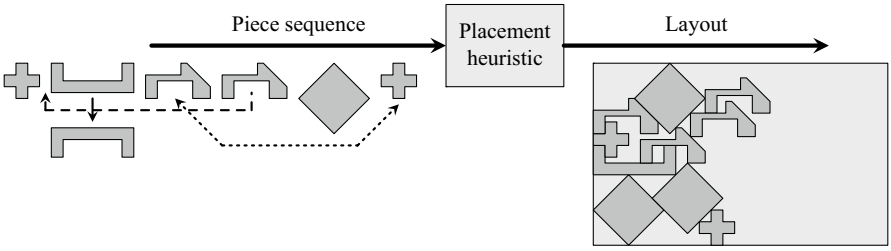

Fig. 29 Search over sequences, with swap (dotted line), insert (dashed line), and rotation (solid line) moves

An alternative search procedure building on piece sequences is based on tree-search methods. Albano and Sapuppo [1] proposed the very first tree-search algorithm for irregular packing problems. A new piece was placed on the board at each level of the tree. The tree's root represented the empty board, and the leaves a full layout. The authors applied strategies to improve the search efficiency by reducing the number of nodes explored. Some examples of these strategies are limiting the number of child nodes generated from a node and limiting the number of nodes kept in the list of nodes waiting to be explored. The decision to keep a node is based on indicators such as the waste of the partial solution or the waste added by placing a piece. These ideas became later rather popular under the name of *beam search* (see section "Metaheuristics").

Heuristics Operating Over Complete Layouts

The other group of local search heuristics operates on actual layouts, directly moving pieces by using the usual neighbor generation operators: swapping two pieces, moving a piece to another place, and rotating a piece (Fig. 30). In this type of heuristics, feasibility is usually not enforced, i.e., solutions where pieces overlap are allowed during the search. This is because only accepting moves to placements without overlap would restrict the search space and eventually lead to premature stopping in poor local optima.

This means that the overlap has to be penalized in the objective function. Once overlap between two pieces is detected, different measures of the overlap can be used in the objective function, being the most common the area, the enclosing rectangle intersection area, the penetration depth, and the orthogonal penetration depth (Fig. 31).

The use of the overlap measure in the objective function will depend on the type of problem tackled:

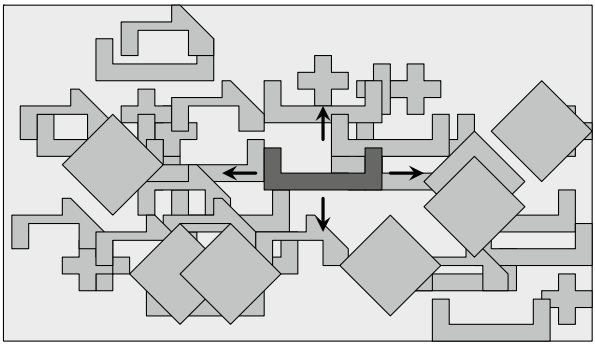

Fig. 30 Search over layouts: illustration of a search move where a piece is selected and moved to a different position

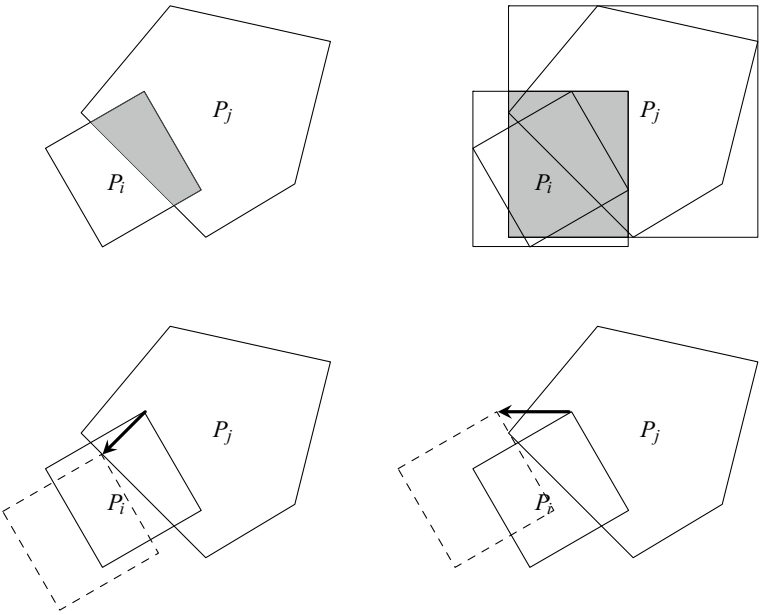

Fig. 31 Different measures of overlap can be used in the objective function: area (up-left), enclosing rectangle intersection area (up-right), penetration depth (down-left), and orthogonal penetration depth (down-right)

- For problems where the width and the length of the board are fixed, the set of pieces to be placed is given, and the objective is to find a placement such that the overlap is minimized. If a solution with no overlap is found, the heuristic is run with an additional piece so that the number of pieces placed on the board is maximum.
- For problems where the board has a fixed width and a variable length, all pieces have to be placed. The objective is to find a placement with no overlap so that the used board's length is minimized. To achieve that goal, the objective function has two components: the length of the layout and the amount of overlap. The weight of the overlap component determines the behaviour of the search algorithm: a high weight leads to a fast convergence to a layout with no overlap but potentially with a big length; a low weight may lead to a solution with a small length but some overlap, an infeasible solution for the irregular packing problem.

Because of their intrinsic difficulty in eliminating overlap, these heuristics have been mainly used embedded in more sophisticated solution approaches, either hybridized with mathematical programming models (section "Matheuristics") or in metaheuristic frameworks (section "Metaheuristics").

Matheuristics

Most of the mathematical programming models for the irregular packing problem rely on the concept of no-fit polygon to write the no-overlap constraints. Consider the polygons P_i and P_j and their $NFP_{P_iP_j}$, represented in Fig. 32. Guaranteeing that P_j does not overlap P_i is simply a matter of imposing conditions on the variables representing the coordinates of the placement point of P_j, i.e., x_j and y_j. These conditions must lead to the consequence that (x_j, y_j) is on the exterior or on the boundary of $NFP_{P_iP_j}$. The mathematical programming models that use the placement points of the pieces as decision variables (e.g. Gomes and Oliveira [55], Fischetti and Luzzi [50] and Alvarez-Valdes et al. [4]) describe the exterior of the no-fit polygon in different ways. The most common approach uses a covering model, i.e., decomposing the exterior into a set of regions that may overlap but completely cover the exterior of the no-fit polygon. In the example depicted in Fig. 32, the equations of the supporting lines of the edges of the no-fit polygon, denoted by $e_{ijk}(x_i, y_i, x_j, y_j)$, $k = 1, \ldots, 12$, would provide the following systems of linear inequalities (in this case, each system has either one or three linear constraints):

$$\begin{bmatrix} e_{ij1}(x_i, y_i, x_j, y_j) \geq 0 \\ e_{ij2}(x_i, y_i, x_j, y_j) \geq 0 \\ e_{ij3}(x_i, y_i, x_j, y_j) \geq 0 \\ e_{ij4}(x_i, y_i, x_j, y_j) \geq 0 \\ e_{ij5}(x_i, y_i, x_j, y_j) \geq 0 \\ e_{ij6}(x_i, y_i, x_j, y_j) \geq 0 \\ e_{ij7}(x_i, y_i, x_j, y_j) \geq 0 \\ e_{ij8}(x_i, y_i, x_j, y_j) \geq 0 \\ e_{ij9}(x_i, y_i, x_j, y_j) \geq 0 \wedge e_{ij10}(x_i, y_i, x_j, y_j) \geq 0 \wedge e_{ij11}(x_i, y_i, x_j, y_j) \geq 0 \\ e_{ij12}(x_i, y_i, x_j, y_j) \geq 0 \end{bmatrix}$$

As only one of the systems has to hold, this leads to using auxiliary binary variables to model the disjunction of constraints. Notice that this set of systems of linear inequalities has to be defined for each pair of polygons, and at least one inequality or system of inequalities has to hold for each pair of polygons. An alternative to this covering model is the partitioning model (e.g., [4]), where the systems of inequalities are defined so that their geometric representations on the plan do not overlap. In this case, exactly one inequality or system of inequalities has to hold for each pair of polygons. However, in any case, a feasible placement for all pieces (a layout) corresponds to fixing specific binary variables. The inequality or system of inequalities that hold for each pair of polygons on this layout will be henceforth designated as the active constraints of the layout and altogether build a linear programming model, as the non-fixed variables (the placement coordinates of all pieces) are real-domain variables.

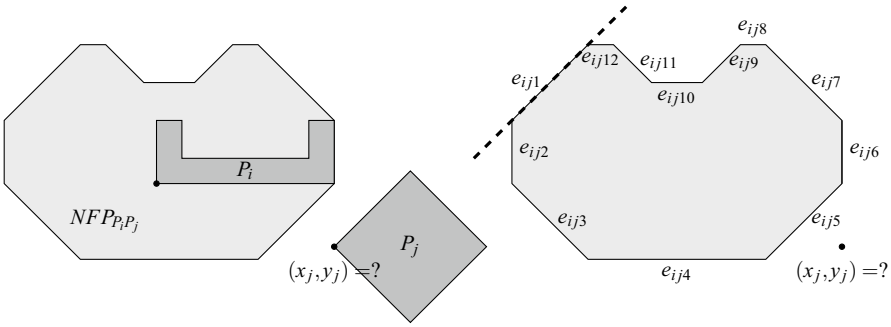

Fig. 32 Geometric information provided by the no-fit polygon to write the no-overlap constraints in a mathematical programming model

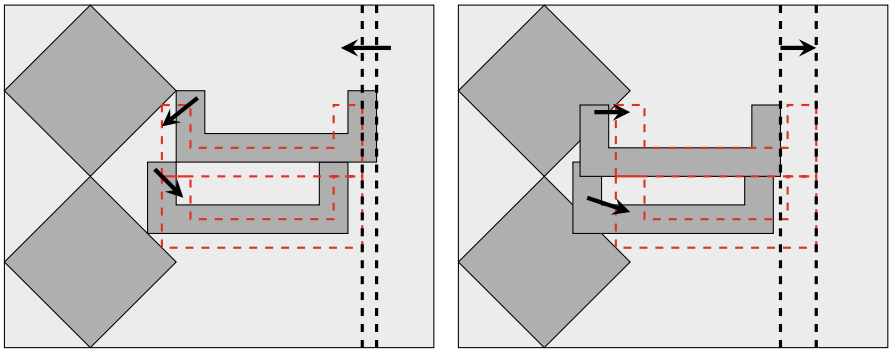

Fig. 33 Applying the compaction (on the left) and separation (on the right) models, with the solid gray pieces representing the initial solution and the dashed outlines representing the optimal solution

The linear programming model describing a feasible layout only defines the relative positions of the pieces, not their absolute positions. Therefore, depending on the objective function, different layouts may be obtained. If the objective function is the minimization of the layout's length (i.e., the right-most vertex of all pieces' vertices), then the *compaction problem* is defined. In this problem, pieces are coordinately and continuously moved so that their relative positions are kept, but the length of the layout is minimized, as represented in Fig. 33 [19,55,80,98]. It is also possible to use a similar model to eliminate overlap in an unfeasible layout (Fig. 33). To achieve this, an active constraint has to be chosen for each pair of pieces. In cases where pairs overlap, an artificial variable is added so that the constraint holds with a non-zero value of the artificial variable, and the objective function will be the minimization of the sum of the artificial variables. If the optimal solution of the linear programming model has all artificial variables equal to zero, then the layout is feasible (without overlap).

Based on these compaction and separation models, hybrid solution methods can be developed [19, 55]. The basis of these methods are local search heuristics that search over the layouts and generate new solutions by swapping two pieces or moving a single piece to a different position on the layout (insertion move). By doing this, most probably the layout will have overlaps. A separation problem will be solved to try to eliminate the overlap and if it obtains a feasible solution, the solution will be improved through a compaction problem. The way the search over the solution space is controlled varies a lot. However, metaheuristic approaches have been used in most cases (see section "Metaheuristics").

Another idea explored by Martinez-Sykora [78] is to design a constructive heuristic based on the mixed-integer mathematical programming model with both the continuous and binary variables. In this approach, a piece is inserted in the layout by adding to the model: its placement variables, the constraints concerning all the no-fit polygons of this piece in relation to all pieces already placed in the layout, and the binary variables related to the edges of these no-fit polygons. All binary variables regarding the pieces already placed are kept at their previous values (i.e., the relative positions of the pieces already placed cannot change), but their continuous placement variables are freed to allow adjustments to make room for the new piece.

Another approach was proposed by Cherri et al. [34]. This heuristic is based on a different model, the *Dotted-Board-Model* [101], a discrete model, where the pieces are constrained to be placed on a discrete set of points of the layout (a grid). The decision variables are the points on the grid and state whether a piece of a given type is placed on that point. To impose the no-overlap constraints, no-fit polygons are used to exclude placement points that would lead to overlapping situations. Although this model solves larger instances than previous models, the *Dotted-Board-Model* is not yet viable for large instances, and a relax-and-fix heuristic with local branching constraints is proposed in [34]. Following the relax-and-fix paradigm, there is a set of variables that are already fixed in each iteration of the method, another set that the model can freely specify, and a third set of relaxed variables. In the following iteration, the variables of the second set become the variables of the first set, a group of variables of the third set is promoted to the second set, and new variables are added to the third set. The method stops when the third set is empty. To solve the irregular packing problem, the board is divided into vertical slices and the decision variables belonging to each slice are progressively relaxed, free, and fixed (Fig. 34). To add some flexibility to the previously placed pieces, some pieces in the fixed set are also freed (local branching constraints).

Metaheuristics

Most of the recent approaches to solving the irregular packing problem solutions are metaheuristics. However, the building blocks of these sometimes rather sophisticated search methods are the constructive, local search and mathematical-

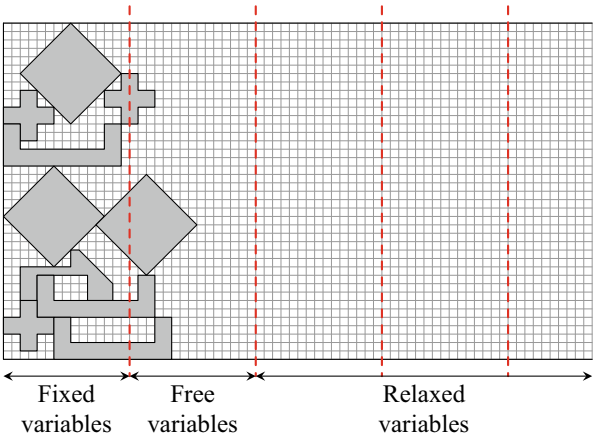

Fig. 34 Relax-and-fix iteration applied to the *Dotted-Board Model*

model-based heuristics presented in the previous sections. After all, metaheuristics are "just" a more sophisticated way of conducting the search over the solution space so that it does not stop at local minima.

Two of the very first metaheuristic approaches for the irregular packing problem were already referred to in the previous section [19, 55]. In both cases, pieces are moved around the layout by swap and insert moves, and overlaps are removed by a separation algorithm and compacted again by a compaction algorithm. In Bennell and Dowsland [19], the search is guided by a tabu search procedure while in Gomes and Oliveira [55] simulated annealing is used.

Egeblad et al. [44] propose a local search scheme in which the neighborhood is any horizontal or vertical translation of a given polygon from its current position. The goal is to minimize the overlap for a given layout length, where the layout length is reduced in each iteration. To escape local minima, the meta-heuristic guided local search is applied as described in Algorithm 2.

A three-level algorithm is proposed by Imamichi et al. [62] for the irregular strip packing problem. As the length of the board is variable, the upper level controls it by increasing the length when it is not possible to place all the pieces without overlapping and decreasing the length when the layout is feasible. The algorithm stops when decreasing the length produces a layout with overlap after a feasible solution (without overlap). The second level minimizes the overlap, given a board of fixed length. An iterated local search metaheuristic is used, where the perturbation phase consists of swapping two randomly chosen polygons, and the local search phase is a separation algorithm that aims to eliminate the existing overlap. The separation algorithm (third level of the approach) is based on solving a mathematical programming model with a nonlinear objective function. The nonlinearity of the objective function results from the use of the penetration depth as a measure of overlap.

Algorithm 2: Guided local search for irregular packing

Given a set of polygons $\mathscr{P}$.
Generate an initial layout p.
for each pair of polygons $s_i, s_j \in \mathscr{P}$ **do**
  Set penalty counter $\Phi_{ij} = 0$.
end for
while $g(p) > 0$ (p contains overlap) **do**
  Local search:
  while p is not a local minimum **do**
    Select polygon s_i.
    Create p' from p by sliding s_i horizontally and vertically
    to the position in which $h(p')$ is minimized, with
    $h(p) = g(p) + \lambda \sum_i \sum_j \Phi_{ij} I_{ij}(p)$, in which $I_{ij}(p) = 0$ if $\text{overlap}_{ij}(p) = 0$, 1 otherwise.
    Set $p = p'$.
  end while
  penalize:
  for each pair of polygons $s_i, s_j \in \mathscr{P}$ **do**
    Compute the utility function $\mu_{ij}(p) = I_{ij}(p) \frac{\text{overlap}_{ij}(p)}{1 + \Phi ij}$.
  end for
  for each pair of polygons $s_i, s_j \in \mathscr{P}$ such that μ_{ij} is maximal **do**
    Set $\Phi ij = \Phi ij + 1$.
  end for
end while
Return p

Umetani et al. [103] propose an approach combining the two previous ones. For the overlap minimization problem, the orthogonal penetration depth is used, while a guided local search is used to generate new solutions during the search for the best layout, given a fixed length for the board. The length starts at a value large enough to admit a feasible solution and is iteratively reduced until the best solution found with the guided local search method has overlap. The algorithm stops and returns the solution obtained with the previous board's length.

The same three-level structure can be found in Leung et al. [71]. The overall approach (Algorithm 3) is rather complex and is based on two neighborhood structures, one based on swapping two polygons and the other based on moving a polygon to a different position in the layout. A nonlinear programming model is used to minimize the overlap during the search process (separation algorithm) and the overall search has two phases: local search and tabu search. At the end, a heuristic is run to improve the final solution. The parameters r_{dec} and r_{inc} control how aggressively the length of the board is decreased and increased during the search procedure.

The same structure is used in Elkeran [46]. The initial solution is generated by the constructive algorithm by Gomes and Oliveira [54]. To improve the algorithm's efficiency, a pairwise clustering of the most non-convex pieces is done, although these clusters do not appear in the final solutions. The board's length is also alternately decreased and increased. The most innovative part of the algorithm is the

Algorithm 3: Extended local search for irregular packing

Best length: L_{best}.
Current length: L_{curr}.
Generate an initial solution $\longrightarrow$ L_{curr}
$L_{best} = L_{curr}$.
while in a time limit **do**
  Decrease the length of the board: $L_{curr} = (1 - r_{dec})L_{best}$.
  Run local search algorithm based on swapping two pieces and minimizing the consequent overlap by a nonlinear separation algorithm $\rightarrow$ L_{curr}.
  if local optimum is feasible (has no overlap) **then**
    $L_{best} = L_{curr}$
  else
    $L_{curr} = (1 + r_{inc})L_{best}$.
    Run tabu search algorithm based on moving a piece to a different position on the layout $\rightarrow$ L_{curr}.
  end if
end while
Run heuristic procedure over the best solution found:
small movements of the pieces + overlap minimization + separation algorithm
Return best solution found

use of the populational metaheuristic Cuckoo Search for the overlap minimization level. The Cuckoo Search algorithm uses a balanced combination of a local random walk and a global explorative random walk, controlled by a switching parameter, to evolve from one population to another. Cuckoo search is responsible for moving a polygon on the board to a less overlapping position, while guided local search is used to escape local minima.

All the metaheuristics presented so far search over the layouts. Other metaheuristic approaches are based on searching over sequences. It is the case of Bennell and Song [21] that propose the use of the Beam Search metaheuristic, which is a tree-search procedure that attempts to avoid the drawbacks of fixed tree-search strategies (e.g., depth-first, breadth-first) without the computational burden of an exhaustive search. In this approach, solutions are represented by a sequence of pieces to be packed. The modified version of TOPOS (see section "Constructive Heuristics") is used to decode these sequences. The tree represents the construction of a partial solution where each node adds a new element to the sequence. At each level, a local evaluation function (in this case, the TOPOS evaluation criteria) evaluates all child nodes. Child nodes compete only with other children branching from the same parent node. This evaluation provides a rough approximation of the solution quality by measuring the incremental cost of adding an element to the partial solution. Using this evaluation, a subset of size α of the best nodes is selected (α is the filter width). The selected filtered nodes are then subject to a global evaluation and the best β nodes are retained for branching (β is the beam width).

Another metaheuristic based on searching over sequences can be found in Sato et al. [94]. It is a bi-level approach, with the top level controlling the board's length (increasing and decreasing it) and the bottom level finding a layout without overlap. The overlap minimization algorithm is simulated annealing. The initial solution is random, and the neighborhood is based on modifications of the placement sequence (two items are swapped), piece orientation (several rotations are allowed), piece position (for non-simple NFPs, in which contour or degenerated vertex or edge the placement occurs). The decoding heuristic is the bottom-left NFP vertex-oriented heuristic of Gomes and Oliveira [54].

Mundim et al. [83] also used a sequence-based search approach managed by a biased random key genetic algorithm. The most notable feature of this work is the consideration of an open-dimensional problem, where both dimensions are variable.

Conclusion

Due to the combinatorial nature of Cutting and Packing problems, exact techniques are not capable of efficiently tackling them for large instances, and therefore, heuristic approaches must be used. In this chapter, the most important heuristic techniques that have been applied to Cutting and Packing problems have been presented, going from simple constructive heuristics to rather complex hybrid metaheuristics approaches, and including local search heuristics and mathematical-model-based approaches. To frame these methods, a comprehensive section on Cutting and Packing problems was written, including the discussion of these problems under Wäscher et al. typology, and the rather important geometric representation layer that these problems require.

Given the broad range of Cutting and Packing problems, it was chosen to focus on two- (both rectangular and irregular) and three-dimensional (just rectangular) problems, as these better illustrate the full use of heuristic methods when approaching this class of problems. One-dimensional problems have no geometric considerations, on the one hand, and, on the other hand, are better solved by exact methods than the other problems. Among the two-dimensional problems, and due to space constraints, circle packing was not referred to in this chapter. However, not only the main approaches closely follow what has been done for the other two-dimensional problems, but also the interested reader can easily refer to the review by Hifi and M'Hallah [58] and following work. Integrating Cutting and Packing problems with other optimization problems that in real life have a direct relation to them, in the sense that the solutions of one problem impact the resolution of the other, is a recent trend in the field. Once more, given the difficulty and complexity of the problems, heuristic techniques have to be used to tackle the integrated problems, such as Vehicle Routing and Container Loading [81].

Abstract

The challenge of maximizing the diversity of a collection of points arises in a variety of social studies, which translates into the growing interest in the treatment of diversity in mathematical models. Although the terms diversity and dispersion can be found in many optimization problems to be indistinguishable, we undertake to explore the different models behind them.

This chapter describes the mathematical models for two diversity problems and three equity problems. In addition, it also includes two related models that have recently received special attention. This chapter also reviews heuristics and metaheuristics for finding near-optimal solutions for these problems, such as GRASP, Tabu Search, Genetic algorithms, Particle Swarm, and Ant Colony Optimization. We include pseudocodes of some of these methods.

Keywords

Maximum diversity problem · Optimizing diversity · Binary optimization

Introduction

Maximizing diversity involves the selection of a subset of elements from a given set in a manner that maximizes the distance or similarity between them [19]. Numerous models have been proposed for this purpose, all of which rely on a diversity measure, typically expressed as a distance function within the space where the objects reside. The definition of this distance between elements is customized for specific applications and may vary in how the overall diversity of the selected elements is calculated. These models represent a significant class of $\mathcal{NP}$-hard problems in combinatorial optimization, with practical applications across a wide range of domains, as outlined in [21]. They include plant breeding, social issues, ecological preservation, pollution control, product design, capital investment, workforce management, curriculum design, and genetic engineering.

As Scott Page asserts in his book [41]: *"Diverse perspectives and tools enable collections of people to find more and better solutions and contribute to overall productivity."* Consequently, the identification of diverse groups of people becomes a focal point in large companies and institutions. The concept of diversity, also known as dispersion, is widely used; however, its definition is often ambiguous, leading to various interpretations. As highlighted by [44], diversity in the context of combinatorial optimization can refer to dispersion among selected points or to representativeness, where the selected points act as class representatives of subsets within the given set.

Arguably, the model most extensively studied concerning diversity is the Maximum Diversity Problem (MDP), also known as the Max-Sum Diversity Model [18], where the objective is to maximize the sum of distances between selected elements. The Max-Min Diversity Problem (MMDP), alternatively, aims to maximize the minimum distance among the selected elements and has also received considerable attention in recent research [50]. Despite their related nature, it is important to note that a method developed for the MDP may not necessarily perform effectively for the MMDP and vice versa. We illustrate this distinction with an example in section "Correlation Between Models."

Equity models, closely related to diversity, integrate the notion of fairness among candidates. These models have been largely ignored and have only recently been considered in the scientific literature. Particular emphasis is needed for the research in [47], where four distinct equity models are introduced. These models emerge within the realms of location of urban public facilities, selection of diverse/similar groups, and identification of sub-graphs, providing avenues to address fair diversification or assimilation among network members. In this chapter, we address both diversity and equity models.

Recently, a review on the state of the art in discrete diversity and dispersion [33] describes the evolution of models and methods from an Operations Research perspective. The authors traced the development of this field, beginning in the late 1980s, and identified three distinct time periods according to the proposal, development, and application of models and solving methods. The field of diversity is today a research area in itself with significant scientific contributions, as shown in a monographic book on it [34]. The book is organized based on the techniques applied, ranging from simple constructive mechanisms to complex evolutionary algorithms, including examples of how to customize these methods to solve specific combinatorial optimization problems. Finally, the MDPLIB 2.0 library has to be mentioned as a reference in the field, which contains data sets widely used in this class of problems. The experiments in this chapter are based on this library.

This chapter is organized as follows. In section "Mathematical Models and Formulation," we define the different diversity models and the correlation between their solutions. In section "Diversity, Dispersion, and Equity," we review the different diversity measures and their mathematical expression and graphically explore their meaning. Finally, in section "Metaheuristics," we describe the most recent papers on heuristic and metaheuristic algorithms to solve the models introduced previously and their pseudocodes.

Mathematical Models and Formulation

Given a graph $G = (V, E)$, where V is the set of n nodes and E is the set of edges, let d_{ij} be the inter-element distance between any two elements i and j, let $M \subseteq V$ be the set of m selected elements, and define $U = V \setminus M$ as the set of unselected elements.

Diversity Models

The *Max-Min Diversity Problem* (MMDP) can be formulated as follows:

$$\begin{aligned} \text{(MMDP) Maximize } z_{MM} = & \min_{\substack{1\le i<j\le n \\ x_i=x_j=1}} d_{ij}x_ix_j \\ \text{st} \quad & \sum_{i=1}^{n} x_i = m \\ & x_i \in \{0,1\} \qquad i = 1,\ldots,n. \end{aligned} \tag{1}$$

The Maximum Diversity problem, MDP, also called Max-Sum can be formulated in a similar way by simply replacing the objective function, $z_{MM}(x)$, in the formulation above with the expression $z_{MS}(x)$ as

$$z_{MS}(x) = \sum_{1\le i<j\le n} d_{ij}x_ix_j. \tag{2}$$

The Max-Sum and Max-Min literature includes extensive surveys [1, 13, 28], exact methods [1, 18, 45], and heuristics [18, 25, 27, 48, 50].

Equity Models

In [47], the authors summarize some of the different dispersion models, defining them as follows. The *Max Mean Dispersion Problem* (Max-Mean) can be formulated as the following 0–1 integer linear programming problem:

$$\begin{aligned} \text{Maximize} \quad & \frac{\sum_{i=1}^{n-1}\sum_{j=i+1}^{n} d_{ij}x_ix_j}{\sum_{i=1}^{n} x_i} \\ \text{st} \quad & \sum_{i=1}^{n} x_i \ge 2 \\ & x_i \in \{0,1\} \qquad i = 1,\ldots,n. \end{aligned} \tag{3}$$

In (3) the cardinality restriction is not imposed. This problem is a version of the Max-Sum problem where the number of elements to be selected is unknown. The generalized version of this problem is called *Generalized Max-Mean Dispersion Problem* and is formulated as follows:

$$\begin{array}{lll} \text{Maximize} & \dfrac{\sum_{i=1}^{n-1}\sum_{j=i+1}^{n} d_{ij}x_i x_j}{\sum_{i=1}^{n} w_i x_i} & \\ \text{st} & \sum_{i=1}^{n} x_i \geq 2 & \\ & x_i \in \{0,1\} & i = 1,\ldots,n, \end{array} \tag{4}$$

where w_i is the weight assigned to element $i \in V$.

Then, the *Maximum Minsum Dispersion Problem* (Max-Minsum DP) consists of selecting a set $M \subseteq V$ of m elements such that the smallest total dispersion associated with each selected element i is maximized. The problem is formulated in [47] as follows:

$$\begin{array}{lll} \text{Maximize} & \left\{ \min_{i:x_i=1} \sum_{j:j\neq i} d_{ij}x_j \right\} & \\ \text{st} & \sum_{i=1}^{n} x_i = m & \\ & x_i \in \{0,1\} & i = 1,\ldots,n. \end{array} \tag{5}$$

Finally, the *Minimum Differential Dispersion Problem* (Min-Diff) consists of finding the best subset $M \subseteq V$ with respect to the measure "Diff" defined in Table 4. This problem is a 0-1 integer linear programming problem and can be described as

$$\begin{array}{lll} \text{Minimize} & \left\{ \max_{i:x_i=1} \sum_{j:j\neq i} d_{ij}x_j - \min_{i:x_i=1} \sum_{j:j\neq i} d_{ij}x_j \right\} & \\ \text{st} & \sum_{i=1}^{n} x_i = m & \\ & x_i \in \{0,1\} & i = 1,\ldots,n. \end{array} \tag{6}$$

Related Models

Given a graph $G = (V, E)$ where V is a set of n nodes and E is a set of edges, let $w_i \geq 0$ be the weight of node $i \in V$ and let c_{ij} be the benefit of edge $(i, j) \in E$. The *Capacitated Clustering Problem* (CCP) involves partitioning V into p clusters in such a way that the sum of the weights of the elements in each cluster is within some integer capacity limits, L and U, and the sum of the benefits between the pairs of elements in the same cluster is maximized. The CCP can be formulated as a quadratic integer program with binary variables x_{ik} that take the value of 1 if

element i is in cluster k and 0 otherwise.

$$\begin{array}{lll} \text{Maximize} & \sum_{k=1}^{p}\sum_{i=1}^{n-1}\sum_{j>i}^{n} c_{ij}x_{ik}x_{jk} & \\ \text{st} & \sum_{k=1}^{p} x_{ik} = 1 & i = 1,\ldots,n \\ & L \leq \sum_{i=1}^{n} w_i\, x_{ik} \leq U & k = 1,\ldots,p \\ & x_{ik} \in \{0,1\} & i = 1,\ldots,n; k = 1,\ldots,p. \end{array} \tag{7}$$

The objective function adds the total benefit of all pairs of elements that belong to the same cluster. The first set of constraints forces the assignment of each element to a cluster. The second set of constraints forces the sum of the weights of the pairs of elements in the same cluster to be between L and U. The maximally diverse grouping problem (MDGP) consists of grouping a set of elements into p mutually disjoint groups in such a way that the diversity among the elements in each group is maximized. The diversity among the elements in a group is calculated as the sum of the individual distance between each pair of elements. The objective of the problem is to maximize the overall diversity, i.e., the sum of the diversity of all groups, when the size of each group is within a specified range. Clearly, MDGP is a special case of CCP for which $w_i = 1$ for all nodes i, and the distance between each pair of nodes (i, j) is the benefit c_{ij}. Therefore, from the CCP formulation above, the MDGP can be formulated as

$$\begin{array}{lll} \text{Maximize} & \sum_{k=1}^{p}\sum_{i=1}^{n-1}\sum_{j>i}^{n} c_{ij}x_{ik}x_{jk} & \\ \text{st} & \sum_{k=1}^{p} x_{ik} = 1 & i = 1,\ldots,n \\ & L \leq \sum_{i=1}^{n} x_{ik} \leq U & k = 1,\ldots,p \\ & x_{ik} \in \{0,1\} & i = 1,\ldots,n; k = 1,\ldots,p. \end{array} \tag{8}$$

The MDGP is called the k-partition problem in [14] and the equitable partition problem in [40].

Correlation Between Models

In [50], the authors illustrated by the example in Table 1 that the correlation between the values of the solutions in the Max-Sum and Max-Min problems can be relatively low.

Let us consider that we have seven elements, of which we must select five. Furthermore, the distances between each pair of elements are given by the matrix of Table 1. For such a small example, we can enumerate all possible solutions (selections of elements) and compute, for each one, the value of the Max-Sum DP

Table 1 Distance matrix of an instance with seven elements

	1	2	3	4	5	6	7
1	–	4.6	6.2	2.1	3.5	3.6	4.4
2	4.6	–	6.6	7.1	8.2	2.4	5.3
3	6.2	6.6	–	2.1	3.5	3.6	4.4
4	2.1	7.1	2.1	–	5.5	1.1	2.3
5	3.5	8.2	3.5	5.5	–	6.4	3.4
6	3.6	2.4	3.6	1.1	6.4	–	5.4
7	4.4	5.3	4.4	2.3	3.4	5.4	–

Table 2 Correlation coefficients among the mean results in the 30 instances, with $d_{ij} \in U[0, 20]$, $n = 20, m = 5$

Mean value				
	Max-Sum	Max-Min	Max-MinSum	Min-Diff
Max-Sum	1	0.60[a]	0.96[a]	−0.17

	Best value			
	Max-Sum	Max-Min	Max-MinSum	Min-Diff
Max-Sum	1	0.78[a]	0.90[a]	0.07
Max-Min	0.78[a]	1	0.77[a]	0.03
Max-MinSum	0.90[a]	0.77[a]	1	−0.07
Min-Diff	0.07	0.03	−0.07	1

[a]Correlation is significative at 0.01 level

and the value of the Max-Min DP. The correlation between both objective functions is 0.61, which can be considered relatively low. Therefore, we should not expect a method for one of these problems to obtain good solutions for the other.

We now extend that analysis by including the Max-MinSum, Min-Diff, Max-Sum, and Max-Min models. We do not include the Max-Mean models because they do not set the number of elements to be selected as the others. We generate 30 instances with 20 elements from which five have to be selected. Distances are generated randomly according to a uniform distribution in the range $[0, 20]$. For each instance, we enumerate all its solutions (selections of five elements) and compute the four objective values (Max-Sum, Max-Min, Max-MinSum, and Min-Diff). Then, we compute two values per instance and objective, the mean and best values across all the solutions. Tables 2 and 3 show the correlations obtained from these two values, respectively.

There is no significant relation between the Min-Diff model solutions and the rest of the models. Despite obtaining a correlation coefficient of -0.63 in the

mean values between Min-Diff and Max-Min, this correlation is very low in the best case. So, this problem can be considered to be different enough from the rest of the models. The largest correlation coefficient is obtained between Max-Sum and Max-MinSum. The correlation coefficient of 0.78 between the Max-Sum and Max-Min best value solutions is also notable. Although these correlation values seem large enough, we have empirically found that a method developed for one model problem does not necessarily perform well on another or vice versa.

Diversity, Dispersion, and Equity

The terms "diversity," "dispersion," and "equity" can be found in many optimization problems in the context of selection. Although the first two are indistinguishable, the term equity seems to have a subtle difference with them. However, in most papers, these three terms are used with a certain ambiguity.

The problem is that the term diversity is not properly defined and therefore results in different interpretations. In any case, we can say that it is associated with a global characteristic of the selected subset and should be evaluated according to the distances d_{ij} considered.

The growing interest in dealing with diversity resulted in an effort to study the management of equity in the last years, i.e., organizations are becoming increasingly interested in ensuring the equitable treatment of individuals or institutions. Generally speaking, equity is synonymous with fairness, objectivity, or impartiality. Many authors, such as French in [16], argue that equity is relative to justice, such as the distribution of resources or public service infrastructure.

In graphical terms, when we select a diverse subset from a given set, we expect it to be scattered. In other words, we do not expect it to be concentrated in a small region. In this section, we graphically show the solutions obtained when solving different models (Max-Sum, Max-Min, Max-Minsum, and Min-Diff), in an attempt to disclose their characteristics. Given a set $V = \{1, 2, \cdots, n\}$, an inter-element relationship d_{ij} defined between each pair of elements, and a subset $M \subseteq V$, we denote the diversity of M as $div(M)$. In the example shown in Fig. 1, inter-element distances are calculated using the Euclidean metric, and the results were obtained with mathematical programming models formulated in section "Mathematical Models and Formulation" and obtained the exact solution with CPLEX.

If we are looking for solutions scattered in the set of elements, we might say that objects selected in Fig. 1b, obtained with the Max-Min model, are better distributed than those selected in the other models in Fig. 1 (see section "Mathematical Models and Formulation" for more details in these models). In this figure the elements with red square icons are the diverse set selected, and the other ones are the unselected elements. In the Max-Sum and Max-MinSum models (Fig. 1a and c respectively), the selected elements are located in the outer part of the graphic, which seems to indicate that they are dispersed.

Notice that in this example, we are using the Euclidean metric, and therefore our interpretation is biased by our geometric conception. In particular, this interpretation

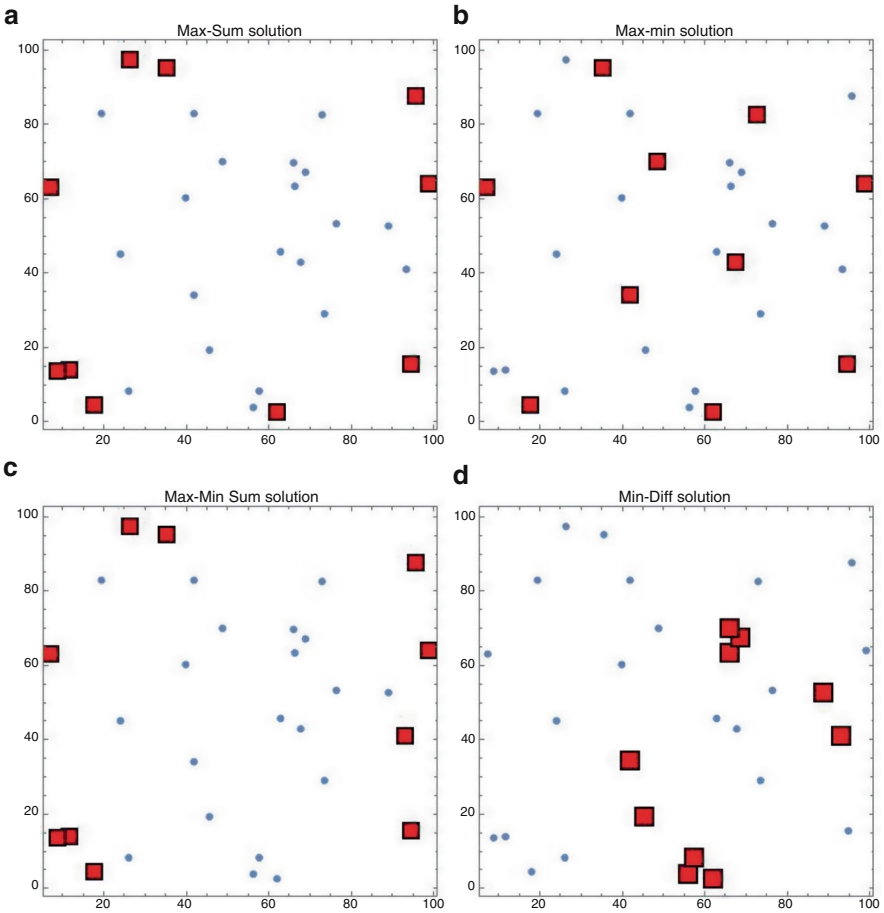

Fig. 1 Comparison of different models of a set of 30 elements with 10 selected elements

is no longer valid for a general measure of affinity or similarity. Then a more general interpretation of diversity implies abandoning this intuitive and geometric conception and establishing diversity from another point of view. Thus, the problem of measuring diversity in a given set is not unique and gives rise to different problems depending on the metric used. We have identified five different measures to compute diversity, equity, or dispersion from a given distance value calculated in M. Table 4 summarizes them.

Consider two examples in the rectangle $[0, 10]\times[0, 10]$ to illustrate the difference among the different dispersion measures based on the Euclidean distance. The position of the elements is obtained at random in both examples. In the first example, Example 1, we consider the elements $n = 12$, whose position is represented in Fig. 2.

Table 4 Description of the different diversity measures

Measure	Mathematical function	Description
Sum	$\sum_{i<j,i,j\in M} d_{ij}$	This measure may address diversification among selected elements to distance.
Min	$\min_{i<j,i,j\in M} d_{ij}$	Focus on the minimum distance between the selected elements.
Mean	$\frac{\sum_{i<j,i,j\in M} d_{ij}}{\lvert M\rvert}$	Related to the Sum Measure, is an average equity measure.
Minsum	$\min_{i\in M} \sum_{j\in n, j\neq i} d_{ij}$	This measure considers the minimum aggregate dispersion among elements.
Diff	$\max_{i\in M} \sum_{j\in M, j\neq i} d_{ij} - \min_{i\in M} \sum_{j\in M, j\neq i} d_{ij}$	This measure can be understood as the difference between the largest and smallest values of the dispersion sum.

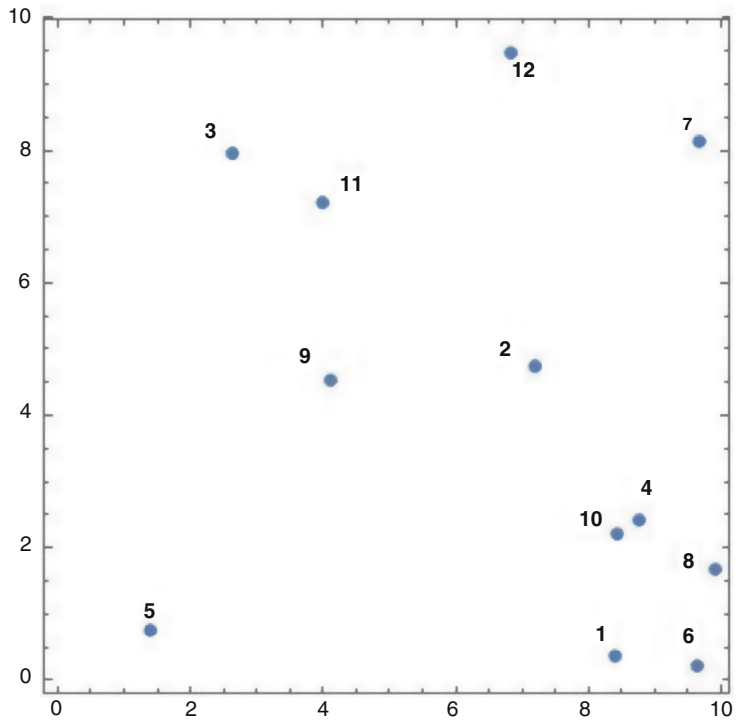

Fig. 2 Position of the elements in Example 1

The aim of this example is to observe the value of the different dispersion measures. Let us consider two different subsets of selected elements. The solution A contains the elements $\{2, 3, 7, 9\}$, and the solution B contains the elements $\{1, 3, 8, 10\}$. In Fig. 3, we show in large squares in red the selected elements of these two solutions.

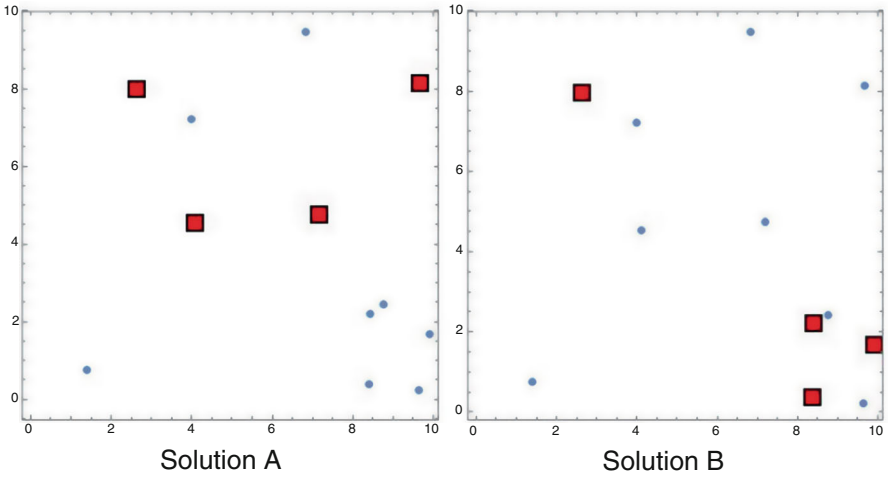

Fig. 3 The two subsets of selected elements in Example 1

Table 5 Diversity measures for the two subsets of selected elements in Example 1

Model	Max-Sum	Max-Min	Max-Mean	Max-MinSum	Min-Diff
Solution A	30.26	3.09	7.56	12.87	4.99
Solution B	32.10	1.70	8.10	12.30	15.30

The numerical value of the different diversity measures is shown in Table 5. We can see that the Max-Min, Max-MinSum, and Min-Diff models give better results in solution A than in B. However, the solution B is better than A in the other models. According to this, one could think that the five models considered can be classified into two categories. However, the next example illustrates that it is not always in this way.

Let us now consider a second example, Example 2, with 500 elements, where we have to select 80 elements. As above, we consider two solutions with different subsets of elements (see Fig. 4) and show the numerical measures of each model in Table 6.

In this example, A exhibits better diversity measures than B in all cases except the Max-Min model. These results seem to confirm that the diversity depends on the model we are applying. Therefore, as is customary when solving an optimization problem, we first have to model it, which in our case means to select the diversity model that better reflects our goal.

Finally, in terms of developing a solution method, the complexity of the objective function evaluation is $\mathcal{O}(m^2)$ for most diversity models, where m is the number of selected elements. This includes the Max-Sum, Max-Min, and Max-Mean models. However, in the Max-MinSum and Min-Diff models, the complexity is $\mathcal{O}(m^3)$ in a direct evaluation of the objective function.

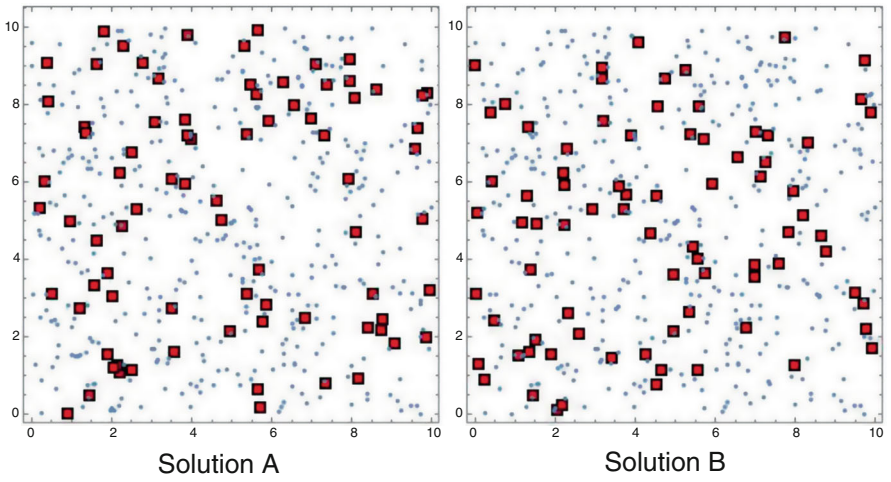

Fig. 4 The two subsets of selected elements in Example 2

Table 6 Diversity measures for the two subsets of selected elements in Example 2

Model	Max-Sum	Max-Min	Max-Mean	Max-MinSum	Min-Diff
Solution *A*	17021.0	0.123	212.76	315.73	264.43
Solution *B*	15995.9	0.169	199.95	293.51	287.97

Metaheuristics

The literature presents a wide range of heuristic and metaheuristic algorithms to address diversity problems. However, research in this field is fragmented due to several factors, such as the lack of standardized nomenclature and the absence of a unifying definition of diversity. Despite these challenges, some efforts have been made to review existing methodologies. This section focuses on the main heuristic and metaheuristic algorithms proposed for specific models such as Max-Sum, Max-Min, Max-Mean, Max-MinSum, and Min-Diff. A notable example is reference [2], which presents a detailed comparison of 10 heuristics and 20 metaheuristics designed specifically for the Max-Sum model.

The Max-Min Model

In [50], two constructive methods based on the Greedy Randomized Adaptive Search Procedure (GRASP) and various approaches to hybridize them with the path relinking methodology are proposed. The first GRASP construction method involves evaluating each candidate element using a greedy function to identify

the best elements, which are then added to the Restricted Candidate List (RCL). Subsequently, the next element to be incorporated into the partial solution is randomly selected from RCL. In contrast, the second GRASP construction method is based on an alternative scheme introduced in [49], where RCL is entirely constructed at random from elements in the Candidate List (CL). Consequently, in this later case, RCL can be viewed as a random sample of CL of a predetermined size. Afterward, the greedy function is applied to assess all elements in RCL to choose the best one. In this alternative design, the sequence of randomness followed by greediness is inverted. The local search mechanism implements the mildest ascent technique along with the path relinking methodology. This second strategy proves to be more efficient than the classic one within this model. Similar behavior of the GRASP scheme is observed in other models of maximum diversity, as observed in [32].

In [46], the authors introduced a straightforward yet efficient tabu search algorithm centered on drop-and-add moves. The local search phase involves swapping a selected element with an unselected one, provided that it results in an improvement over the current solution. The algorithm terminates when no further improvement is observed after a specified number of iterations. In addition, a short-term tabu search memory is incorporated by marking the most recent moves as tabu. Della Groce et al. proposed an Iterated Local Search heuristic algorithm in [9]. This algorithm tackles the Max-Min Dispersion Problem by reformulating it into a dichotomic search. At each iteration of the search, a clique decision problem is resolved.

In [22], the objective is to identify a subset of p locations to achieve two main objectives: to minimize the maximum dissimilarity between the selected locations and the others and to maximize the minimum distance between the selected locations themselves. Taking advantage of the relationship between the max-min diversity problem and the node packing problem, they propose an integer programming model and an incremental algorithm to find the non-dominated frontier in the biobjective optimization problem.

An interesting variant is recently proposed [54] under the name Fair Maximum-Minimum Diversity (FDM). Each point belongs to one of s different groups, and we are given a set of integers $k_1, \ldots, k_s$, the FDM problem is to select k_i points belonging to group $i \leq s$, such that the minimum pairwise distance between selected points is maximized. The authors proposed a $1 - \epsilon/4$ approximation for FDM when dealing with two groups in the data set, and a second algorithm, SFDM2, provides a $1 - \epsilon/3m + 2$ approximation for FDM with an arbitrary number m of groups.

We can find many metaheuristic algorithms applied to the Max-Min diversity problem. To illustrate one of them, we briefly describe a Particle Swarm Optimization (PSO).

The pseudocode in Algorithm 1 presents a Particle Swarm Optimization (PSO) specifically designed to solve the Max-Min Diversity Problem (MMDP). The PSO algorithm operates by initializing a swarm of particles, with each particle representing a potential solution (subset M). These particles have positions and velocities, where the position encodes a candidate subset, and the velocity dictates how the particle moves within the solution space. The diversity measure for each

Algorithm 1: PSO for Max-Min Diversity Problem

Require: Set $V = \{1, 2, \ldots, n\}$, subset size m, distance function d
Ensure: Subset $M \subseteq V$ that maximizes the minimum distance between elements
Initialize particles with random positions and velocities
Initialize $pBest$ and $gBest$
while the stopping criterion is not met **do**
  for each particle i in the population **do**
    Update the particle's velocity based on $pBest$ and $gBest$ and the particle's position based on the new velocity
    Evaluate the minimum distance between the elements of the new position
    if the diversity of the new position (min distance) is greater than $pBest$'s diversity **then**
      Update $pBest$ with the new position
    end if
  end for
  Update $gBest$ with the best $pBest$ found among all particles
end while
return M, the subset from $gBest$ that maximizes the minimum distance between its elements

particle is calculated as the minimum distance between any two elements within its subset. Throughout the optimization process, the particles update their velocities and positions based on two factors: the best solution found in the trajectory of this particle ($pBest$) and the best global solution ($gBest$), which is the best subset identified by any particle in the swarm. By iteratively refining these subsets, the algorithm directs the swarm toward regions of the solution space that exhibit higher diversity according to the MMDP criterion. This iterative process continues until a predefined stopping condition, such as a maximum number of iterations, is met. Ultimately, the algorithm returns the subset with the best value (the largest minimum pairwise distance encountered during the search), effectively solving the Max-Min Diversity Problem.

The Max-Sum Model

In this section, we turn our attention to the Max-Sum model and review the most effective algorithms to solve it. We start with a memetic algorithm [26], which is initiated by creating the initial population through a greedy randomized procedure. To ensure diversity within this initial pool of solutions, each solution of size n contains m bits set to 1, adhering to the classical binary pattern. Two parents are randomly selected with the condition that neither one is used more than once per generation. In subsequent iterations, new parents are chosen by selecting the best from previous parents and the top-performing offspring without repetition. Subsequently, $p/2$ children are produced through crossover and mutation procedures, where p represents the number of parents. The uniform crossover generates a single child, with chromosomes selected from one parent with a

probability less than or equal to 0.5 and from the other parent with a probability greater than 0.5. Mutation involves flipping bits from 1 to 0 or vice versa, which can occur at each bit position in the string with a certain probability. After each crossover and mutation, a repair process is employed to ensure feasibility, i.e., the chromosome contains m bits set to 1.

A local search process, based on $k - opt$ movements, is applied to the feasible solutions within the memetic algorithm. This process consists of two loops. The inner loop generates solutions by flipping elements of a solution x, until the best solution is not found over t repetitions. In the outer loop, the best solution found is evaluated. Overall, the algorithm proves effectiveness, but with longer execution times compared to other algorithms.

In [15], the authors introduce a memetic self-adaptive evolution strategy. Evolution strategies belong to a class of evolutionary algorithms primarily based on mutation. The authors conduct comparisons with state-of-the-art algorithms: Variable Neighborhood Search (VNS) [4], Learnable Tabu Search (LTS) [53], and Iterated Tabu Search (ITS) [43]. The evolution strategy yields satisfactory results when the aim is not to achieve optimal outcomes; otherwise, simpler heuristics may be preferable.

An improved technique is presented in [6] for analyzing the local search algorithm applied to the problem of maximum sum diversification (max-sum). This enhancement of the local search focuses on negative distances, including those that do not satisfy metric properties. The authors prove that applying local search to these distances provides approximation schemes with polynomial-time complexity. In line with that, [56] address problems where constraints are not symmetric, which means that the relationships between variables are not necessarily bidirectional. This expands the algorithm's applicability to a broader range of real-world optimization problems in the context of the Max-Sum model.

One of the seminal papers on metaheuristic optimization for the Max-Sum problem [11] describes the adaptation of GRASP and Tabu Search to this context, providing Tabu Search with better outcomes. Algorithm 2 shows a pseudocode of a standard tabu search for the Max-Sum model.

Algorithm 2 starts by initializing a current solution, the best solution found so far, and a tabu list that prevents revisiting recently explored solutions. In each iteration, candidate solutions are generated and evaluated, looking for solutions that achieve high values in the sum of their distances between elements, with the best candidate that is not in the tabu list or that meets an aspiration criterion based on the best neighbor. If this neighbor solution improves upon the current solution, the algorithm updates it and the tabu list accordingly. The process continues for a fixed number of iterations, ultimately returning the best solution found. This approach ensures an effective exploration of the solution space while avoiding local optima by incorporating strategic diversification through the tabu mechanism.

Some publications on the Max-sum model approach new applications. This is the case of [52], which considers continuously arriving data sets, such as social media streams or online transactions, while ensuring fairness in the representation of different groups of elements. The paper proposes streaming algorithms, which

Algorithm 2: Tabu Search for Max-Sum Model

Require: Set V, size n, subset size m, distances, max_iter, $tabu_list_size$, $candidate_list_size$, $aspiration_criterion$, Initialize $current_solution$, $best_solution$, $tabu_list$

for i = 1 to max_iter do
    Generate candidates
    for each candidate in candidates do
        if candidate ∉ tabu_list or aspiration_criterion(candidate) then
            Generate and evaluate neighbor
            if neighbor better than best_neighbor then
                best_neighbor ← neighbor
            end if
        end if
    end for
    if best_neighbor ≠ NULL then
        Update current_solution, best_solution and tabu_list
    end if
end for
```

are capable of online data processing. These algorithms are designed to efficiently select items in real time, simultaneously optimizing both diversity and equity in the selection process.

In [42], an innovative algorithm is presented that combines the biased random-key genetic algorithm (BRKGA) with local search to solve this model. The uniqueness of this is the fact that the BRKGA algorithm considers a population of size p, represented by a chromosome composed of genes. This chromosome consists of a vector with random values (keys). In [42], the authors use an open-source application programming interface (API) proposed in [51] for the implementation of the BRKGA. This API enables the parallelization of certain operations, such as solution decoding and independent evolution of multiple populations, with inter-population solution exchange, which helps convert the encoded solution (random keys) into a solution of the MDP model.

Several metaheuristics for this problem in [2] are compared to identify additional characteristics for the best improvement. All these metaheuristics are based on a common tabu search module [20]: an Exploring Tabu Search [8], a Variable Neighborhood Search [23], a Scatter-Search [29], and a Random Restart algorithm. These algorithms exhibit competitiveness with the current state of the art. Particularly noteworthy are algorithms based on a random restart or a nearly random restart, where elements of the current best-known solution are prohibited. The authors suggest that due to the simple structure of the MDP, simpler algorithms might yield better results. They argue that the best algorithm available in the literature is the one proposed in [4]. In that paper, the authors present a study to solve the "heaviest $k-$sub-graph" (HSP) problem, with the Max-Sum problem being a special case of HSP. Computational experiments are conducted using instances of the Max-Sum problem to evaluate the efficiency of the proposed algorithms. The authors propose construction methods based on GRASP, Greedy, Scatter-Search, Tabu Search, and

a multi-boot method. The variable neighborhood search method used in the article is equivalent to the one proposed in [24]. This method proves to be more efficient due to the adopted mechanism of variable neighborhoods compared to state-of-the-art heuristics employing specialized hybrid versions of GRASP and Tabu Search. The conclusion drawn is that VNS-based methods can be advantageous for both the HSP and Max-Sum problems, yielding higher quality results albeit at a higher computational cost.

A broader problem related to the Max-Sum problem is the Capacitated Clustering Problem (CCP). This problem involves creating a predefined number of clusters or groups from a set of elements, ensuring that the total weight of elements in each cluster stays within specified capacity limits while maximizing the total benefits of elements within the same cluster. A special case of CCP is the Maximally Diverse Grouping Problem (MDGP), where all elements have a weight of one unit. MDGP is also known as the k-partition problem in [14] or the equitable partition problem in [40].

In [17], the authors introduce a heuristic approach to MDGP based on Tabu Search with Strategic Oscillation (TS-SO). Initially, a greedy construction method is employed to generate an initial solution. Subsequently, the search space in TS-SO encompasses all possible node insertions and swaps. The third phase, Strategic Oscillation (SO), explores solutions where group cardinality constraints might be violated. Specifically, the method allows the number of elements in a group to exceed the specified limits by a certain amount denoted so. After each successful application of the improvement method, the value of so is reset to one to establish an oscillation pattern.

In [35], the authors propose a tabu search and various GRASP (Greedy Randomized Adaptive Search Procedure) variants to find high-quality solutions to this NP-hard problem. These variants leverage different neighborhoods, including a novel one that features a one-for-two swapping strategy. The authors also hybridize both methodologies in this chapter to achieve better outcomes. These algorithms are benchmarked against state-of-the-art techniques. In [10], a GRASP coupled with VNS was proposed for a facility planning application in the context of US mail processing in Postal Service distribution centers.

The Max-Mean Model

In recent years, there has been a growing interest in developing innovative heuristic methods to solve the Max-Mean model.

The authors in [32] propose a GRASP (Greedy Randomized Adaptive Search Procedure) algorithm that combines greedy search with randomization. It exploits the quasi-concave nature of the models for an effective exploration and utilizes a variable neighborhood search with multiple neighborhoods to intensify the search. Additionally, it employs path relinking with a diversity control mechanism to explore a wider search space. The authors compare their algorithm with adaptations of existing Max-Sum solvers.

On the other hand, [5] introduce a method based on greedy construction and tabu search (TS). It first constructs an initial solution with two greedy algorithms, followed by a two-stage TS process. The first stage intensifies the search around the current solution (short-term TS), while the second stage (long-term TS) diversifies the search by potentially accepting worse solutions to escape local optima. Both stages begin from the current solution and terminate when the best solution remains unchanged for a set number of iterations.

Among recent works, in [7], the authors propose a novel approach to parallel ant colony systems (ACS). It introduces a new visibility calculation method and a pheromone trail inspired by the tabu list memory structure of tabu search algorithms. The visibility is based on the frequency of solutions in the global set, increasing the probability of selecting more frequent solutions. Conversely, the pheromone trail reduces the probability of revisiting elements that have already been chosen. In addition, the algorithm considers elements that were not selected for a long time as dispensable and eliminates them with a higher probability.

Here, in Algorithm 3, we present a simplified pseudocode to illustrate the implementation of an Ant Colony Optimization (ACO) algorithm designed to solve the Max-Mean model.

This streamlined pseudocode describes an Ant Colony Optimization (ACO) algorithm designed to solve the Max-Mean Diversity Problem, which focuses on maximizing the average pairwise distance (mean diversity) between elements in a selected subset. The algorithm begins by initializing the levels of pheromones at all edges connecting elements, which influences the probability of selecting elements during subset construction. Each ant in the algorithm iteratively builds a subset by probabilistically choosing elements based on these pheromones and visibility, a heuristic measure related to maximizing mean diversity. After constructing the subsets, the mean diversity of each subset is evaluated. The pheromone levels are

Algorithm 3: ACO for Max-Mean Model

Require: Set $V = \{1, 2, \ldots, n\}$, cardinality m, distance function d
Ensure: Subset $M \subseteq V$ with maximum mean diversity
Initialize pheromones τ on all edges with a small value, and define parameters α, β
for $iter = 1$ to max_{iter} **do**
  for each ant k **do**
    Select the initial element for M_k randomly
    while $|M_k| < m$ **do**
      Calculate probabilities for each $i \notin M_k$ based on τ and η
      Select the next element based on these probabilities
    end while
    Evaluate mean diversity of M_k using the average pairwise distance
  end for
  Apply pheromone evaporation and update pheromones on edges of the best M found (Pheromone update favors edges with higher mean diversity contribution)
end for
return Best M found

then updated, reinforcing edges that contribute to the best subsets to guide the search in future iterations. This process continues until a predefined number of iterations is reached, which ultimately returns the subset with the highest mean diversity found. The ACO algorithm effectively combines exploration and exploitation to iteratively enhance the search for a highly diverse subset according to the Max-Mean model.

In [39], the authors present a hybrid metaheuristic algorithm that combines the Estimation of Distribution Algorithm and Tabu Search (EDA-TS). The algorithm starts by creating an initial elite set of diverse, high-quality solutions and records the best solution. Then it generates a conditional preference probability matrix ($CPPM$) to guide the construction of a solution, since this matrix contains information about the probability of assigning specific values to variables. Then, the Tabu Search method is applied to improve the constructed solution by exploring the solution space locally. An update criterion determines whether the improved solution should be included in the elite set. Finally, when the current solution shows no improvement, a reconstruction method generates a new solution to avoid becoming trapped in local optima.

Furthermore, in [38], the authors present a hybrid reinforcement learning algorithm with tabu search, where the innovation lies in the design of a strategy using a Q-learning mechanism to identify possible regions where the tabu search algorithm may get trapped in a local optimum. This mechanism is used to construct a feasible set of initial solutions.

The Max-MinSum Model

The Max-MinSum DP problem is a challenging combinatorial optimization task, ideal for evaluating search strategies. In their study, [47] present computational experiments applying a GRASP approach to solve the Max-MinSum dispersion problem. They define M_k as a partial solution with k elements selected ($1 \leq k < m$). GRASP initializes M_1 by randomly selecting an element and then builds a candidate list (CL) of unassigned elements in each iteration. For each element i in CL, the method calculates its marginal contribution to the objective function associated with $M_k C1$. Elements in CL are sorted according to their contributions, forming a restricted candidate list (RCL) from which an element is randomly chosen to add to $M_k C1$. An improvement phase follows construction, where elements are exchanged if it improves the objective function; otherwise, the pair is discarded.

In [36], the authors explore six GRASP variants, focusing on different solution generation and improvement methods. The improvement phases involve an exhaustive exploration of all possible exchanges (IM1) or prioritizing contributions of selected and unselected elements (IM2). The best construction phase, CM3, incorporates strategic oscillation (SO) to navigate the feasibility boundary defined by constraints. Experiments show that double-sided strategic oscillation with CM3 and IM2 provides the best overall results, outperforming existing specialized procedures and general-purpose optimizers.

In [30], the authors efficiently solve the computational complexity problem of this model. For this reason, they propose a tabu search algorithm with dynamic neighborhood size (TSDNS), which integrates a solution based on a tabu search strategy with new hash functions and a mechanism to adjust the neighborhood size. For the initialization of tabu lists, three hash vectors are created and an initial solution is generated by randomly selecting m different elements from the set V of elements. The generation of a neighborhood of dynamic size is done using a swap operator, which swaps the values of two variables to generate a new neighboring solution. These swaps are stored in the neighborhood N_{swap}^{full}. However, evaluating the entire neighborhood would consume too much time, so they propose to build a high-quality subset of N_{swap}^{full} as the neighborhood for the TSDNS algorithm. The three hash functions are used to map the neighborhood of the solution, and the three binary hash vectors are used to record the status of the tabu solutions. All of them are considered to avoid possible collisions when using a single hash vector and a single hash function.

In [55], the authors propose a two-phase tabu search intensification algorithm (TPITS), which combines an intensification-based tabu search to avoid revisiting previously found solutions and an attribute-based tabu search to refine the search in the second phase. For initialization, two tabu lists are used: one for solutions and another for attributes. The elements are then randomly selected from the set of available elements to generate the initial solution, with the best solution chosen during this search. In general, the TPITS algorithm consists of three main components: a dynamic neighborhood size to build a neighborhood, a tabu search strategy focused on intensification, and a tabu search strategy based on attributes.

Genetic algorithms can also be used for the Max-MinSum model. In Algorithm 4, we present a simplified pseudocode to demonstrate the implementation of a Genetic Algorithm (GA). This pseudocode describes a Genetic Algorithm implementation tailored to solve the Max-MinSum Diversity Problem, where the goal is to find a subset M that maximizes the minimum sum of inter-element distances. The algorithm begins by generating an initial population of candidate solutions, each representing a subset of elements. These solutions are evaluated on the basis of the Max-MinSum diversity criterion. Through iterative steps, the algorithm selects parent solutions, applies the crossover operator to generate offspring, and introduces the mutations to maintain genetic diversity. The offspring are then evaluated, and the population is updated by selecting the best solutions. This process continues until a stopping criterion, such as a maximum number of iterations, is reached. At this point, the best solution found is returned as the optimal subset that addresses the diversity problem.

The Min-Diff Model

Recent research on the Min-Diff model is summarized in four key papers:[3,12,37]. In [3], a two-phase heuristic algorithm is introduced. The constructive phase

Algorithm 4: Genetic algorithm for Max-MinSum DP

Require: Set $V = \{1, 2, \ldots, n\}$, subset size m, distance function d, population size p, maximum iterations max_iter

Ensure: Subset $M \subseteq V$ that optimizes the diversity criterion by maximizing the minimum sum of inter-element distances

1: Generate an Initial Population with p solutions, where each solution is a subset of m elements from V
2: Evaluate the diversity of each solution in the Initial Population using the Max-MinSum criterion
3: **for** $iter = 1$ to max_iter **do**
4: Select Parents from the Population based on their diversity values
5: Apply Crossover to generate Offspring from selected Parents
6: Apply Mutation to Offspring to introduce genetic diversity
7: Evaluate the diversity of the Offspring using the Max-MinSum criterion
8: Update Population by selecting the best solutions from the combined pool of current Population and Offspring
9: **end for**
10: Extract the BestSolution M from the final Population
11: **return** M

leverages the connection between this problem and the Maximum Clique Problem (MCP), while the improvement phase employs a tabu search procedure. These phases are iteratively repeated, with a simple diversification mechanism added to the constructive phase. Furthermore, this work presents a method to decrease computational complexity at each iteration, transitioning from a quadratic evaluation to a linear update mechanism.

In [12], the authors propose various hybrid heuristics, with the most effective being a GRASP combined with greedy construction samples and a variable neighborhood search for local improvement. Eight constructive procedures, four local search procedures (including one based on VNS), and four path relinking strategies are considered. Using exterior path relinking, a variant introduced by Glover in [22], proved competitive in extensive computational experiments in 190 cases of the existing literature. This algorithm not only outperformed the GRASP heuristic of [43] and nearly reached optimality for most instances solvable by CPLEX, but it also improved CPLEX's upper bound for challenging instances.

The pseudocode shown in Algorithm 5 illustrates a simplified implementation of the Greedy Randomized Adaptive Search Procedure (GRASP) algorithm for solving the Min-Diff Dispersion Problem.

The algorithm begins by initializing the best solution and best diversity values. For each iteration, a candidate solution is constructed using a greedy randomized approach, followed by a local search to refine the solution. The diversity of each candidate is then calculated as the difference between the maximum and minimum dispersion sums. If the calculated diversity of the current solution is lower than the best diversity recorded previously, the current solution is stored as the best new solution. This iterative process continues until the maximum number of iterations is reached, at which point the algorithm returns the best subset found that minimizes

Algorithm 5: GRASP to solve the Min-Diff DP

Require: Set $V = \{1, 2, \ldots, n\}$, subset size m, distances $distances$, maximum iterations max_iter, α

Ensure: Subset $M \subseteq V$ that optimizes diversity criterion by maximizing the difference between the largest and smallest values of the dispersion sum

```
best_solution ← ∅
best_diversity ← −∞
for i = 1 to max_iter do
    solution ← ConstructSolution(V, n, m, distances)
    local_solution ← LocalSearch(solution, distances)
    diversity ← CalculateDiversity(local_solution, distances)
    if diversity > best_diversity then
        best_solution ← local_solution
        best_diversity ← diversity
    end if
end for
return best_solution
```

the Diff diversity criterion. This approach effectively balances exploration and exploitation, focusing on maximizing the dispersion difference to ensure a robust search for the most diverse subset.

In [37], the authors propose a basic variable neighborhood search (VNS) heuristic, focusing primarily on interchanged neighborhood structures for both the intensification and diversification phases. They demonstrate that VNS outperforms a complex method that combines GRASP, variable neighborhood search, and exterior path relinking metaheuristics. The authors emphasize that their results underscore the essence of heuristics: creating efficient and effective algorithms that remain as simple as possible, a succinct expression of "less is more."

Finally, in [31], the authors propose an intensification-driven tabu search algorithm to solve the Min-Diff dispersion problem by integrating a restricted neighborhood, a solution-based tabu strategy, and an intensified search mechanism to create a search that effectively takes advantage of both intensification and diversification elements.

Conclusions

In this chapter, we reviewed two diversity and three equity models and also considered two related models. We identified previous mathematical models and heuristic methods for these variants. Most of them are based on constructive and local search-based methods. This is the case of the GRASP and Tabu Search methodologies, which have been customized for some of these models with excellent results. Surprisingly, evolutionary methods, such as popular genetic algorithms, have been considered in just a few cases.

We noted that although the problems considered here are related, all previous efforts have been devoted to tackle very specific models, and no generic solver has been proposed to deal with the entire family. In addition, we studied the solution structure obtained with the different models, and we identified some differences and similarities between them.

The literature on heuristic and metaheuristic methods for solving diversity problems is extensive; however, the current state of the art for exact methods remains less satisfactory. Although efficient exact methods have been developed specifically for the Max-Min Diversity Problem, there are relatively few studies on the exact resolution of other diversity models. In addition, the development of generic solvers that deal with several models would be of interest. So, there is a definite need for further research on algorithms, mainly for exact algorithms but also for heuristics.

Abstract

Protein structure prediction is an essential step in understanding the molecular mechanisms of living cells with widespread application in biotechnology and health. The inverse folding problem (IFP) of finding sequences that fold into a defined structure is in itself an important research problem at the heart of rational protein design. In this chapter, a multi-objective genetic algorithm (MOGA) using the diversity-as-objective (DAO) variant of multi-objectivization is presented, which optimizes the secondary structure similarity and the sequence diversity at the same time and hence searches deeper in the sequence solution space. To validate the final optimization results, a subset of the best sequences was selected for tertiary structure prediction. Comparing secondary structure annotation and tertiary structure of the predicted model to the original protein structure demonstrates that relying on fast approximation during the optimization process permits to obtain meaningful sequences.

Introduction

The relation between the amino acid sequence of a protein and its three-dimensional structure is a principal research effort of structural biology. Obtaining the folded structure of a protein allows functional studies in silico and has given rise to the field of protein engineering.

Proteinsare responsible for the majority of molecular functions in a cell. A simplified illustration of a real protein is provided in Fig. 1. Understanding protein folding has immense implications from health to biotechnology applications. Protein engineering in general aims at designing molecules with desired properties, and a method that allows to successfully design such molecules would find applications in a number of areas. For example, it could allow to design improved enzymes for biotechnology applications such as wastewater treatment or biomass

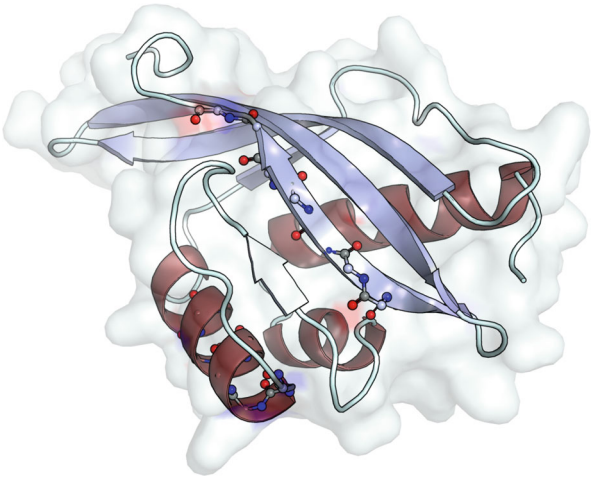

Fig. 1 Protein example *1OH0* with its surface shown semitransparent. *Helix* and *sheet* secondary structure segments are shown in dark red and light blue, respectively. Selected atoms are displayed for further clarification

production [7] or new antibodies specific toward already known targets, e.g., a given pathogen like HIV, by binding to its envelope spikes to neutralize the virus [19]. Since the advent of genome sequencing, all protein-coding genes of an organism can be obtained with ease, but structure prediction capabilities were only slightly improved over the last two decades and remain poor. If no homologous structure to a given sequence exists (the ab initio problem), finding the correct structure remains an essentially intractable, which hampers even the comparably easy task of classifying protein sequences into families.

Amino Acids and Protein Structure

A protein sequence is the code that describes the linear combination of any of the 20 common amino acids, also referred to as residues. The amino acid residues are basic organic building blocks consisting mainly of carbon (C), hydrogen (H), oxygen (O), and nitrogen (N) atoms. Common for all amino acids are their *amine* and *carboxylic acid* functional groups which bind through peptide bonds to form the protein backbone of $N - C_\alpha - C$ atoms as shown in Fig. 2. When ordered from left to right, as in the figure, the *amine* group, here represented by its nitrogen (N) atom for simplicity, is situated to the left of the amino acid, respectively, at the beginning of the chain. The side chains, noted as R_i, vary with each of the possible amino acids and can vary both in size and other properties, such as charge, acidity, and hydropathy. A typical protein sequence is 50–300 residues long. Due to the rotational freedom of the atom bonds and the molecular forces acting between the residues, it folds into one canonical three-dimensional structure. These intermolecular forces are the sum of a number of complex interaction forces largely depending on the mentioned properties of the residues, but also on the

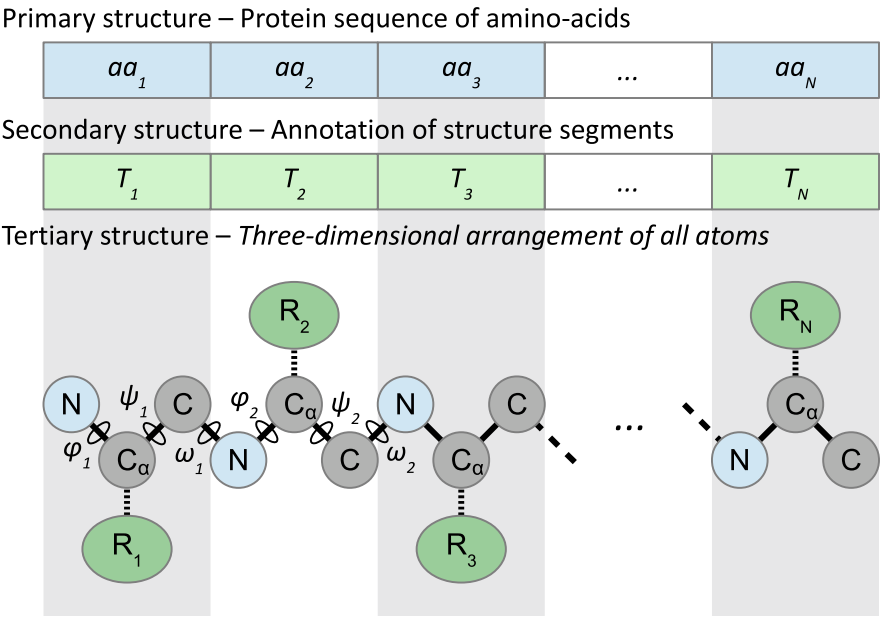

Fig. 2 Three levels of protein structure

distance and orientation of interacting atoms and structures. In general the protein structure will try to adapt a lower-energy configuration like a bolder that will roll down a mountain into the valley due to the gravitational force. In the case of proteins, such a more relaxed state corresponds to parts of the protein being either stacked or curled together referred to as *sheets* or *helices* as seen in Fig. 1. The remaining unstructured segments are commonly referred to as *loops* and serve as flexible connections between the other segments. The structure of a protein can be defined in different levels (see Fig. 2). The primary structure is the protein sequence of N amino acids $\{aa_i\}$ where $1 \leq i \leq N$ is the residue position. The secondary structure defines the organization of *helices*, *sheets*, and *loops* of the tertiary structure and can be expressed by a type $\{T_i\} \in \{H, E, L\}$ for each position i in the protein. If, for example, a protein consists of a *helix* and two *sheets*, its secondary structure would look like this: $\{L, L, H, H, H, H, L, E, E, L, E, E, L\}$. The tertiary structure completely describes the arrangement of all atoms of a protein in the three-dimensional space. The ensemble of three-dimensional positions of C_α atoms is commonly referred to as the alpha-trace which provides a rough residue type- and rotation-independent view of the protein configuration. Similar protein sequences generally obtain the same configuration or fold, but sequences not recognizable by similarity can nevertheless fold into 3D structures that are easily brought into congruence. Recommended reading for more in-depth information about proteins and their function in cells is the book by Alberts et al. [2].

Inverted Protein Folding

Conventional protein folding prediction research is concerned with finding or predicting the folded structure of a given amino acid sequence. As the problem is not solved, even to the present day, scientists have early on sought to simplify the task by solving the inverse problem. With the hierarchical definition of Fig. 2 in mind, the inverse folding problem (IFP) can be defined as follows: given a primary structure (protein sequences) and its corresponding tertiary structure, find alternative sequences that will result in the same tertiary structure. The inverted problem is thought of as a simplification because the structure is given, and sequence to structure compatibility becomes the main difficulty. When the structure is unknown (the ab initio case), the number of possible configuration solutions is enormous. A central part of any protein design process is to obtain, or come close to, a target tertiary structure with a certain degree of freedom in the choice of protein sequence. Hence solving the IFP would be a key to successfully engineer proteins. Furthermore, the IFP is of general scientific interest to study the size, shape, and characteristics of the sequence space that matches a given target structure.

Diversity Preservation as a Tool

In this chapter, the fact that matching secondary structures is a necessary, but not a sufficient condition for proteins to have the same tertiary structures, is exploited to reduce the IFP to its simplest formulation: given a protein's secondary structure and its corresponding protein sequence as input, find a set of highly dissimilar protein sequences that could result in the most similar secondary structure. The multi-objective genetic algorithm (MOGA) variant presented here is hence designed for maintaining high diversity, which in turn allows it to explore the decision space of sequences more efficiently and find better solutions than a conventional algorithm. This essentially makes the diversity preservation characteristic central in two aspects: (1) it increases the algorithm's performance in that it continuously pushes the exploration to new areas of the search space while (2) addressing the part of the problem statement of finding a set of protein sequences (i.e., problem solutions) that show large diversity among each other. The latter aspect is thoroughly covered in ▸ Chap. 40, "Diversity Optimization Models," though it should be noted that the representation of solutions and distance among them is different from this work.

An extended validation test is run predicting the final folded structure of as many as 300 generated sequences which are then analyzed in terms of secondary and tertiary structure. This test aims at answering the question of how well the target tertiary structure can be matched solely by taking the secondary structure into account.

The remainder of this chapter is organized as follows: in section "Related Work" the current work is situated in related literature; then a detailed description of the problem and the biological background is introduced in section "Problem

Description" and modeling thereof described in section "Problem Model". In section "Algorithm Design" the methodology achieving adjustable level of diversity in the genetic algorithm is presented. Section "Algorithm Experiments" describes the experiments conducted and the results obtained in terms of algorithm performance, with a validation study of secondary and tertiary structure in sections "Primary and Secondary Structure Validation Results" and "Tertiary Structure Validation Results". Finally the results and perspectives are summarized in section "Conclusion".

Related Work

This section reviews some of the most relevant works related to the two main areas covered in this chapter: protein design and diversity preservation in metaheuristics.

Protein Design

Most applied work of the IFP is concerned with protein design. Since the first design of a peptide by Gutte et al. [14] using secondary structure rules, numerous works have described different approaches to the IFP problem. The earliest reference to the inverted approach is found in an article by Pabo [24] referring to Drexler [11] stating that protein design engineers could in theory choose from a vast subset of possible sequences containing strategically placed groups that would have a predictable fold. Another early attempt at tackling the IFP is done by Ponder and Richards [25] who used a systematic exhaustive approach of enumerating a selected subset of residue positions. Central to the approach is the focus on packing criteria of core residues, taking a latest available side-chain rotamer library into account. Core residues are internal or buried residues not in contact with solvent. They contribute to the general structure of the protein and rather seldom to its primary function. A rotamer library is a library of known side-chain arrangements in 3D for each residue which is important to consider when evaluating the space filling of the core structure.

A few years later, Bowie et al. [5] introduced a 3D to 1D score for each secondary structure type and six environmental classes determined by (1) area buried in the protein structure and (2) fraction of polar side-chain area. By analyzing 16 known structures, the overall relative probability of observing a residue in a defined environment class is computed. From this and the target tertiary structure, a 3D profile can be generated taking the environment at each residue position into account. The 3D to 1D score is calculated by matching a sequence to the 3D profile of a structure. The result is expressed relatively using the Z-score, indicating the number of standard deviations above the mean of other sequences of same length. Using this method they were able to clearly separate homologs (evolutionary-related proteins) in terms of Z-score from a large set of sequences. Kuhlman and Baker [21] used a Monte Carlo approach of residue and rotamer substitution at 11 nonadjacent core positions, evaluating a free energy function. The lowest energy sequence of five

algorithm runs was chosen, and as a final result half of the generated residues were identical to the reference protein, referred to as "wild type."

The first to use a genetic algorithm (GA) was Jones in [17]. To assess 3D-1D compatibility and define an objective function, a set of statistically determined potentials known from fold recognition are used: pairwise potential and solvation potential. To prevent the generation of unlikely sequences, a residue composition term with an arbitrary weight is added corresponding to the target folding class ($\alpha\alpha$, $\alpha\beta$, $\beta\beta$). Jones concluded that there is no way to be sure the resulting sequences have not been overdesigned as the optimal sequence scores significantly better than the reference. He speculates that the energy optimal shape might be very steep and too hard for the real-world protein to fold into. Therefore, the algorithm should possibly be stopped earlier.

Mayo et al. [29] successfully used backbone flexibility in the design process by generating a set of perturbed backbones and applying enumeration of ten varying residue positions applying dead-end elimination to cut the search space. Similarly, Harbury et al. [15] incorporated such backbone freedom in their design approach. Both latter approaches were evaluated by synthesizing the proteins in the lab. Isogai et al. [16] used a recursive approach searching the 3D profile of the target structure keeping two residues fixed and applying a penalty to residues that protrude into the space with a repulsive function. Collisions among side chains were removed manually by replacing residues with smaller ones. The design was successfully synthesized, but the binding site did not stably bind oxygen.

Wernisch et al. [33] sought to combine the latest approaches into an automatic software solution named DESIGNER. The CHARMM package [6] is used for force-field calculation among side chains and backbone taking all hydrogen atoms bonded and nonbonded into account as well as adding van der Waals forces and electrostatic interaction. Both an exact enumeration approach (branch and bound) and a simple heuristic selecting the optimal rotamer for one random position at the time until a local optimum has been reached were tested. Different experiments aimed at analyzing different setting effects on the results were conducted. One test compares the effect of neglecting the reference energy and solvation energy terms, respectively, when redesigning 11 buried positions in the core. The choice of energy terms largely impacts the amount of polar amino acids, and neglecting the solvation term produced better packing with less cavities. Another test aimed at optimizing the protein surface with its larger proportion of polar amino acids. Again 11 positions are variable and varying settings are tested. First backbone and rotamers are kept fixed, and then alternative rotamers were allowed. Wernisch et al. consider that the energy calculations are approximations. Therefore, the software allows for outputting multiple solutions within a user-defined energy window. When packing constraints apply, DESIGNER generated sequences close to the reference.

Voigt et al. [32] combined the field of directed evolution with that of computational design and seek to benefit from both. Directed evolution is concerned with improving specific protein properties or functions mainly by applying a series of mutations to the target as mutagenesis in nature. In their computational

method, energy was used to predict structural stability, and residues with low entropy are detected as more tolerant to mutations. They also argued that coupled residues should be substituted together as several replacements need to take place to demonstrate improvement. High variability was observed on the exposed residues, and in general the variability should guide mutagenesis to allow the generation of a family of divergent sequences with structural integrity intact.

Klepeis et al. [20] presented a two-stage approach where an integer program is first used to generate a list of low-energy sequences which are then evaluated in terms of their fold. Using a force field based on pairwise C_α, distance-dependent interaction potential gives a more relaxed backbone flexibility constraint with less empirically tuned parameters. Validation was done by improving the activity of Compstatin, a 13-residue-long peptide fundamental in inhibiting complement activation. Certain residue positions and types were restricted based on knowledge about the functional nature and with the goal of increasing activity. Experimental results on 14 designed sequences showed significant activity improvements in most cases, one analogue was six to seven times more active than the wild-type underlining. This two-stage approach with small variations is used to design a template for human β-defensiv-2 in [12] and with more advanced second stage in [3, 4].

Smadbeck et al. [28] have recently streamlined the two-stage process and present a server implementation with a usage example. The web interface allows for specifying all inputs: template (rigid/flexible), energy function (C_α, centroid, or any), and biological constraints (on charge and content). Stage two workflow consists of two independent fold specificity and approximate binding affinity modules. These include programs such as CYANA, TINKER, and AMBER for the, first, Rosetta (ab initio, dock, and design) and OREO for the latter.

Finally, Mitra et al. [23] used templates of structure families in combination with a force field to guide the search rather than physics-only-based force fields. Due to shortcomings of the latter, evolutionary-based designs have been demonstrated to be more stable. Experiments were conducted with one of the leading protein structure prediction frameworks, I-TASSER [37]. Previous works have shown that I-TASSER is able to distinguish successful designs from unsuccessful ones and is therefore used as validation of the results also in this work.

The research of the last three decades on the IFP problem has produced many methods, but their complexity and exhaustive nature effectively limits the size of the sequence or decision space that can be sampled. In addition, the final output of these methods consists of a single or few sequences close to the input sequence, where a larger and more diverse set of sequences would be desirable for practitioners.

Multimodal Optimization and Niching

In metaheuristics the subject of exploration vs. exploitation characteristics has been thoroughly studied. For population-based optimization algorithms, it is well

known that a higher level of population diversity results in more exploration at the expense of exploitation. An elevated population diversity is especially desirable for *multimodal*, *deceptive*, and/or *dynamic* problems. In general, if diversity tends toward zero, it indicates that the algorithm has converged toward a single solution, which might be an undesired behavior if it occurs too early. A number of works have focused on maintaining and controlling diversity, such as crowding methods by DeJong [8], fitness sharing by Goldberg and Richardson [13], cellular algorithms by Alba and Dorronsoro [1], and diversity-preserving selection strategies based on hamming distance by Shimodaira [27] and on altruism by Laredo et al. [22]. Another approach consists in designing new objectives through multi-objectivization, with which the problem is transformed into a bi- or multi-objective one. Extending problems with an objective designed specifically for diversity preservation has been proposed by Toffolo and Benini [30], by Deb and Saha [9], and most recently by Wessing et al. [34]. In these works, objectives have been designed based on the hamming distance to the closest neighbor, the distance to the nearest better, and number of individuals in the neighborhood.

In this chapter, the diversity-preserving objective is based on the average distance of each individual to all others which directly targets the global diversity measure stated by the problem, contrary to the pairwise local view of existing works. Given the discrete nature, complexity, and multimodality of the problem, an effective diversity limiting mechanism is required. The proposed approach achieves this with the added value of making the population diversity highly variable depending on a single algorithm setting.

Problem Description

The focus in this work is on finding multiple and diversified solutions to the inverse folding problem (IFP).

A simplified model is developed to match solely the reference secondary structure—a requirement for the tertiary structure; see Fig. 3 for a schematic representation. This is motivated by the fact that computing the tertiary structure of a given input sequence is computationally very expensive which would prevent the usage of a metaheuristic on the entire sequence. The found solutions should be a collection of very dissimilar sequences, as well as dissimilar to the input sequence or its homologs, the naturally occurring, evolutionary-related sequences of the input sequence.

A single solution is represented as a sequence $A = \{aa_i\}$ composed of N residue positions, where $1 \leq i \leq N$ and $aa_i \in \{1, 2, \ldots 20\}$ correspond to the set of 20 possible amino acids. As the solution space consists of a total of 20^N different combinations, considering that N is around 50–200 for typical design targets, alternatives to exhaustive exploration are mandatory.

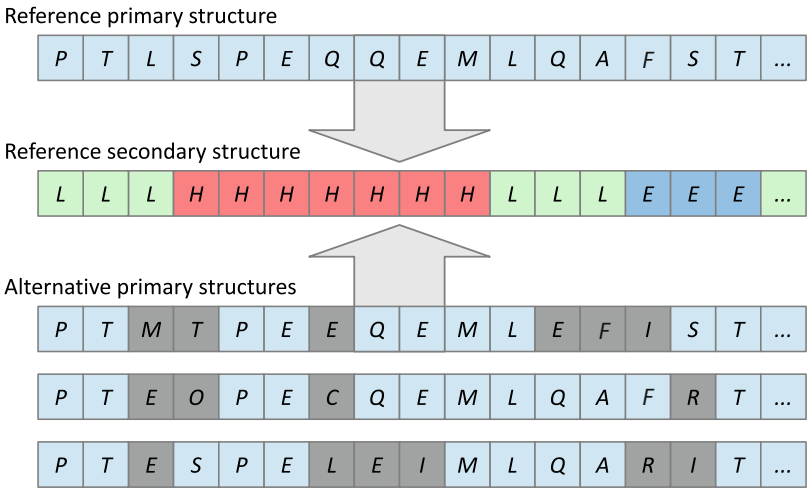

Fig. 3 Primary and secondary structure in the inverted folding problem

Sequence Identity

Sequence identity is a common measure designed to assess the similarity of proteins occurring in nature in terms of their primary structure only. When computing sequence identity, gaps are taken into account during the alignment of the sequences to be able to detect evolutionary relations among the compared proteins even if their sequences are of different lengths. In this work, all sequences being compared have the length of the target sequence and are generated by a random process. The chances of the same subsequence to occur in two different sequences with an offset diminish quickly as the subsequence length increases, which justifies ignoring gaps in the model. For the comparison of final results, the generally accepted approach with taking gaps into account is used.

Problem Model

This section presents the corresponding optimization problem. Two objective functions are first defined for integer encoded solutions $A = \{aa_i\}$. The first function estimates the similarity of secondary structure, in which definition and estimation are provided in sections "Secondary Structure Definition" and "Secondary Structure Estimation," respectively. The second function presented in section "Diversity Measure" is designed to address the diversity requirements of the problem and of the algorithm.

Secondary Structure Definition

Secondary structure refers to the annotation of structure segmentation as seen in Figs. 2 and 3. These segments are the result of the protein naturally folding so that different parts of its 3D structure connect through bonds between amino acids on separated residue positions in the sequence. Tertiary structure annotations are done using the "Define Secondary Structure of Proteins" (DSSP) tool [18]. As only the three structure types, *helices (H)*, *sheets (E)*, and *loops (L)*, are considered throughout this work, some simplification is required. In the documentation of DSSP, the following possible annotation types are found:

- $G =$ 3-turn helix (310 helix). Min length three residues.
- $H =$ 4-turn helix (α helix). Min length four residues.
- $I =$ 5-turn helix (π helix). Min length five residues.
- $T =$ hydrogen-bonded turn (three, four, or five turn)
- $E =$ extended strand in parallel and/or antiparallel β-sheet conformation. Min length two residues.
- $B =$ residue in isolated-bridge (single pair β-sheet hydrogen bond formation)
- $S =$ bend (the only non-hydrogen bond-based assignment).
- $C =$ coil (residues which are not in any of the above conformations).

With *helices* characterized by a corkscrew shape, *sheets* as parallel-connected segments, and *loops* as everything else, the above structure types are simplified as follows:

$$G, H, I \Rightarrow H; E, B \Rightarrow E; T, C, S \Rightarrow L$$

Secondary Structure Estimation

The goal of this objective is to distinguish sequences by assigning better score to sequences that may match the reference secondary structure better. Using the tool PROFphd, updated to ReProf [26], the likely secondary structure type $T_{\text{pred}}(i)$ can be predicted per amino acid aa_i in A with a reliability $R_{\text{pred}}(i) \in \{0 \ldots 9\}$ by means of posterior neural network training. With $T_{\text{ref}}(i)$ the actual type found at position i of the reference secondary structure, the estimated similarity score $F_{\text{sec}}(A)$ is calculated as a sum of reliability weighted (mis)matches:

$$F_{\text{sec}}(A) = \frac{\Sigma_{\max} - \sum_{i=1}^{N} s_i \cdot \left(C^R_{\text{pred}} + R_{\text{pred}}(i) \right)}{\Sigma_{\max}}, F_{\text{sec}}(A) \in \{0 \ldots 2\}. \quad (1)$$

where

$$s_i = \begin{cases} 1 & \text{if } T_{\text{pred}}(i) = T_{ref}(i) \\ -1 & \text{if } T_{\text{pred}}(i) \neq T_{ref}(i) \end{cases}$$

and

$$\Sigma_{\max} = \left(C^R_{\text{pred}} + \max R_{\text{pred}}\right) \cdot N$$

Equation 1 is normalized by the maximum possible sum, $\Sigma_{\max}$, which may occur if all positions are perfectly matched with the highest possible probability. In this case the score becomes 0 and it can never become negative. C^R_{pred} is a constant which purpose is to increase the contribution to the score of a matching type prediction that has a low reliability R_{pred}. In the current work, it was chosen such that $C^R_{\text{pred}} + \max R_{\text{pred}} = 20$. The reference types $T_{\text{ref}}(i)$ are extracted from the reference structure S_{ref} per residue position i as described in section "Secondary Structure Definition".

Diversity Measure

As a requirement stated in the problem description, the algorithm should not only find a single very good solution, but rather a number of good solutions as different as possible from each other and from the reference sequence. This diversity requirement is closely related to the models described in ▸ Chap. 40, "Diversity Optimization Models." However, as the problem solutions in this work represent protein sequences, not binary selection of elements, a slightly different approach to the distance measure is taken. An effective and simple measure of distance between two sequences is the Hamming distance, defined as the number of single-point permutations necessary to convert one into the other. Not taking gaps or varying sequence lengths into account, for two sequences $A = \{aa_i\}$ and $A' = \left\{aa'_i\right\}$ where $1 \leq i \leq N$, the Hamming distance between them is defined as:

$$d_{\text{Hamm}}\left(A, A'\right) = \sum_{i=1}^{N} d_i, \quad d_i = \begin{cases} 0 & \text{if } aa_i = aa'_i \\ 1 & \text{otherwise} \end{cases}. \tag{2}$$

To obtain a *nonnegative* objective value for minimization, the average Hamming distance to all other $M - 1$ individuals in the current population minus the sequence length N is computed:

$$F_{\text{div}}(A) = N - \frac{1}{M-1} \sum_{i=1}^{M-1} d_{\text{Hamm}}\left(A, A_i\right), F_{\text{div}}(A) \in \{0 \ldots N\}. \tag{3}$$

This function favors individuals farthest away from the rest of the population. In addition, if a sequence similar to the input sequence exists in the population, the function will have a mutually repulsive effect and penalize it. In summary the function addresses two problem requirements: (1) promoting diversity and (2) promoting sequences which are not equal to the reference sequence.

Algorithm Design

In this chapter the DAO-QC NSGA-II algorithm proposed to tackle the IFP is presented. The modification of the NSGA-II [10], a well-known multi-objective genetic algorithm, includes the diversity objective (DAO) $F_{\text{div}}(A)$ that enhances the explorative characteristic of the algorithm.

This favorable feature for solving *multimodal* problems is complemented by two modifications of the original algorithm highlighted in Algorithm 1: removal of doubles described in section "Removal of Doubles" and quantile constraint to promote good individuals in section "Quantile Constraint".

Algorithm 1: DAO-QC NSGA-II

1: $Initialize(P_0)$ {randomly generated individuals}
2: $t \leftarrow 0$
3: **while** $t < t_{\max}$ **do**
4: $\quad Q_t \leftarrow makeNewPop(P_t)$ {selection, mutation, recombination}
5: $\quad R_t \leftarrow P_t \cup Q_t$
6: $\quad mutateDoubles(R_t)$ {eliminate doubles by mutation}
7: $\quad F \leftarrow fastNonDominatedSort(R_t)$
8: $\quad P_t \leftarrow truncate(F)$ {based on domination and crowding}
9: $\quad setQuantileConstraint(P_t)$ {to penalize worst quantile}
10: **end while**

Removal of Doubles

In the context of diversity preservation, having two or more identical individuals in the population is undesired. Especially as in [30] when diversity for a sequence A is defined as the minimal distance to any other sequence A', a sequence $A = A'$ must be avoided. With the diversity calculation proposed in section "Diversity Measure", this issue has less impact, but nevertheless doubles are removed in this work. The procedure is executed in line 6 of Algorithm 1 after the application of genetic operations and before non-dominated sorting and crowding-based truncation of the unified population R_t takes place in NSGA-II.

When two identical sequences are detected, one of them is mutated with a probability of $\frac{5}{N}$ to distance the individual with a Hamming distance of 5 on average.

Quantile Constraint

A consequence of the nature of the objectives $F_{\text{sec}}(A)$ and $F_{\text{div}}(A)$ is that the latter is much easier to optimize; hence, the population quickly consists of very diversified individuals with poor fitness according to $F_{\text{sec}}(A)$. To counter this effect, the quantile constraint (QC) is introduced at the end of every generation, in line 9 of Algorithm 1. Given a quantile size C_q, the population P_t at time t is divided according to $F_{\text{sec}}(A)$ into a C_q%-sized partition and a $100 - C_q$%-sized partition. All individuals in the former, less fit, partition are assigned a constraint penalty that prevents the constrained individuals from mating and surviving the next generations. Hence, the population is cleaned from individuals far spread in the solution space, but with poor $F_{\text{sec}}(A)$ score. The selection pressure can then be selectively adjusted by changing the size of the quantile C_q, which has been tested using $C_q \in \{0\%, 5\%, 10\%, 25\%\}$.

Algorithm Experiments

This section presents and compares the experimental results obtained with the proposed DAO-QC MOGA to a standard generational GA on two protein samples. The experimental setup is first introduced, starting with the two protein samples used and followed by the algorithms' parameters. These initial experiments focus on analyzing the effect of different quantile constraint settings on the proposed algorithms' performance. To this end, the diversity, convergence, and final fitness are compared to a standard generational GA for both of the test samples.

Protein Samples

The two chosen protein samples, namely, *1OAI* and *1URR*, are illustrated in Fig. 4a, b, respectively. *1OAI* is characterized by a length of 59 residues and a secondary structure that consists of 4 helices. *1URR* is 97 residues long, and its secondary structure is composed of 2 helices and 6 beta-sheets.

Experimental Setup

Table 1 summarizes the settings of both the standard generational GA and the proposed DAO-QC MOGA, i.e., the GA extended by multi-objectivization with diversity as objective (DAO) and quantile constraint (QC). Both algorithms use a population of 100 individuals, a binary tournament selection, 1-point crossover with probability $p_c = 1.0$, and uniform mutation with probability $p_m = \frac{1}{N}$. The termination condition was set to 30,000 fitness function evaluations, and each experiment was repeated 30 times. Four different values of quantile constraint C_q are considered for DAO-QC NSGA-II: 0%, 5%, 10%, and 25% of the population.

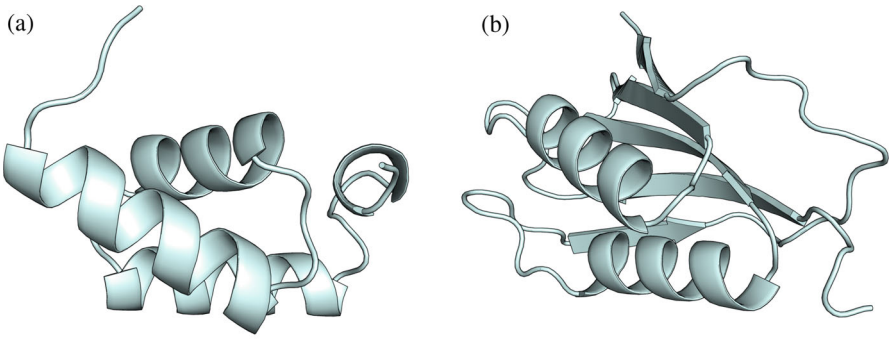

Fig. 4 Three-dimensional structure of the samples. (**a**) *1OAI*. (**b**) *1URR*

Table 1 Algorithm settings

Setting	Value
Population size	100
Algorithm	NSGA-II and std. GA
Termination condition	30,000 function evaluations
Selection	Binary tournament (BT)
Crossover operator	1-point, $p_c = 1.0$
Mutation operator	Uniform, $p_m = \frac{1}{N}$
Quantile constraint	$C_q \in \{0\%, 5\%, 10\%, 25\%\}$

Algorithm Results

In the following the results of the standard GA and the DAO-QC NSGA-II with four different C_q settings are presented and compared in terms of average population fitness, population diversity, and convergence of these indicators based on 30 individual runs.

Tables 2, 3, 4, and 5 show all pairwise comparisons of the algorithm mean value difference. The Wilcoxon test indicator [35] with a 5% significance level provides statistical confidence in comparing the sets with symbols "▲," "▽," and "-" indicating superior, inferior, and no difference. In terms of fitness, the algorithms are ordered in the following way: DAO-QC25 > DAO-QC10 ∼ GA > DAO-QC5 > DAO-QC0 for sample *1OAI* and DAO-QC25 > DAO-QC10 > GA > DAO-QC5 > DAO-QC0 for sample *1URR* with statistical confidence. In terms of diversity, the order becomes DAO-QC0 > DAO-QC5 > DAO-QC10 > DAO-QC25 > GA and DAO-QC0 > DAO-QC5 > DAO-QC10 > DAO-QC25 ∼ GA for samples *1OAI* and *1URR*, respectively. As expected, the higher diversity of the DAO-QC0 approach comes at the expense of a lower average fitness due to the exploration/exploitation trade-off. However, an increase of C_q to 10% or 25% leads to increased exploitation, allowing the DAO-QC NSGA-II algorithm to be constantly ahead of the GA in terms of average fitness until depletion of the evaluation budget as seen in Figs. 5 and 6. Further, the appropriate setting ($C_q = 25\%$ for *1OAI*, $C_q = 10\%$ for *1URR*) allows

the DAO-QC NSGA-II to outperform the GA in terms of fitness and diversity *at the same time*. Remaining observations to mention are steeper final fitness slopes for the sample *1URR* with settings $C_q \in \{10\%, 25\%\}$, than the standard GA and specifically for the sample *1OAI*; the diversity is observed to clearly start increasing once the fitness has converged. The steeper final slopes and the increased performance in fitness can be partially explained by the constantly high, and at times increasing, diversity combined with the highly *multimodal* nature of the problem. An elevated diversity clearly increases the chances of the algorithm discovering good new solutions in the rugged fitness landscape of this type of problem.

DAO-QC25	$0.105_{\pm 1.37e-01}$	$47.484_{\pm 1.11e+01}$	$0.193_{\pm 1.65e-01}$	$34.182_{\pm 1.39e+01}$

Table 6 shows the final average fitness and diversity values of all algorithms on both samples with their respective standard deviation. In each column the darker background emphasizes the best result, while the lighter background emphasizes the worst result. With $C_q = 25\%$ the proposed algorithm clearly outperforms the GA with statistical confidence for both samples with average values 0.105 vs. 0.136 and 0.193 vs. 0.242, respectively. From the figure and the table, it is also evident that the

value of the quantile or QC setting has a direct impact on the population diversity, providing an effective tool for achieving the level of exploitation vs. exploration preferred.

Structure Validation

In this second experimental step, the protein sequences generated by the best performing algorithm are validated. To this end the I-TASSER [37] prediction tool is used to generate their secondary and tertiary structures that will be compared to the structure of the targeted protein. For each sample, the 5 best generated sequences of the final population in each of the 30 individual runs are selected. This means a total of 300 I-TASSER runs for the 2 protein samples, each run taking around 2 days, which amounts to almost 2 years of CPU time. It is to be noted that the I-TASSER prediction itself is subject to erroneous results; hence, a 100% certainty can never be achieved unless the proteins are synthesized in a wet lab. In the following, the sequences and their I-TASSER predictions are analyzed in terms of primary and secondary structure in section "Primary and Secondary Structure Validation Results" and then tertiary structure in section "Tertiary Structure Validation Results".

Primary and Secondary Structure Validation Results

The goal in this section is to analyze how well the secondary structure of the reference protein is reproduced in the predicted model.

Table 7 shows a summary of the two proteins tested. Clearly, the generated sequences share very little resemblance with the original input sequence seen from a sequence identity of about 20% and 15%, respectively, with a very low deviation. Achieving low sequence identity by itself is not a challenging task unless a good structure match is obtained at the same time. The table shows this as the average percentage, μ, of positions in the secondary annotation of the I-TASSER predicted model that correctly matches those of the input annotation. Average percentage μ and standard deviation of the average percentage σ are given for each of the three structure types *H*, *E*, and *L*. As it can be seen, the helices are correctly predicted on more than 90% of the positions in both proteins. For the slightly bigger *1URR* sample which contrary to *1OAI* contains many extended sheets, the sheet match percentage is lower—slightly below 50%.

Table 7 Summary of secondary structure prediction match

Protein	μ_{Identity}	σ_{Identity}	μ_{Helix}	σ_{Helix}	μ_{Sheet}	σ_{Sheet}	μ_{Loop}	σ_{Loop}
1OAI	20.67	4.100	93.348	6.343	0	0	82.814	7.368
1URR	15.23	3.225	93.787	6.563	42.108	8.898	85.523	8.239

Figures 7 and 8 illustrate the same data as histograms. Figures 7a and 8a clearly demonstrate that *helix* structures are very well matched in all 300 structure predictions. Almost all of the tested generated individuals have a match percentage of over 80%, and the majority is above 90% for both samples.

For *loop* segments presented in Figs. 7b and 8c, the majority is still above 80% but with a high spread. The statistics for *sheet* segments show that there is a limit to

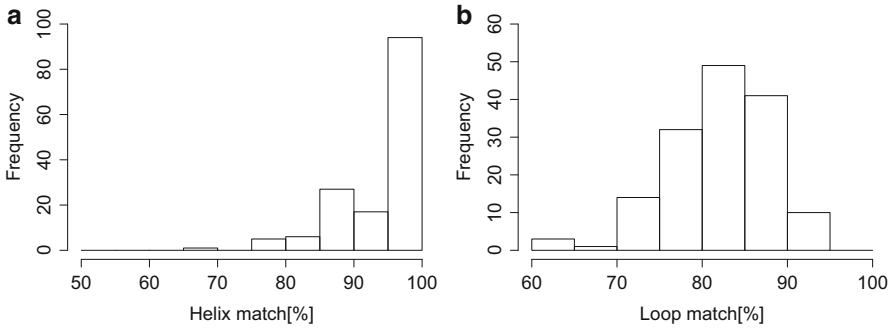

Fig. 7 Match histograms of *1OAI*. (**a**) *Helix* match histogram. (**b**) *Loop* match histogram.

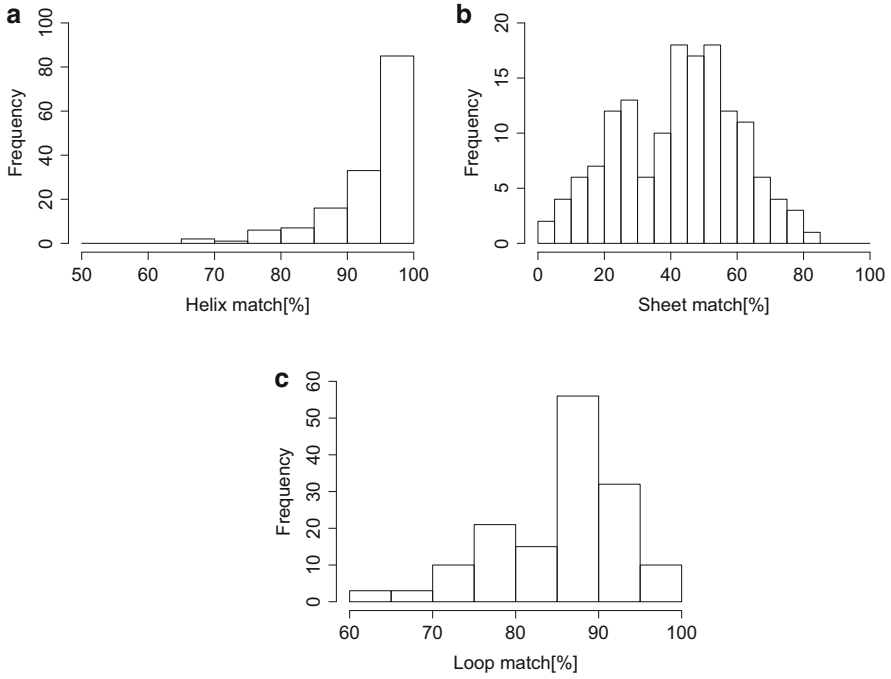

Fig. 8 Match histograms of *1URR*. (**a**) *Helix* match histogram. (**b**) *Sheet* match histogram. (**c**) *Loop* match histogram

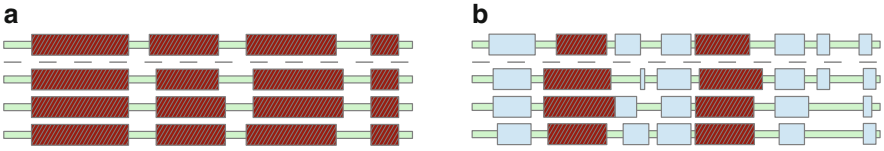

Fig. 9 Secondary structure of reference (on top) compared to three selected generated models. Darker sections are *helices*, lighter are *sheets*, and the rest represents *loop* structure. (**a**) *1OAI*. (**b**) *1URR*

the performance of an approach optimizing only an approximate secondary structure prediction. Considering that the *1URR* sample consists of *six sheet* segments across the whole of its length, then 42% can be considered as a rather good result. The lower success rate of predicting sheets is due to the fact that a sheet can only be observed in the secondary structure if the I-TASSER predicted structure actually did fold close enough to the reference tertiary structure, to allow the extended sheet to form. A *helix* is a much more local structure mostly independent of the global fold, hence easier to achieve in this analysis.

Figure 9 and Table 9 show the alignment of three of the best aligned individually generated sequences. This is to show specific examples of the results which have been averaged in Table 7, and the tendency remains the same: *helices* are very well defined with above 95% positions matched, *loops* slightly less with ±90%, and ±80% for samples *1OAI* and *1URR*, respectively. The *1OAI* sample is clearly an easier target due to its *helix*-only structure compared to the majority of *sheet* structures in the *1URR* sample. The other columns of the table will be discussed in the next section.

Tertiary Structure Validation Results

In the following the tertiary structure of the predicted proteins is validated by three-dimensional comparison.

The TM-Score detailed in [39] is a measure that is used to assess the similarity between two structures, with larger values indicating greater resemblance and 1.0 a maximum value for identical structures. According to Xu and Zhang [36], two proteins can be considered to be in the same fold if comparing them gives a TM-Score above 0.5. Though the average TM-Score is above 0.4 and close to 0.5 for the first sample, this is actually the case for $1{-}in{-}5$ for *1OAI* and $1{-}in{-}15$ for *1URR* as seen in Table 8. The table further shows the number N of predictions that had a TM-Score above 0.2, 0.4, 0.6, 0.7, and 0.8. The general results presented in section "Primary and Secondary Structure Validation Results" are confirmed here, and it is clear that the *sheet* structures of *1URR* are hard to match and that the approach is much more successful in predicting *helix* structures (see Table 9).

Table 8 Summary of tertiary structure prediction match

Protein	$\mu_{TM\text{-Score}}$	$\sigma_{TM\text{-Score}}$	$N_{TM>0.2}$	$N_{TM>0.4}$	$N_{TM>0.5}$	$N_{TM>0.6}$	$N_{TM>0.7}$	$N_{TM>0.8}$
1OAI	0.493	0.135	150	102	51	32	18	4
1URR	0.416	0.061	150	91	10	0	0	0

Table 9 Three selected generated models and their alignment scores with *1OAI* and *1URR* as reference

Nr.	Identity	N < 5*A*	$RMSD_{N<5A}$	RMSD	GDT_{TS}	TM-Score	Helix	Sheet	Loop
1	13.6	58	1.21	1.760	92.797	0.8667	95.12	0	94.44
2	25.4	58	1.35	1.838	88.983	0.8350	95.12	0	88.89
3	18.6	56	1.84	2.722	88.136	0.8015	97.56	0	94.44

Nr.	Identity	N < 5*A*	$RMSD_{N<5A}$	RMSD	GDT_{TS}	TM-Score	Helix	Sheet	Loop
1	19.6	73	2.85	7.484	50.258	0.5374	96	75.68	71.43
2	20.6	67	3.20	4.933	50.773	0.5027	100	81.08	80
3	17.5	74	2.94	9.059	48.711	0.5138	100	72.97	80

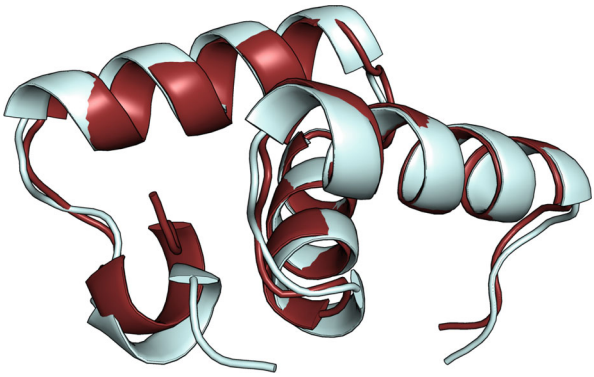

Fig. 10 Super-positioning of a predicted model (dark) with 1OAI reference (light)

The last step in the tertiary validation consists in superposing the fully I-TASSER predicted tertiary structure model of one generated sequence with the target reference. This is illustrated in Figs. 10 and 11 where the first of the three individually generated sequences in Table 9 and Fig. 9 is used.

The models for *1OAI* are all very close to the reference seen from the high *helix* and *loop* match percentage, and in addition the first model for *1OAI* has a very low sequence identity and at the same time very high *TM* and *GDT* scores (see Table 9). The first model for *1URR* also has very high *helix* match percentage and good *loop* and *sheet* percentages. However, the *TM* and *GDT* scores are less satisfactory. This result is visible in Fig. 11 where the *helices* and *sheets* cannot be fully aligned with the reference and the fact that one *sheet* has been bound to the structure in the wrong location (at the top of the figure rather than at the bottom).

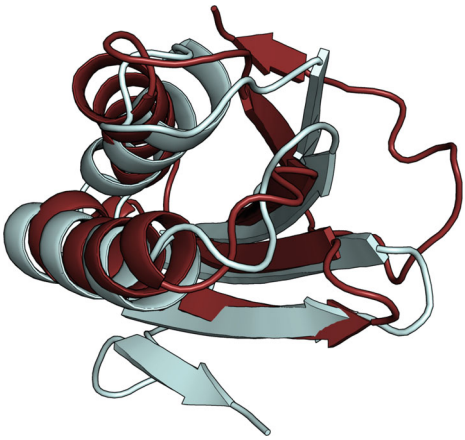

Fig. 11 Super-positioning of a predicted model (dark) with 1URR reference (light)

In Table 9 the second column shows sequence identity with gaps, the third shows the length of the longest continuous segment $N < 5A$ that can be fitted below a $5A$ threshold after super-positioning the two structures. The root-mean-square deviation (RMSD) measure is based on the pairwise distance between every residue position in the two tertiary structures, and the fourth column regards only those positions counted in column three, the fifth column regards the total of position. The global distance test (GDT) total score (TS) is a measure indicating the total average of the average percentage of residue positions that can be fitted below each of the thresholds $\{0.5A, 1.0A, 1.5A, \ldots 10.0A\}$. The final four columns are TM-Score and the percentage match of *helix*, *sheet*, and *loop* positions already discussed. Columns three to six were computed with the tertiary structure alignment tool LGA detailed in [38] with default global distance test (GDT) and longest continuous segment (LCS) analysis settings.

Conclusion

In this chapter an evolutionary-based approach to find a large amount of protein sequences that may result in a given reference secondary and tertiary structure was presented. This problem, referred to as the inverse folding problem (IFP), has received a lot of attention in theoretical chemistry and biophysics over the last 30 years, mostly for its potential application in protein design. It is also of interest to study the extent of the sequence space that may produce similar tertiary structures and how far from the original reference sequence such solutions can be found.

By defining the task as finding highly diverse sequences with most similar secondary structures, an optimization problem was modeled to find many well-scoring sequences in a few hours, which is fast compared to state-of-the-art methods. To achieve high diversity, the requirement has been adapted as an additional objective and extending the problem through *multi-objectivization* to become multi-objective

with diversity as objective (DAO). Combining the quantile constraint (QC) with the DAO approach allows to shift focus arbitrarily between diversity and fitness, and final results found significantly better than the standard GA with statistical significance. At the same time, the final diversity remains significantly higher for all QC-settings except the DAO-QC25 which produces diversity comparable to the standard GA for the *1URR* sample. For the *1OAI* sample with increased QC setting, a clear increase in diversity is observed toward the end of the run, once very good fitness values have been found. In addition to the higher performance on diversity, the algorithm fitness convergence was observed as being generally faster and partially steeper toward the end of runs, than for the standard GA.

For further validation, the five best generated sequences of each independent run of the $DAO - QC25$ algorithm variant were selected systematically and their folded structure predicted by I-TASSER, an established structure prediction software. The 300 predicted tertiary structures were annotated by DSSP for secondary structure analysis of *helix*, *sheet*, and *loop* formations. As could be expected, the method works better for the sample with more defined *helical* secondary structure, and less well in *sheet* and *loop* regions, especially as the latter region is not expressed by the objective function. Indeed *sheet* formations require the tertiary structure to fold properly to be captured in secondary structure. Nevertheless the *1URR* sample *sheet* match percentage is slightly below 50% averaged over all generated predictions. In addition the majority of match percentages are above 80% for *loops* and above 90% for *helices* in both samples. Tertiary structure validation was done by comparing the predicted structures to their respective reference by tertiary structure super-position. For both samples meaningful predictions were generated with a $TM-Score$ above 0.5 observed $1-in-5$ for *1OAI* and $1-in-15$ for *1URR*. These results indicate that this approach is able to generate a massive amount of sequences, with a reasonable amount being likely to actually fold as expected. At the same time, the limits in terms of achieving larger formations of *sheets* are demonstrated.

Future and ongoing works will address the identification of those sequences that actually fold into the reference structure by designing new objectives and constraints and also addressing *loop* and *beta-sheet* regions. Independent of this, sequences found could already be used as starting points for other exact protein design methods and possibly generate successful designs with a very low sequence identity compared to the reference. Additional possible applications could be generating meaningful decoy sets for other studies or finding bridges in sequence space between known proteins of the same structural classes.

grid graph, among others. In this chapter, we review the five most relevant graph layout problems: the Cutwidth, the Minimum Linear Arrangement, the Vertex Separation, the SumCut, and the Bandwidth. Each problem is presented with its formal definition, and it is illustrated with a detailed example. Additionally, we describe their state-of-the-art heuristic methods and the instances used in their evaluation. Since graph layouts represent a challenge for optimization methods in general and for heuristics in particular, this review pays special attention to strategies and methodologies that provide high-quality solutions.

Introduction

In recent years, there has been a growing interest in studying graph layout problems. From a historical perspective, the terms *layout* and *layout problem* come from their early application to the optimal layout of circuits in Very Large-Scale Integration (VLSI) design. A VLSI circuit can be modeled by means of a graph, where the edges represent the wires and the vertices represent the modules. Specifically, given a set of modules, we look for placing these modules on a board in both a nonoverlapping manner and wiring together the terminals on the different modules. In general, there are two stages: placement and routing. The former consists of placing the modules on a board, while the latter consists of wiring together the terminals on different modules that should be connected. Figure 1 presents an example of a circuit design with six modules (identified with a different letter, A–F) and their corresponding connections through different tracks. This circuit can be modeled as a graph, as is shown below. Notice that the order of the modules can determine, among others, the number of tracks needed to wire the circuit and, therefore, the space needed to build it.

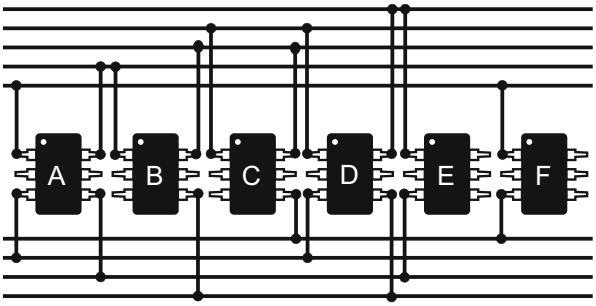

Fig. 1 Circuit design with six modules and its corresponding connections

From a theoretical point of view, the main objective of graph layout problems is to project an original graph $G = (V_G, E_G)$ onto a predefined host graph $H = (V_H, E_H)$. This projection, commonly known as embedding, consists of defining a function, mapping the vertices of G into the vertices of H, and associating a path in H for each edge of G. This function assesses that $V_G \subseteq V_H$ and $E_G \subseteq E_H$. According to [53], the quality of an embedding depends on the *dilation*, the *congestion*, and the *load*. The *dilation* of an embedding is the length of the largest associated path in H. The *congestion* is the largest number of paths that share an edge of H. Finally, its *load* is the maximum number of vertices of G that are mapped to a vertex of H.

Let G be a graph (finite, undirected, and without loops), where its set of vertices is denoted by V (with $|V| = n$) and its set of edges by E (with $|E| = m$). The notation (u, v) stands for an undirected edge between the vertices u and v. In Fig. 2, an example is shown of a general graph G obtained as the result of modeling the circuit in Fig. 1 as a graph. The graph is made up of six vertices corresponding to each of the modules in the circuit (say the vertex set $V = \{\texttt{A}, \texttt{B}, \texttt{C}, \texttt{D}, \texttt{E}, \texttt{F}\}$) and nine edges corresponding to the circuit connections (say the edge set $E = \{(\texttt{A}, \texttt{B}), (\texttt{A}, \texttt{D}), (\texttt{A}, \texttt{E}), (\texttt{A}, \texttt{F}), (\texttt{B}, \texttt{C}), (\texttt{B}, \texttt{D}), (\texttt{C}, \texttt{D}), (\texttt{C}, \texttt{F}), (\texttt{D}, \texttt{E})\}$). Notice that vertex A in Fig. 2 corresponds with module A in Fig. 1, vertex B in Fig. 2 corresponds with module B in Fig. 1, and so on.

The case in which a graph with n vertices is projected over a path graph with *load* equal to 1 is perhaps the simplest nontrivial embedding problem. In particular, it consists of defining a bijective function, ϕ, where each vertex and edge of G have a unique correspondence in H. The function $\phi : V \rightarrow \{1, \ldots, n\}$ assigns distinct integer numbers (from 1 to n) to each of the n vertices of G. Then, the resulting graph H is usually represented by aligning its vertices on a horizontal line, where each vertex u is located in position $\phi(u)$. This graphical representation is usually known as linear layout, although it has received other names in the literature, for example, linear ordering [4], linear arrangement [188], numbering [36], embedding in the line [153], or labeling [98]. In Fig. 3, an example of linear layout is shown where vertex A occupies the first position on the line, vertex B the second one, and so on. The horizontal dotted line represents the host graph structure. For the sake of simplicity, the linear layout is usually represented as an array $\phi = \{\texttt{A}, \texttt{B}, \texttt{C}, \texttt{D}, \texttt{E}, \texttt{F}\}$, where the position of each vertex $u \in V$ in this array corresponds to $\phi(u)$.

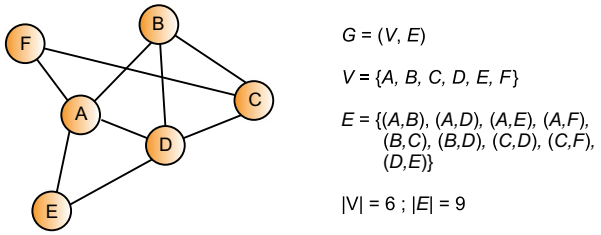

Fig. 2 The graph G with six vertices and nine edges represents the circuit in Fig. 1

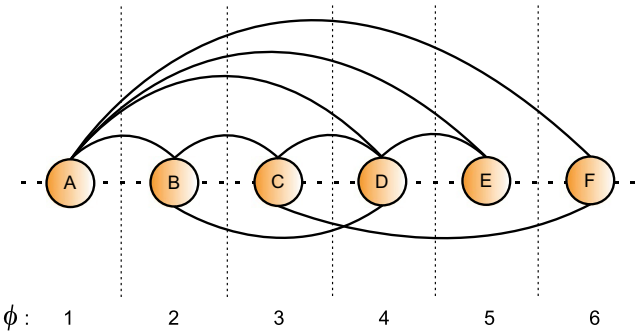

Fig. 3 A possible linear layout of graph G

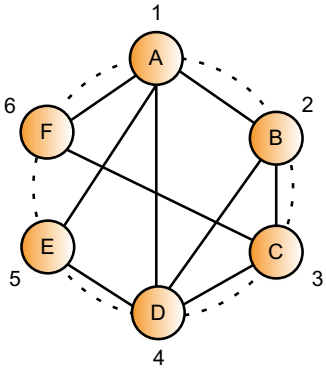
Fig. 4 A possible circular layout of graph G



Linear layout is, probably, the most studied family of problems in the context of graph layout problems, as shown below. However, there exist other interesting embeddings in host graphs that are more general than a path, for instance, in closed paths, usually known as cycles [30, 129, 161, 191]. A circular layout is a function $\rho : V \rightarrow \{1, \ldots, n\}$ that also assigns distinct integer numbers (from 1 to n) to each of the n vertices of the graph, but arranging the vertices of the graph in a cycle where the last vertex (the one with label n) is next to the first vertex (the one with label 1). This embedding also has a *load* equal to 1. In Fig. 4, a possible circular layout of the vertices of the graph in Fig. 2 is shown, where the dotted circle represents the corresponding circular host graph structure.

The embedding of graphs in grids has been studied in [11, 125, 140]. When dealing with grids, it is convenient to label each vertex with a pair of coordinates. A grid layout is a function $\delta : V \rightarrow \{1, \ldots, n_1\} \times \{1, \ldots, n_2\}$ where n_1 denotes the maximum horizontal number, while n_2 indicates the maximum vertical number. Notice that in optimization problems where the *load* is equal to 1, it means that $n = n_1 * n_2$. In Fig. 5, an example of embedding the graph depicted in Fig. 2 on a 3×2 grid is shown. Again, the dotted lines represent the corresponding host graph structure.

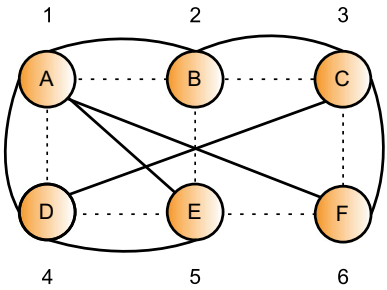


Fig. 5 A possible grid layout of graph G

There are also other embeddings of practical importance, where the host graph is neither a line nor a cycle nor a grid. Only to mention a few, in [5, 55, 92, 95], the embedding of graphs on trees is studied, in [97, 198] the embedding of graphs on torus, and in [112, 127] the embedding of graphs in hypercubes.

In this chapter, the attention is focused on minimization layout problems, by reviewing some of the most relevant optimization problems that fall into this category. We start by introducing the version of the problem onto a linear layout and then review the embedding on other types of graph. In particular, this review is focused on the problems that have been intensively studied by the heuristic community. See the following sections for each problem: "The Cutwidth Minimization Problem," "The Minimum Linear Arrangement Problem," "The Vertex Separation Problem," "The SumCut/Profile Problem," and "The Bandwidth Minimization Problem." Finally, in section "Conclusions and Future Lines of Research," we present the conclusions of this study and outline potential lines for future research.

The Cutwidth Minimization Problem

The Cutwidth Minimization Problem (CMP) is an NP-hard min-max linear layout problem [76]. It consists of finding an ordering of the vertices of a graph on a line, in such a way that the maximum number of edges between each pair of consecutive vertices is minimized. In terms of graph embedding theory, this problem consists of finding the linear layout (*load* equals to 1) that minimizes the *congestion* (see the definition above).

The classical combinatorial formulation can be described as follows. Given a graph $G = (V, E)$ with $|V| = n$, a linear layout $\phi : V \rightarrow \{1, 2, \ldots, n\}$ of G assigns the integers $\{1, 2, \ldots, n\}$ to the vertices in V, in such a way that each vertex receives a different label. Therefore, the host graph H is a path with the same number of vertices and edges. The cutwidth of a vertex v with respect to ϕ, denoted as $Cut(v, \phi, G)$, is the number of edges $(u, w) \in E$ satisfying $\phi(u) \leq \phi(v) < \phi(w)$. Therefore,

$$Cut(v, \phi, G) = |\{(u, w) \in E : \phi(u) \leq \phi(v) < \phi(w)\}|$$

The cutwidth of G with respect to ϕ is defined as the maximum value of all $Cut(v, \phi, G)$ for $v \in V$. More formally:

$$Cut(\phi, G) = \max_{v \in V} Cut(v, \phi, G)$$

The optimum cutwidth of G is then defined as the minimum $Cut(\phi, G)$ over all possible layouts Φ of G.

Figure 6a shows a possible linear layout ϕ of the graph G depicted in Fig. 2. This layout sets the vertices in a line, as it is commonly represented in the CMP. Specifically, since $\phi(\mathtt{A}) = 1$, vertex A comes first, followed by vertex B ($\phi(\mathtt{B}) = 2$), and so on. In Fig. 6b it is depicted the computation of the *Cut*-value for each vertex. For example, the *Cut*-value of vertex A is $Cut(\mathtt{A}, \phi, G) = 4$, because the edges (A, B), (A, D), (A, E), and (A, F) have an endpoint in A, labeled with 1, and the other endpoint is a vertex labeled with a value larger than 1. Similarly, the *Cut*-value of vertex C is $Cut(\mathtt{C}, \phi, G) = 6$, computed by counting the appropriate

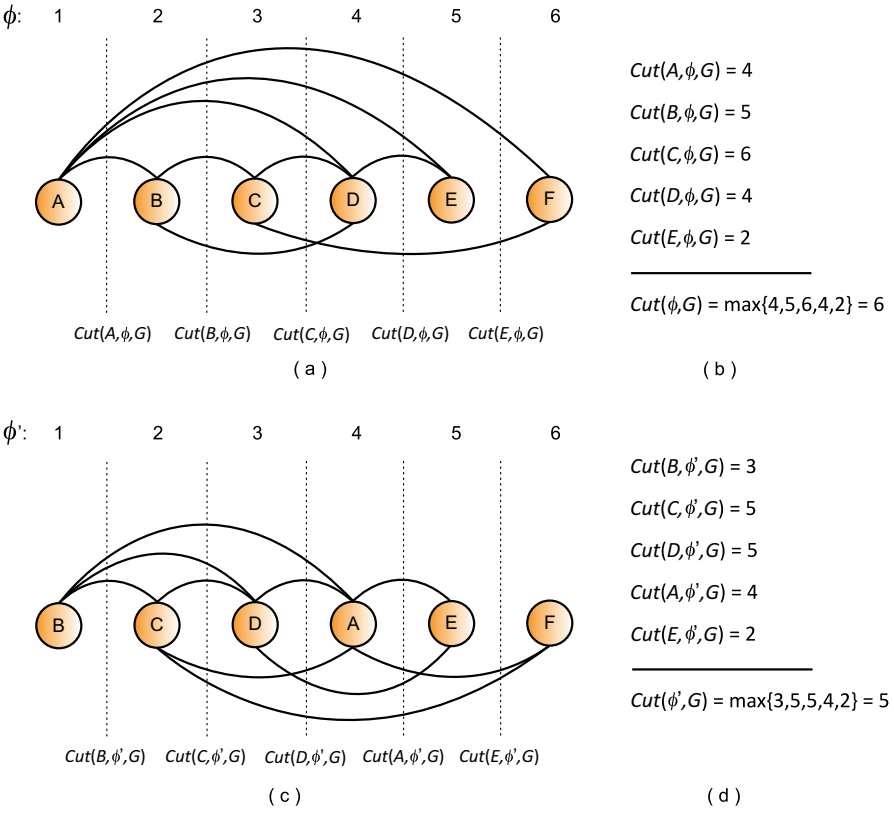

Fig. 6 (**a**) Example of linear layout ϕ. (**b**) Computation of *Cut*-values associated to ϕ. (**c**) Example of linear layout ϕ'. (**d**) Computation of *Cut*-values associated to ϕ'

number of edges (i.e., (A, D), (A, E), (A, F), (B, D), (C, D), and (C, F)). Then, since the cutwidth of G, $Cut(\phi, G)$, is the maximum of the $Cut(v, \phi, G)$ for all vertices $v \in V$, in this example, it is obtained that $Cut(\phi, G) = Cut(\mathtt{C}, \phi, G) = 6$.

In Fig. 6c, a different linear layout ϕ' of the graph G is shown. The associated *Cut*-values are depicted in Fig. 6d. Considering that the CMP is a minimization problem, this second linear layout ϕ' is better than ϕ since $Cut(\phi', G) = Cut(\mathtt{D}, \phi', G) = 5$, which is smaller than $Cut(\phi, G) = Cut(\mathtt{C}, \phi, G) = 6$.

The CMP has been referred to in the literature with different names, such as Minimum Cut Linear Arrangement [50, 192] or Network Migration Scheduling [7, 8]. There can also be found a generalization of the CMP for hyper-graphs named Board Permutation Problem [40, 41]. Several practical applications of this problem have been reported in different areas of engineering and computer science, such as circuit design [4, 41, 132], network reliability [101], information retrieval [22], automatic graph drawing [33, 146, 187], protein engineering [12], or network migration [165]. This last application is, as far as the authors know, the newest one. It refers to the problem where internodal traffic from an obsolete telecommunication network needs to be migrated to a new network. This problem appears nowadays in phone traffic, where it is performed a migration from 4ESS switch-based networks to IP router-based networks [165]. Nodes are migrated, one at each time period, from the old to the new network. All traffic originating or terminating at a given node in the old network is moved to a specific node in the new network, with the objective of minimizing the connections, at the same time, between the old and the new networks.

In the scientific literature, the CMP has been addressed from theoretical, exact, and heuristic approaches. From a theoretical perspective, researchers studying the CMP proposed lower and upper bounds, and also its connection with other related problems [9, 15, 38, 73, 111, 113, 118]. Most of the exact approaches present polynomial-time algorithms for particular graphs, such as hypercubes [87], trees [37, 194, 199], or grids [174], among others [89, 90]. There are also several exact methods for general graphs: integer linear programming formulations [45, 128, 130] and Branch and Bound algorithms [137, 147]. These approaches can only solve relatively small instances. Therefore, different heuristic procedures have been proposed to address this problem.

The work by Cohoon and Sahni [41] was the first approach to propose heuristic algorithms for the generalized version of the problem. These authors introduced several constructive methods and local search procedures, embedded into a Simulated Annealing metaheuristic [108]. Twenty years later, Andrade and Resende [7, 8] customized a Greedy Randomized Adaptive Search Procedure (GRASP) [69, 70] hybridized with a Path Relinking method [80]. Later, Pantrigo et al. in [149] introduced a Scatter Search algorithm [79, 117], which outperformed previous methods. More recently, Pardo et al. [151, 152] proposed several heuristics based on the Variable Neighborhood Search (VNS) methodology [142]. In particular, in [151], the authors applied several reduced VNS and basic VNS schemas to tackle the problem. Later, in [152], they applied a new variant of VNS, called Variable Formulation Search (VFS), to the CMP. This new algorithm is especially useful for

dealing with min-max (or max-min) optimization problems, where it is usual that many solutions have the same value of the objective function, which makes them especially hard for a heuristic search. VFS makes use of alternative formulations of the problem to determine which solution is more promising when they have the same value of the objective function in the original formulation.

Another interesting variant of VNS was presented by Duarte et al. in [59] by introducing different parallel designs of VNS to solve the CMP, which differs in the VNS stages to be parallelized as well as in the communication mechanisms among processes. Duarte et al. [58] investigate the potential of VNS to address multi-objective combinatorial optimization problems, with the CMP serving as a case study. Additionally, Fraire-Huacuja et al. [72] studied the implementation of a fuzzy logic controller, which is used to modify the parameters of a genetic algorithm during its execution to facilitate the exploration process. This method, which is referred to as a Fuzzy Genetic Algorithm (FGA), was evaluated and compared to a basic genetic algorithm that did not employ fuzzy logic. The authors tested their hypothesis using the CMP, and their findings indicated that the FGA exhibited marginal superiority over the corresponding genetic algorithm. However, when the VFS proposed in [152] was considered, the FGA demonstrated suboptimal performance and also had a longer run time.

In 2021, Santos et al. proposed a heuristic based on Adaptive Large Neighborhood Search that outperforms previous methods [183]. The algorithm consists of a greedy constructive procedure coupled with a swap local search including insert and remove operators to effectively explore the search space. Statistical tests proved that the proposed method exhibits a notable advantage in solution quality, when compared to state-of-the-art algorithms. Finally, in a recent publication, Cavero et al. [34] show that the correlation between the CMP and other similar problems (which are also introduced in this chapter) permits their simultaneous optimization of the others. The paper presents an analysis of various strategies based on VNS, which provides insights about the effectiveness of this methodology.

The literature on CMP is extensive and can be further enriched by including research studies with other host graphs. In particular, in recent years, embedding in a cycle graph has gained prominence among the community. For this specific case, CMP is known as the "Cyclic Cutwidth Minimization Problem" (CCMP). The CCMP has been studied both theoretically [1, 10, 26, 39, 66, 94, 96, 166, 184–186] and empirically [28, 29, 88, 93]. The cutwidth has also been studied for embedding specific graphs into trees, hypercubes, and grids. In this context, only theoretical studies have been published (such as [11, 14, 113]). These studies primarily focus on the structural properties and potential applications of such embeddings, providing a foundation for future practical implementations.

Regarding the instances used to evaluate this problem, most of the aforementioned authors have considered the instances reported in [149]. In particular, authors proposed the use of three sets of instances: *small*, *grid*, and *Harwell-Boeing*. The *small* data set consists of 84 graphs introduced in the context of the Bandwidth Reduction Problem [134]. The number of vertices of the graphs in this set ranges from 16 to 24. The exact value of the CMP for the instances in this set is known,

as they were solved to optimality in [137]. The *grid* data set consists of 81 matrices constructed as the Cartesian product of two paths [161], and they were originally introduced in the context of CMP by [174]. The size of the considered instances ranges from 9 vertices to 729. In this case, the optimal value is also known by construction [161]. Finally, the *Harwell-Boeing* data set is a subset of 87 instances extracted from the Harwell-Boeing sparse matrix collection which is accessible at the public domain matrix market library [42]. This collection was originally developed by Iain Duff, Roger Grimes, and John Lewis [61], and it consists of a set of standard test matrices arising from problems in linear systems, least squares, and eigenvalue calculations from a wide variety of scientific and engineering disciplines [62].

In the context of CMP, the instances have a number of vertices that range from 30 to 700. This data set is, in fact, the hardest for the algorithms, among the previously defined in the state of the art. A new set of instances, named as *Rome Graphs*, has recently been incorporated into the benchmark for this problem. This novel set comprises 11,534 instances, where the number of vertices ranges from 10 to 100. It was first introduced in [45] as a means of testing the efficacy of integer linear programming formulations within a linear ordering context. Compared to other sets, this one is relatively recent and has not been widely utilized.

The Minimum Linear Arrangement Problem

The Minimum Linear Arrangement Problem, usually known as MinLA, is also based on the *Cut*-value defined in section "The Cutwidth Minimization Problem." In this case, a linear layout with *load* equal to 1 is sought that minimizes the sum of the *congestion* on each position of the layout. It is equivalent to the minimization of the sum of *Cut*-values. More formally, given graph G and a linear layout ϕ, the linear arrangement value $LA(\phi, G)$ is defined as follows:

$$LA(\phi, G) = \sum_{v \in V} cut(v, \phi, G)$$

The optimum MinLA of G is then defined as the minimum $LA(\phi, G)$ in all possible layouts Φ of G.

Considering the linear layouts depicted in Fig. 6a, c it is shown in Fig. 7a, b the computation of the LA-values, respectively. In particular, the objective function value associated with the first layout ϕ is $LA(\phi, G) = 4 + 5 + 6 + 4 + 2 = 21$. Similarly, the objective function value associated with ϕ' is $LA(\phi', G) = 3 + 5 + 5 + 4 + 2 = 19$. Therefore, ϕ' is a better solution than ϕ since the MinLA is a minimization problem.

The Minimum Linear Arrangement Problem is an NP-hard problem [75], and it is related to two other well-known layout problems: the Bandwidth and Profile minimization problems. However, as pointed out in [139], an optimal solution for one of these problems is not necessarily optimal for the other related problems.

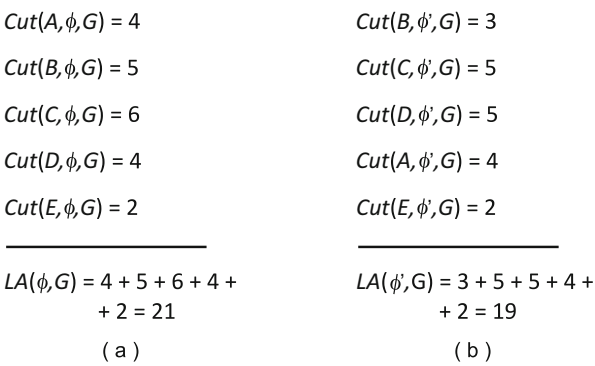

Fig. 7 (**a**) Computation of the objective function of the MinLA for the linear layout ϕ shown in Fig. 6a (**b**) Computation of the objective function of the MinLA for the linear layout ϕ' shown in Fig. 6c

The Minimum Linear Arrangement Problem is also known as the Optimal Linear Ordering, Edge Sum, Minimum-1-Sum, Bandwidth Sum, or Wire-Length problem. It was originally introduced in [86], with the goal of designing error-correcting codes with minimal average absolute errors on certain classes of graphs. Twenty years later, this problem was considered in [141] as an oversimplified model of some nervous activity in the cortex. The MinLA also has applications in single machine job scheduling [3, 162] and in graph drawing [187] among others [3, 35, 74, 102].

While MinLA is generally challenging (NP-hard in terms of its complexity), polynomial-time exact algorithms have been developed for specific graph types, including trees, rooted trees, hypercubes, meshes, and outerplanar graphs, among others. For a comprehensive overview, we refer the reader to [156] and [201]. Additionally, upper and lower bounds have been proposed for general and specific graphs [24, 25]. From an exact perspective, it is possible to find different mathematical formulations for small instances [6, 46].

Many different heuristic algorithms have been proposed for solving the MinLA problem. Juvan and Mohar [98] introduced the spectral sequencing method (SSQ). This method computes the eigenvectors of the Laplacian matrix of G. Then, it orders the vertices according to the second smallest eigenvector. As stated by Petit in [156], the rationale behind the SSQ heuristic is that vertices connected to an edge will tend to be assigned to numbers that are close to each other, thus providing a good solution to the MinLA problem. McAllister proposed [139] a heuristic method for the MinLA, which basically consists of a constructive procedure that labels the vertices in sequential order. Vertices are selected according to their degree with respect to previously labeled ones. This method compares favorably with previous methods for this and related problems. Later, Petit in [156] reviewed the existing lower bounds and heuristic methods, proposed new ones, and introduced a set of instances that were considered since then the standard for this problem. Among the methods reviewed in [156], it is possible to find the Juvan-Mohar method [98], the Gomory-Hu tree method [4], and the edge method, which the author improved by adding a degree method. Petit concluded that the Juvan-Mohar method and the degree method provide the best lower bounds; however, their values are far from

those of the best-known solutions, and therefore they are of very limited interest from a practical point of view.

In [156], Petit additionally introduced both constructive and local search procedures. The Successive Augmentation (SAG) is a greedy heuristic that constructs a step-by-step solution, by extending a partial layout until all vertices have been enumerated. At each step, the best free label is assigned to the current vertex. Vertices are examined in the order given by a breadth-first search. Once a solution has been constructed, three different heuristics, based on local search, are considered: hill climbing, full search, and Simulated Annealing (SA). In the hill-climbing method, moves are selected at random; in the full search, the entire neighborhood of a solution is examined at each iteration, in search of the best available move. Finally, the SA algorithm implements the temperature parameter as described in [108] for move selection. Petit, in [156], considered two neighborhoods, called *flip2* and *flip3*. The former exchanges the label of two vertices, while the latter "rotates" the label of three vertices. The experimentation in [156] shows that the neighborhood based on the exchange of two labels (*flip2*) produces better results than the rotation (*flip3*). Overall, the experimentation concludes that the SA method outperforms the others, although it employs much longer running times (not reported in the paper). Therefore, the author recommends employing the hill climbing as well as the spectral sequencing methods.

A more elaborate Simulated Annealing algorithm was proposed in [155]. The author introduced a new neighborhood, *flipN*, based on the normal distribution of the distances between the vertices labels. The Simulated Annealing algorithm based on the *flipN* neighborhood (SAN) improves upon the previous SA method described above. Moreover, to speed up the method, the initial solution is obtained with the SSQ algorithm. The combined method, SSQ + SAN, is able to outperform previous methods.

Later, Safro et al. [176] introduced a multilevel algorithm for the MinLA problem, employing weighted edge contractions to create a hierarchy of graphs. This approach significantly reduced the size of the problem while preserving its structure. In [167], Rodriguez-Tello et al. proposed a Memetic Algorithm [145] that exhibits competitive results on benchmark instances. Sharma and Srivastava [177] developed a hybrid evolutionary algorithm that integrates a genetic algorithm with simulated annealing, achieving improved solutions for various graph types, particularly for sparse graphs with a large number of vertices.

In [168], the authors proposed a new algorithm based on the Simulated Annealing methodology. The Two-Stage Simulated Annealing (TSSA) performs two steps. In the first one, a solution is constructed with the procedure described in [139]; then, in the second step, it performs a Simulated Annealing procedure based on exchanges of labels. This method introduces two new elements to solve the MinLA: a combined neighborhood and a new evaluation function. Given a vertex v, the first neighborhood, selected with a probability of 0.9, examines the vertices u such that their label $\phi(u)$ is close to the median of the labels of the vertices adjacent to v (at a maximum distance of 2). The second neighborhood, selected with a probability 0.1, exchanges the labels of two vertices selected at random with diversification

(exploration) purposes. The method evaluates the solutions with a function that is more discriminating than the original one. The authors compared their TSSA method with the best-known algorithms, and they concluded that their method outperforms the previous algorithms. This method has been the state of the art for many years.

More recent approaches include the one by Martí et al. [136] with an algorithm based on a Scatter Search with Path Relinking and the one proposed by Mladenovic et al. [143], with a Skewed General Variable Neighborhood Search (SGVNS), which is, as far as the authors know, the latest proposal for the problem. The method presented in [143] starts from a greedy-constructed solution as an initial point. The authors propose the use of a local search, based on four different neighborhood structures. These neighborhoods are explored with a Variable Neighborhood Descent (VND) procedure. Then, the VND, together with a shake procedure, based on random moves within the four neighborhoods defined, conforms a General VNS (GVNS) method. This method is finally extended by the use of several ideas from Skewed VNS where the sharp move acceptance criterion is relaxed. However, the procedures proposed in [136] and [143] were unable to outperform the results obtained by the TSSA presented in [168].

Researchers in this field have recently considered MinLA as a test case for new proposals in heuristic optimization, shifting their focus from solely attempting to surpass the state-of-the-art algorithms to exploring novel methodological approaches and applications. For instance, Glover and Rego [82] investigated new relationships for multi-neighborhood search in the context of MinLA, emphasizing theoretical insights rather than purely computational performance. Similarly, as previously introduced, Cavero et al. [34] considered MinLA, along with other graph layout problems, to showcase their variable formulation search approach.

Regarding the connections of MinLA with other graph layout problems, it is interesting to discuss the Cyclic Bandwidth Sum Problem (CBSP) which exhibits a strong correlation with it. Specifically, the CBSP can be conceptualized as the study of MinLA on a cycle host graph. This relationship is formally expressed by the inequality: $\text{MinLA}(G)/2 \leq \text{CBSP}(G) \leq \text{MinLA}(G)$. Although CBSP has not received as much attention as MinLA in the literature, the past decade has witnessed significant advancements in heuristic approaches to address it [31, 171, 172].

As mentioned above, there is a set of instances considered standard as the comparison framework in the literature for MinLA. In particular, this set was introduced by Petit et al. [156], and it consists of 21 graphs ($62 \leq n \leq 10{,}240$) being n the number of vertices of the graph. As the authors indicate in [156], choosing a particular class of graphs to serve as a benchmark for the MinLA problem is difficult, because there are no large real instances for this problem. The purpose of the authors, when they formed the data set, was to measure heuristics in sparse graphs, so, therefore, they selected different kinds of graphs belonging to the following families: general random graphs, geometric random graphs, graphs with known optima (trees, hypercubes, meshes), graphs from finite element discretizations, graphs from VLSI design, and graphs from graph drawing competitions.

The Vertex Separation Problem

The Vertex Separation Problem (VSP) was originally motivated by the idea of finding good separators for graphs [126].

In particular, the VSP consists of finding a linear layout (*load* equals to 1) where the separator is minimized. In mathematical terms, being p a position in the layout, the set $L(p, \phi, G) = \{u \in V : \phi(u) \leq p\}$ is defined, which represents the set of vertices in the linear layout placed in a position lower than or equal to p. Symmetrically, the set $R(p, \phi, G) = \{u \in V : \phi(u) > p\}$ contains those vertices placed in a position greater than p. In general, $L(p, \phi, G)$ can simply be referred to as the set of *left vertices* with respect to position p in ϕ, and $R(p, \phi, G)$ is the set of the *right vertices* with respect to p in ϕ. The separation value at position p of the layout ϕ, $Sep(p, \phi, G)$, is defined as the number of vertices in $L(p, \phi, G)$ with one or more adjacent vertices in $R(p, \phi, G)$. More formally:

$$Sep(p, \phi, G) = |\{u \in L(p, \phi, G) : \exists\, v \in R(p, \phi, G) \wedge (u, v) \in E\}|$$

The vertex separation (VS) value of a layout ϕ is the maximum of the *Sep*-values among all positions in ϕ:

$$VS(\phi, G) = \max_{1 \leq p < n} Sep(p, \phi, G)$$

The Vertex Separation Problem (VSP) then consists of finding a layout, $\phi^\star$, that minimizes the *VS*-value of the graph G. In mathematical terms:

$$\phi^\star = \arg\min_{\phi \in \Phi} VS(\phi, G)$$

where Φ represents the set of all possible linear layouts of G.

Considering the graph example introduced in Fig. 2 and the layout ϕ' shown in Fig. 6c, in Fig. 8a–e, the *Sep*-value of each position p in the layout ϕ' is depicted, denoted as $Sep(p, \phi', G)$. For instance, $Sep(1, \phi', G) = 1$ (see Fig. 8a) because $L(1, \phi', G) = \{\texttt{B}\}$ and $R(1, \phi', G) = \{\texttt{C}, \texttt{D}, \texttt{A}, \texttt{E}, \texttt{F}\}$, and there is only one vertex in L having an adjacent vertex in R. Similarly, $Sep(4, \phi', G) = 3$ (see Fig. 8d) because $L(4, \phi', G) = \{\texttt{B}, \texttt{C}, \texttt{D}, \texttt{A}\}$ and $R(4, \phi', G) = \{\texttt{E}, \texttt{F}\}$, and the vertices C, D, and A in L have an adjacent vertex in R. Notice that the vertex B does not affect the *Sep*-value, since it does not have adjacent vertices in R. The objective function is then computed as the maximum of these *Sep*-values. In particular, this value is $VS(G, \phi') = 3$, associated with positions 3 and 4. For the sake of completeness, all the *Sep*-values as well as the objective function value are shown in Fig. 8f.

As in the previous optimization problems defined above, a second example of the layout ϕ'' (see Fig. 9a, b) is included. The value of the objective function of this solution is 4.

The VSP is strongly related to other well-known graph problems, such as the Path Width [107], the Node Search Number [110], or the Interval Thickness [109],

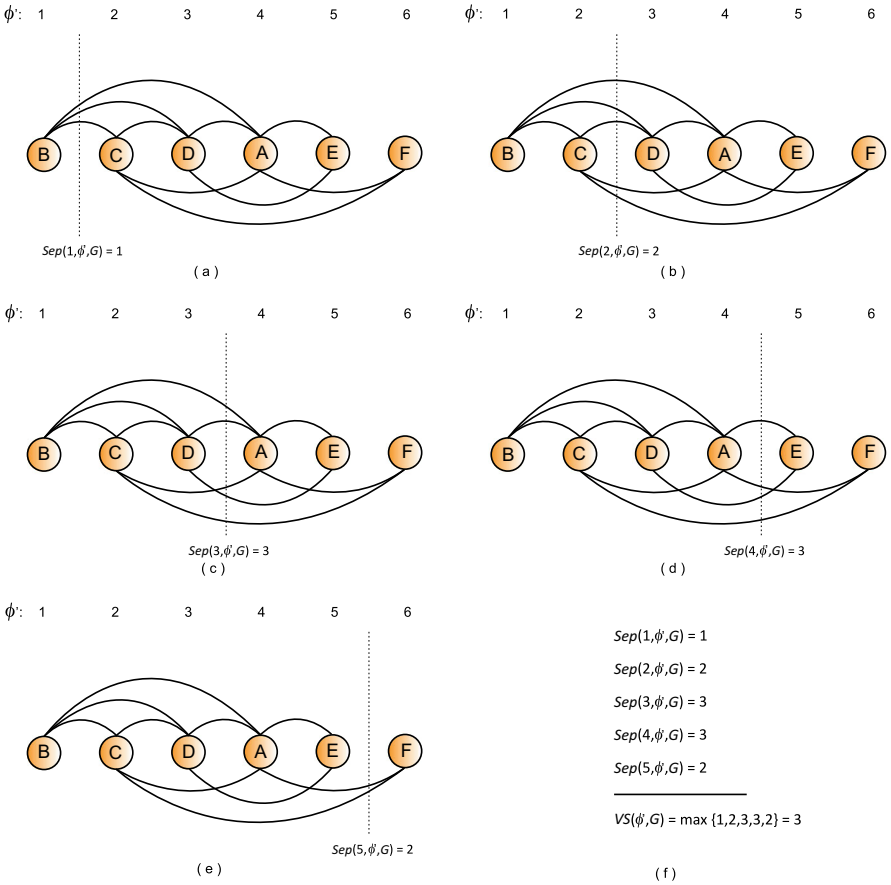

Fig. 8 (**a**)–(**e**) Computation of $Sep(p, \phi', G)$, with $p = \{1, \ldots, 5\}$, for the layout $\phi' = \{\mathtt{B}, \mathtt{C}, \mathtt{D}, \mathtt{A}, \mathtt{E}, \mathtt{F}\}$ introduced in Fig. 6c. (**f**) Computation of $VS(\phi', G)$

among others. The description of the equivalences among these problems can be found in [68, 107, 110]. All these optimization problems are NP-hard and have practical applications in VLSI design [119], computer language compiler design [17], or graph drawing [63].

It is possible to find efficient exact approaches to solve the VSP on special classes of graphs. A linear algorithm to compute the optimal vertex separation of a tree is proposed in [64] as well as an $O(n \log n)$ algorithm to find the corresponding optimal layout. The algorithm was improved in [189] with a linear-time procedure to find the optimal layout. In [154], an alternative method to compute the vertex separation of trees was also proposed, and in [65] an $O(n \log n)$ algorithm computes the vertex separation of unicyclic graphs (i.e., trees with an extra edge). A polynomial-time algorithm to compute the Path Width (which is identical to VSP) is proposed in [19]. However, the algorithm cannot be considered from a

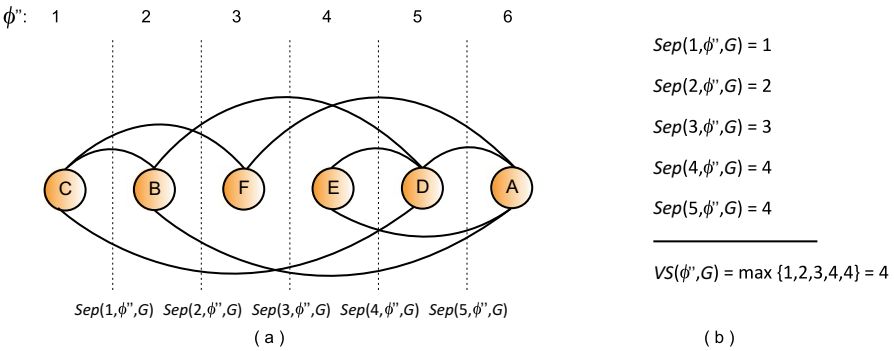

Fig. 9 (**a**) Computation of $Sep(p, \phi'', G)$ with $p = \{1, \ldots, 5\}$, for the layout $\phi'' = \{\mathtt{C}, \mathtt{B}, \mathtt{F}, \mathtt{E}, \mathtt{D}, \mathtt{A}\}$. (**b**) Computation of $VS(\phi'', G)$

practical point of view, since the bound on its time complexity is $\Omega(n)$, see [65]. In [21] a polynomial-time algorithm is proposed to optimally solve the VSP for n-dimensional grids. Co-graphs and permutational graphs can also be optimally solved as it was stated in [18–20]. More recently, Mallach [133] proposed MIP formulations based on linear ordering for this problem, providing new insights into exact solution approaches and improving the results obtained in [13, 190].

Approximation algorithms have also been proposed for the VSP together with complex metaheuristics based on Variable Neighborhood Search. Specifically, [16] proposes an $O(\log^2 n)$-approximation algorithm for general graphs and a $O(\log n)$-approximation algorithm for planar graphs. Similar results for binomial random graphs are presented in [53]. Castillo-García et al. [27] conducted a comparative study on constructive heuristics for the VSP, providing insights into their performance. Later, Duarte et al. [57] proposed a Basic VNS for the VSP, introducing two constructive procedures and a local search based on interchange moves, which showed promising results. Building upon this work, Huacuja et al. [71] explored the optimization of VSP using genetic algorithms, thus expanding the range of metaheuristic approaches applied to the problem. More recently, Sánchez-Oro et al. [182] proposed three VNS algorithms: Reduced VNS (RVNS), VND, and General VNS (GVNS). RVNS mainly focuses on the diversification, VND mainly focuses on the intensification, and GVNS balances intensification and diversification. Computational experiments reveal that the best procedure (GVNS) improves the state of the art in both quality and computing time. These results were validated using nonparametric statistical tests, establishing GVNS as the current state-of-the-art heuristic for the VSP.

In terms of the instances used to evaluate these heuristic algorithms, the first set of instances was defined in [57]. The authors selected 173 instances divided in three different subsets as a test bed. In particular, two of the subsets were formed by instances with a defined structure (trees and grids). For those instances, the optimum value is known by definition for the VSP. Additionally, they also selected

an additional subset of random graphs, whose instances have previously been used in the literature to evaluate other linear layout optimization problems. The grid subset consists of 50 matrices constructed as the Cartesian product of two paths. The number of vertices of this subset ranges from 25 to 2916. The tree subset is made up of 50 instances where the number of vertices ranges from 22 to 202. Finally, the random graph subset was formed by 73 instances derived from the Harwell-Boeing sparse matrix collection [42, 61, 62] introduced at the end of section "The Cutwidth Minimization Problem." In this case, the size of the instances, in terms of the number of vertices, ranges from 24 to 960. The aforementioned set of instances has been used later in [178] and [182].

The SumCut/Profile Problem

Considering the separation value defined in the previous section, the SumCut of a graph G with respect to the linear layout ϕ, denoted as $SC(\phi, G)$, is calculated as the sum of Sep-values of each position. In mathematical terms:

$$SC(\phi, G) = \sum_{i=1}^{n} Sep(i, \phi, G)$$

The SumCut Minimization Problem then consists of minimizing the value of $SC(\phi, G)$ in all possible linear layouts Φ of G:

$$SC(G) = \min_{\phi \in \Phi} SC(\phi, G)$$

Considering the linear layouts ϕ' and ϕ'' depicted in Figs. 8a and 9a, respectively, in Fig. 10a, the computation of the SC-values associated to each layout is shown. In particular, the objective function value associated with the first layout ϕ' is $SC(\phi', G) = 1 + 2 + 3 + 3 + 2 = 11$. Similarly, the objective function value associated with ϕ'' is $SC(\phi'', G) = 1+2+3+4+5 = 14$. Therefore, ϕ' is a better solution than ϕ'' since the SumCut is a minimization problem.

The SumCut was proved to be NP-complete for co-bipartite graphs in [200] and for general graphs in [51, 84]. This optimization problem is equivalent to the Profile Minimization Problem, as stated in [162]. Specifically, the reverse solution of the SumCut corresponds to a solution of the Profile. Both optimization problems have been extensively studied. See, for instance, [52–54]. Practical applications of these problems appear in genetics. The goal of the Human Genome Project is to sequence the DNA of humans, as well as other species, with the goal of elucidating the genetic information contained therein. In order to construct a physical map of a large DNA molecule, it is necessary to extract clones from it. Then, a fingerprint of each clone is obtained. Finally, DNA molecule is reassembled, determining how the clones overlap among them. Each clone is a sequence of nucleotides drawn from the set {adenine, cytosine, guanine, thymine}, so the reassembly process consists of

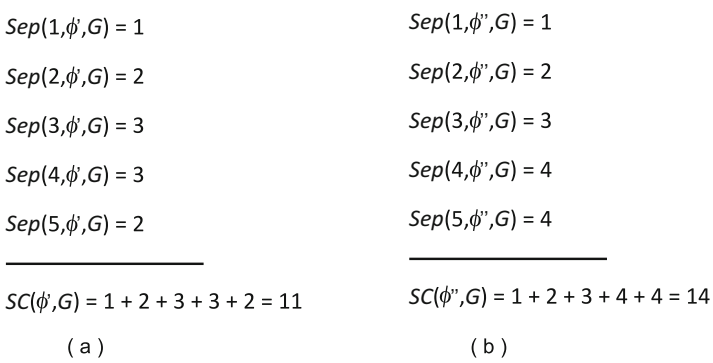

Fig. 10 (**a**) Computation of the objective function of SC for the linear layout shown in Fig. 8a. (**b**) Computation of the objective function of SC for the linear layout shown in Fig. 9a

permuting a linear layout of a graph. In [103] the author described an application in archeology, where it is necessary to serialize different artifacts (fossil, hardware, jewels, etc.). The serialization is known in archeology as "seriation" and consists of placing in chronological order different artifacts in the same culture using a relative dating method. Specifically, the practical application is based on the rearrangement of a matrix, which can be translated on the reordering of a linear layout of a graph.

Reducing the profile of a matrix is a relevant problem in mathematics since it leads to a reduction of the amount of space needed for some storage scheme. On the whole, it achieves an improvement of the performance of several operations such as Cholesky factorization of non-singular systems of equations [175]. Recently the profile reduction has been used in new areas like information retrieval to browse hypertext [22]. The Profile Minimization Problem was originally proposed as a way to reduce the storage space needed to save a sparse matrix [193], but it was shown to be equivalent to the SumCut Minimization Problem [162]. An important application of the Profile Minimization Problem arises in clone fingerprinting [102].

As far as the heuristics are concerned, Cuthill and McKee proposed in [43] the reverse Cuthill-McKee (RCM) algorithm, in order to get the minimum profile of a graph. In order to obtain a solution for the SumCut Minimization Problem, it is only needed to reverse the solution generated. Gibbs et al. [78] solved the SumCut using a new algorithm based on the RCM. The paper describes three problems of the RCM and presents a new algorithm that solves the described problems. Lewis described a method to reorder sparse matrices in order to reduce their profile [120], using the Gibbs-King algorithm to improve the results from the RCM algorithm. The previous algorithms were used not only in Profile and SumCut problems but also in the Bandwidth Minimization Problem, making a small adjustment in the last step: the numbering of the nodes. Lewis [121] presented a Simulated Annealing to reduce the profile of a matrix. The algorithm starts with a previously calculated solution, and it improves the solution by using the Simulated Annealing technique. The original solution is calculated using either the RCM algorithm or the Gibbs-

King algorithm, and the instances used are a subset of the Harwell-Boeing sparse matrix collection [42, 61, 62].

In [180] a new heuristic method based on the GRASP methodology is introduced. As it is shown in the computational experience, the proposed method is competitive with respect to previous approaches. This algorithm is further improved in [179] by coupling it with a Path Relinking post-optimization stage. Then, Sánchez-Oro et al. [181] proposed a new method based on the Scatter Search methodology. Among several mechanisms, this procedure includes Path Relinking as the basis for combining solutions to generate new ones. The most effective heuristic procedure identified in the existing literature is presented by Palubeckis [148] and implements a hybrid VNS with simulated annealing. In a recent contribution, Kardam and Srivastava presented a tabu-embedded simulated annealing algorithm to identify optimal solutions to specific graph classes, including trees of degree four and complete bipartite graphs [100]. This approach represents an advance over a previous research study published by the same authors [99].

In addition to heuristic approaches, some researchers have worked on identifying and proving the optimal profiles of specific classes of graphs. See, for example, [77, 116, 196, 197].

The current reference instances to evaluate the performance of the heuristic algorithms for this problem were proposed in [181] which is, as far as we know, the most complete data set of instances for the problem. In particular, they propose the use of the three different subsets of instances: Harwell-Boeing, bipartite, and tree. The Harwell-Boeing subset was formed by 73 sparse matrices whose number of vertices ranges from 24 to 960, extracted from the well-known collection Harwell-Boeing sparse matrix collection [42, 61, 62]. Notice that instances belonging to this family had been used before in [43] as a test bed for the problem. The bipartite subset is formed by 98 bipartite graphs with a number of vertices ranging from 4 to 142. A complete bipartite graph is such that the set of vertices V can be divided into two subsets V_1 and V_2 in such a way that there exists an edge between every pair of vertices belonging to different subsets. Finally, the tree subset consists of 91 instances based on trees with diameter 4 and a number of vertices ranging from 10 to 100. Optimal objective function values are known by construction for the instances in bipartite and tree subsets.

The Bandwidth Minimization Problem

The Bandwidth Minimization Problem (BMP), also known as Bandwidth Reduction Problem or Matrix Bandwidth Minimization, is an NP-hard min-max linear layout problem [150]. It consists of finding an ordering of the vertices of a graph on a line, in such a way that the largest distance between two adjacent vertices in the corresponding line is minimized. In terms of graph embedding theory, this problem consists of finding the linear layout (*load* equals to 1) that minimizes the *dilation*. In terms of circuit design, the BMP asks for a layout that minimizes the maximum edge length between each pair of connected modules.

Given a graph G and a linear layout ϕ, the bandwidth of a vertex v, $B(v, \phi, G)$, is the maximum of the differences between $\phi(v)$ and the labels of its adjacent vertices. That is:

$$B(v, \phi, G) = \max_{(u,v)\in E} \{|\phi(v) - \phi(u)|\}$$

The bandwidth of a graph G with respect to a layout ϕ is then

$$B(\phi, G) = \max_{v\in V} B(v, \phi, G)$$

The optimal bandwidth of graph G is thus the minimum $B(\phi, G)$ value over all possible layouts Φ of G.

Considering the linear layouts ϕ and ϕ' depicted in Fig. 6a, c, respectively, in Fig. 11a, b, the computation of their bandwidth value is shown. In particular, the objective function value associated with the first layout ϕ is $B(\phi, G) = \max\{5, 2, 3, 3, 4, 5\} = 5$. Similarly, the objective function value associated with ϕ' is $B(\phi', G) = \max\{3, 3, 4, 2, 2, 4\} = 4$. Therefore, ϕ' is a better solution than ϕ since the BMP is a minimization problem.

This problem has also been defined in terms of matrices. In particular, given the incidence matrix of graph G, the problem consists of finding a permutation of the rows and columns of this matrix that keeps all the nonzero elements in a band that is as close as possible to the main diagonal. For that reason, it is possible to find references to this problem as the Matrix Bandwidth Minimization problem.

The main application of the BMP is to solve non-singular systems of linear algebraic equations. The preprocessing of the coefficient matrix to reduce its bandwidth results in substantial savings in the computational effort associated with

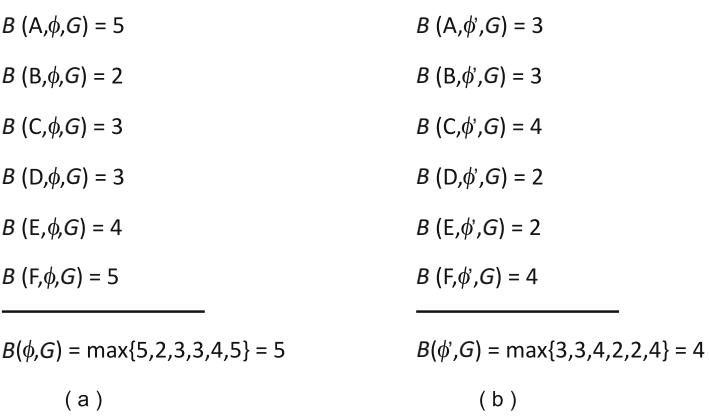

Fig. 11 (**a**) Computation of the BMP objective function for the linear layout ϕ shown in Fig. 6a. (**b**) Computation of the BMP objective function for the linear layout ϕ' shown in Fig. 6c

solving the system of equations. The context of these applications includes aircraft structures, liquid nitrogen gas tanks, propel blades, and submarines. In order to tackle the problem, Del Corso and Manzini in [44] proposed two exact algorithms to solve randomly generated graphs up to 100 nodes.

Similarly, Martí et al. proposed an exact method in [134] based on a branch and bound algorithm, together with several lower bounds, to compute the optimal solution for small- and medium-sized instances. However, the complexity of the problem makes that most of the efforts performed by researchers have been heuristic approaches. In this sense, for many years, researchers were only interested in designing relatively simple heuristic procedures and sacrificed the quality of the solution for speed. This is the case of the reverse method by Cuthill and McKee [43] and the GPS procedure by Gibbs et al. [78]. These two methods yield similar results in terms of solution quality; however, GPS is considerably faster, with an average speed that is about eight times faster than the reverse Cuthill-McKee procedure.

Metaheuristic algorithms have been widely and successfully applied to this problem for several decades. A Simulated Annealing procedure was introduced by Dueck and Jeffs in [60], which is based on an insertion mechanism and does not take advantage of the graph structure as the GPS method does. Martí et al. in [135] propose a Tabu Search method [81] for this problem, based on swap moves that exchange the labels of a pair of vertices and with a memory structure that proves to be remarkably effective. In 2004, Piñana et al. in [157] proposed an algorithm based on GRASP for the problem. In this proposal, the constructive step is based on GPS and the local search is based on exchanges. The GRASP method is coupled with a Path Relinking phase for improved outcomes. This algorithm clearly outperforms all the previous heuristic approaches. In 2006, Lim proposed several algorithms for the problem. In [122] they proposed an Ant Colony Optimization (ACO) [56] method with hill climbing. The same year, in [124], they introduced the node-shift heuristic which computes the desired label of each vertex according to the label of its adjacent vertices and then orders all the vertices in the graph with respect to these desired labels; finally, all the vertices are relabeled following this ordering. This innovative method is repeated until no vertex changes its label and it is coupled with a local search hill climbing. These authors also proposed a Genetic Algorithm [83,91] that generates the solutions in the initial population with a level structure procedure (as the GPS does) and implements a classic midpoint crossover as a combination operator.

In 2007, Lim et al. [123] proposed a Particle Swarm Optimization (PSO) [104] and a hill-climbing method. In 2008, Rodríguez-Tello et al. [169] presented a Simulated Annealing method based on a new neighborhood definition. Instead of swapping the labels of two vertices, these authors introduced a more elaborated move definition that leads to an efficient search, as shown in their computational results. Other notable approaches from this period include several strategies based on Variable Neighborhood Search proposed by Mladenovic et al. in [144], an adaptation of Tabu Search and Scatter Search by Campos et al. in [23] and a Genetic Algorithm proposed by Pop and Matei [158].

In 2011, Koohestani and Poli [114] introduced a hyper-heuristic approach for bandwidth reduction based on genetic programming, marking a shift toward more sophisticated metaheuristic techniques. Since then, there have been significant advances in metaheuristic approaches for this problem. Pop et al. [159] further improved their genetic algorithm proposed in [158], demonstrating its efficiency compared to other existing methods. Torres-Jimenez et al. [195] introduced a dual representation simulated annealing algorithm (DRSA) that showed superior performance in benchmark instances and which is considered, since then, the state of the art of the problem. Gonzaga de Oliveira et al. [85] conducted a comprehensive evaluation of low-cost heuristics for matrix bandwidth and profile reductions, identifying the most promising methods for various applications.

In recent years, there has been a trend toward hybridization. Mafteiu-Scai et al. [131] applied Brain Storm Optimization to the problem, while De Oliveira and Silva [47] proposed an ant colony hyper-heuristic approach for evolving reordering algorithms. Later, De Oliveira and Silva [48] combined low-cost heuristics with a Hill-Climbing strategy, demonstrating improved performance on matrices with symmetric sparsity patterns. In 2023, Koohestani [115] introduced a new metric to guide informed search methods, addressing limitations in previous approaches. Most recently, Abreu and Gonzaga de Oliveira [2] proposed a hybrid method combining Iterated Local Search and Tabu Search, while Maues et al. [138] introduced a multi-centrality heuristic for the Bandwidth Reduction Problem, showcasing the ongoing innovation in this field.

While the classical BMP focuses on linear layouts, there is growing interest in studying this problem where the embedding is performed into alternative host graph structures. Of particular significance are embeddings into cycles, grids, and trees. The Cyclic Bandwidth Problem (CBP), which considers embeddings into cycle graphs, has garnered attention with works such as Rodriguez-Tello et al. [170] proposing a tabu search approach, Ren et al. [163, 164] developing iterated local search algorithms, and more recently, Fertin et al. [67] combining preexisting knowledge with constraint programming techniques. Grid embeddings, explored in the Two-Dimensional Bandwidth Minimization Problem (TDBMP), have been addressed by Rodríguez-García et al. [173] with exact and heuristic approaches, Cavero et al. [32] proposing an efficient iterated greedy algorithm, and Khandelwal et al. [105, 106] exploring reduced variable neighborhood search and simulated annealing techniques. On the other hand, the study of graphs into trees has been mainly studied from a theoretical perspective, with seminal works by Bienstock [14] characterizing graphs that have small optimal overlap, Ostrovskii [49] investigating minimal congestion trees, and Rajasingh et al. [160] focusing on embedding cycles and wheels into arbitrary trees.

The data set of instances used as a reference to test algorithms for the BMP is again derived from the Harwell-Boeing sparse matrix collection [42, 61, 62]. Its application can be traced back to the first papers on heuristic approaches. In particular, the current data set is composed of 113 instances, and it is divided into two subsets. The first subset consists of 33 instances with a number of vertices ranging from 30 to 199, and the second subset includes 80 instances with a number

of vertices ranging from 200 to 1000. This data set was first introduced in [135], where the authors selected 126 instances, and then it was reduced to its current state in [157] by considering just 113 instances. The data set has been used in almost all the papers in the latter literature of the BMP.

Conclusions and Future Lines of Research

In this chapter, a family of graph layout problems is reviewed. Graph layout problems are optimization problems where the main objective is to project an original graph into a predefined host graph. In particular, five linear layout problems are reviewed, where the host graph is a path graph, and the aim is to minimize an objective function. This is probably the most studied family of problems in the heuristic literature within the context of graph layout problems. Specifically, this chapter reviews the Cutwidth Minimization Problem, the Minimum Linear Arrangement Problem, the Vertex Separation Problem, the SumCut Problem, and the Bandwidth Minimization Problem. Each problem is first defined and then illustrated with a detailed example. Additionally, the most relevant methods in the literature and the sets of instances used to evaluate them are also reviewed. The wide variety of heuristic algorithms sets a deep understanding of strategies to reach high-quality solutions to the minimization of linear layout problems. However, recent trends are pushing the boundaries of what is possible in graph layout optimization:

- Integration of exact algorithms with heuristics to find the optimal solution for larger graphs.
- Parallel algorithms enable the processing of significantly larger graphs by distributing computations.
- Machine learning techniques are being explored to learn effective layout strategies from the input data.
- Multi-objective optimization approaches are being developed to balance competing layout criteria.
- Techniques for dynamic graphs are emerging to efficiently update layouts as graphs evolve over time.
- Domain-specific heuristics are being tailored for applications in areas like social networks and bioinformatics.
- Interactive visualization systems are incorporating user feedback to guide the layout process.

These advancements are not only improving the scalability and efficiency of graph layout algorithms, but also expanding their applicability to more complex, real-world scenarios. In this sense, future research should also focus on extending current knowledge to embeddings graphs in nonlinear structures like grids, trees, cycles, or even general graphs.

Abstract

Vehicle routing problems are among the most widely studied combinatorial optimization problems. Different classes of routing problems exist which all share a common set of decisions: assigning customers to vehicles and defining the sequence of visit for each vehicle, i.e., determining vehicle routes in order to minimize a given cost function. Problems might differ in the objective function and in the presence of additional constraints. However, routing decisions (plus eventually additional problem-specific decisions) make routing problems extremely challenging. For this reason, the research community has concentrated big efforts on the development of efficient heuristic solution approaches. In this chapter, we first briefly introduce the earliest and most classical heuristic algorithms. Then we concentrate on the most recent developments on heuristics for routing problems, namely, metaheuristics, matheuristics, learning approaches, and heuristics for large-scale problems. We provide reference contributions and discuss the key features of each class of methods, concentrating on the most recent research trends.

Introduction

The Capacitated Vehicle Routing Problem (CVRP) was first introduced by [39] under the name "The Truck Dispatching Problem." The CVRP can be defined on a directed graph $\mathcal{G} = (\mathcal{V}, \mathcal{A})$ where $\mathcal{V} = \{0, 1, \ldots, N\} = \{0\} \cup \mathcal{N}$ is the set of vertices and $\mathcal{A}$ is the set of arcs. Node 0 represents the depot and $\mathcal{N} = \{1, \ldots, N\}$ is the set of customers to be served. Each customer $i \in \mathcal{N}$ requires a positive quantity Q_i of a product. At the depot, a fleet of M vehicles, each of capacity Q, is available to perform deliveries. Each arc $(i, j) \in \mathcal{A}$ is associated with a nonnegative weight C_{ij} which represents the traveling cost to reach node $j \in \mathcal{V}$ from node $i \in \mathcal{V}$.

The CVRP calls for determining at most M routes such that:

- Each route starts and ends at the depot 0.
- Each customer is visited exactly once.

- The sum of the demands of the customers served in each route does not exceed the vehicle capacity Q.
- The total traveling cost is minimized.

Since its introduction, a huge number of papers have studied the CVRP. Scholars have also concentrated their efforts on variants and extensions of the problem. These variants are meant to better capture the reality of operations by considering real-life aspects of routing problems. One of the most studied variants is for example the Vehicle Routing Problem with Time Windows (VRPTW, [28, 29, 42, 119]) in which each customer $i \in \mathcal{N}$ is associated with a time interval $[E_i, L_i]$ during which service should take place. The VRPTW has attracted a lot of attention and recently more complicated variants emerged, like the VRP with multiple time windows (see, e.g., [65] for an interesting methodological contribution).

An extensive review of the complete vehicle routing domain is out of the scope of the present chapter. The interested reader is referred to [27, 37, 56, 95, 123] and the references therein. Even providing an exhaustive list of variants has become a complicated task. Some efforts have been made to provide a taxonomy or to classify routing problems based on the problem attributes considered (e.g., [27, 45, 76]). A more recent discussion of problem attributes can be found in, e.g., [133].

Scope The scope of the present chapter is to specifically review heuristic methods that have been developed to solve Vehicle Routing Problems (VRPs). Works with a similar aim have already been conducted, as for example in the book chapters of [81, 82] or the papers by [28, 29, 88, 129].

As a result, we only briefly discuss classical heuristics for VRPs as this topic has already been widely covered in previous published material. On the other hand, we concentrate our discussion on state-of-the-art metaheuristics, on matheuristics and on recent advances on the topic such as knowledge discovery, machine learning, and the resolution of large-scale instances.

Still, due to the huge amount of publications on the subject, it is not possible to provide an exhaustive list and discussion within the context of a single chapter. We rather provide an overview on some selected topics and guide the reader toward references for an in-depth analysis.

Organization The reminder of the chapter is organized as follows. Section "Classical Heuristics" provides an overview on classical heuristics for VRPs. The topic of this section has already been covered by other works. Thus, it is simply intended to provide a glance at the subject and guide the interested reader toward appropriate material. Section "Metaheuristics" is dedicated to metaheuristics for VRPs. As for section "Classical Heuristics," the topic of this section has been already partially covered by other works. As a consequence, we only concentrate on recent advances on the subject. Section "Matheuristics" concentrates on matheuristics for VRPs where the focus is on discussing the most popular schemes and commenting on the potential of matheuristics. Section "New Research Trends" presents latest trends on

the subject such as the inclusion of knowledge discovery or machine learning bricks in the resolution of VRPs. Section "Instances and Libraries" lists available open-source codes dedicated to the resolution of VRPs and instances classically used by the community to compare solution approaches. Finally, section "Conclusion" concludes the chapter.

Classical Heuristics

The term *classical heuristics* indicates procedures that do not contain components that allow the objective function to deteriorate from one iteration to the next [80]. As a consequence, classical heuristics get trapped at the first local optimum they encounter. Including mechanisms to escape from local optima leads to the so-called *metaheuristics*.

Classical heuristics have been the focus of the research development from the introduction of the VRP to the 1990s. The main characteristics of classical heuristics are simplicity and rapidity of execution. Despite that, successful classical heuristics are able to provide good-quality solutions. This is the reason why they are still embedded in most of the state-of-the-art solvers.

Classical heuristics are usually classified in two categories: constructive (section "Classical Constructive Heuristics") and improvement heuristics (section "Classical Improvement Heuristics"). Procedures in the former family build one step after the other a solution from scratch. Procedures in the latter family get a solution as input and attempt to improve its quality.

The material presented in this section has already been largely discussed in previous papers or book chapters such as for example [28, 82, 88, 129] to which the interested reader is referred. To avoid repetitions and due to space limitations, here we present the conventional classification of heuristics, report what we believe are the key concepts, and provide references to the interested reader.

Classical Constructive Heuristics

Constructive heuristics, as the name indicates, have the objective of constructing a solution from scratch. Classical constructive methods for routing problems are usually categorized into two subcategories. The first contains construction methods properly said, whose objective is to build a solution from scratch attempting to minimize the routing cost of the overall solution. Simple insertion heuristics that insert customers one after another in routes fall in this category [31]. Another well-known example of such methods is the Clarke and Wright heuristic [35].

The second category contains two-phase methods which take advantage of the two decisions to be taken in routing problems, that is, which customers are served together by the same vehicle and how to route vehicles, to decompose the construction in two phases. Based on which decision is taken first, such methods fall in the *Route First-Cluster Second* category or *Cluster First-Route Second* category.

An example of former is the Split algorithm [17, 103], whereas an example of the latter is the Sweep algorithm [54].

Classical Improvement Heuristics

Classical improvement heuristics start from a given initial solution and attempt to improve its quality, usually by applying a sequence of modifications to the initial solution received as an input.

Modifications are usually classified into *intra-route* and *inter-route* modifications. The procedures in the former category do not modify the assignment of customers to vehicles but rather focus on improving the routing cost needed to visit all customers assigned to a given vehicle. Instead, *inter-route* heuristics allow moving customers from one route to another.

As *intra-route* heuristics, one can use heuristics designed for the Traveling Salesman Problem (TSP) such as the k-opt heuristic. Basically, k-opt removes k edges of the current solution and replaces them with k other edges. The reader is referred to [62, 87]. Recent works have proposed procedures to reduce the exploration burden of 2-,3-, and 4-opt neighborhoods [77–79]. Classical *inter-route* heuristics are relocation of sequences of customers from one route to another route or the exchange of sequences of customers between routes.

For a more detailed discussion of both *intra-route* and *inter-route* operators for routing problems, we refer to [88, 129]. Clearly, specific problem variants may require specific types of heuristics; see, for example, [99] for a discussion of neighborhoods for paired pickup-and-delivery problems and their efficient exploration.

The performance of the improvement heuristics relies on the efficient exploration of the neighborhood of a solution and evaluation of the impact of modifications. Constant time evaluation and feasibility checks can be easily obtained when the problem at hand is the CVRP. However, when side constraints such as time windows are taken into account, achieving such constant time evaluations requires special care.

A first work in this direction in the context of the VRPTW is the paper of [114], which proposes a methodology to check the feasibility of a move in constant time, which allows to fully explore the neighborhood defined by k-opt moves in $O(N^k)$, given the requirement that the lexicographic order induced by the arcs in the current solution is followed to perform subsequent checks.

However, most heuristics for the VRPTW allow violations of the TW constraints by penalizing them in the objective function. Usually, a penalization function that is linear on the delay is used (see, for example, [15]). This allows an evaluation of classical neighborhoods in $O(N)$. Nagata et al. [97] propose the concept of *time-warp*: Whenever the vehicle arrives late at a customer, it is assumed that it can travel back in time to meet the closing of the TW and to start the service of the corresponding customer without delay, but at the expense of paying a penalty proportional to the original delay. This result is extended in [129], which shows that classical operators for routing problems can be seen as a concatenation

of subsequences of customers and TW penalty violation can be evaluated in constant time.

It goes without saying that specified information needs to be stored to obtain such computational complexity. The interested reader is referred to [129, 132].

Metaheuristics

Historically, metaheuristic methods have been classified into two categories: trajectory-based and population-based methods. The first class of methods manage a single solution at a time, which is attempted to be improved as much as possible. The second class of methods simultaneously manage a set of solutions.

Trajectory-based metaheuristics Until the 1990s the heuristic procedures developed by researchers to solve routing problems were mainly trajectory-based due to the fact they are rather simple, easy to understand and to implement. A well-known example includes the TABUROUTE algorithm of [53]. Trajectory-based procedures start from an initial solution s_0 and, at each iteration, move from a solution s_i to another one s_{i+1} in its neighborhood. If only improving solutions are accepted, the procedure converges to a so-called local minimum. To allow the process to continue the exploration of the solution space, also non-improving solutions may be accepted. However, in such case, care should be taken to avoid cycling.

Different mechanisms have been proposed in this regard. This has led to well-known procedures such as Iterated Local Search (ILS), Tabu Search (TS), Simulated Annealing (SA), Deterministic Annealing (DA), Variable Neighborhood Search (VNS), and Guided Local Search (GLS), which have all been widely applied to routing problems. The interested reader is referred to [75, 81, 88]. These procedures typically make use of the classical improvement heuristics from section "Classical Improvement Heuristics" in the local search part.

Population-based metaheuristics Population-based metaheuristics maintain a set of solutions (a *population*) and are often inspired by natural phenomena to gradually find better solutions. Evolutionary Algorithms (EA), such as Genetic Algorithms (GA), are one example. They simulate the paradigm of evolution by creating new solutions (i.e., *individuals*) from combining interesting parts of current solutions in the population. Other population-based approaches that rely on recombining solutions include Path Relinking (PR) and Scatter Search (SS). Finally, approaches such as Ant Colony Optimization (ACO) and Particle Swarm Optimization (PSO) are based on ideas from swarm intelligence. See for example [75, 129] for a more detailed discussion.

Although these population-based methods gained some initial attention, they were often not very popular neither competitive. Good-quality results started to be achieved when local search procedures were systematically embedded in the design of the algorithm, giving rise to procedures that are sometimes called *memetic* algorithms ([98], see also section "Hybridization and State-of-the-Art

Frameworks"). In addition, it is noteworthy that many current well-performing population-based algorithms rely on a giant tour representation of a solution (i.e., a solution is encoded as a single sequence of customer visits). This concept has gained much popularity since [103] made use of the Route-First Cluster-Second procedure proposed in [17] to evaluate such individuals in the population. Prins [103] applies a procedure, called *Split*, to cut/split the sequence of visits in the routes to be performed by vehicles. The strength of the *Split* procedure is to be able to obtain the optimal solution associated with a sequence of visits in polynomial time. More recently, [126] showed that *Split* can be implemented to obtain a linear complexity in the cardinally of $\mathcal{N}$.

Finally, in the past two decades, we have witnessed a myriad of new metaheuristic approaches based on all kinds of human, natural, or other phenomena, which are often population-based. However, these so-called metaphor-based heuristics are receiving increasing levels of criticism from the metaheuristics research community, among others due to their common lack of novelty and use of nonstandard terminology (see, e.g., [120, 134]). For a recent discussion on this matter, we refer to [6].

In the remainder of this section, we turn to current state-of-the-art metaheuristic approaches for routing problems (section "Hybridization and State-of-the-Art Frameworks"), discuss some unification attempts (section "Unified Methods"), and provide a concluding discussion (section "Metaheuristics: Discussion").

Hybridization and State-of-the-Art Frameworks

It is well known by now that most well-performing metaheuristic algorithms rely on some form of local search and typically use ideas of different classical frameworks [123]. This leads to the so-called hybrid metaheuristics. Commonly applied ideas in the context of trajectory-based algorithms include the use of multiple neighborhoods (cfr. VNS), restart procedures (cfr. Greedy Randomized Adaptive Search Procedure, GRASP), accepting worsening solutions (cfr. SA), perturbation mechanisms (cfr. ILS), and short- and long-term memory aspects (cfr. TS, GLS). For population-based methods, hybridization often results in the integration of local search procedures to improve new individual solutions.

There is no single metaheuristic algorithm that can deal with every routing problem (see also section "Unified Methods,") and the best-performing algorithms on different problem variants may be composed of considerably different building blocks. Yet, the remainder of this section focuses on a few algorithm frameworks that have become highly popular in recent years and/or have recently obtained state-of-the-art results on the classical CVRP and several closely related variants. We provide a discussion of the advantages of each framework. Although this is by no means an exhaustive list, we believe that these algorithm frameworks are representative of the current state of the art on metaheuristic algorithms. Note that some other recent and highly competitive algorithms (e.g., [3, 13]) are discussed in section "New Research Trends."

Hybrid Genetic Search

A state-of-the-art algorithm for the CVRP and many of its variants is the Hybrid Genetic Search with Advanced Diversity Control algorithm (or Hybrid Genetic Search (HGS) in short) introduced in [128, 130]. It was later extended to allow addressing an even wider set of VRP variants [131], while recently an open-source re-implementation specifically for the CVRP was presented [127]. The algorithm provides state-of-the-art results on numerous problem variants and, exemplary for its effectiveness and popularity, it was the backbone for most of the competitive approaches in the recent 12th DIMACS Implementation Challenge on vehicle routing (http://dimacs.rutgers.edu/programs/challenge/vrp/).

The HGS algorithm relies on three key elements: exploration via the use of a population-based evolutionary search framework, intensification via local search procedures to improve new individuals in a population, and advanced population management with specific attention for population diversity.

In terms of the evolutionary search, solutions are encoded using a giant tour representation, and the algorithm maintains a subpopulation of feasible solutions and one of infeasible solutions. For the latter solutions, infeasibilities are penalized in the objective function. New individuals (*offspring*, *childs*) are found by applying a crossover operator on two solutions (*parents*) from the current population, selected via a binary tournament. Next, they are improved (*educated*) using local search operators, and, if required, restoring feasibility is attempted (*repair*). The population management scheme, which decides which solutions to add and maintain in the population, evaluates solutions on a measure that combines their objective value and a diversity measure, indicating a solution's diversity from other solutions in the population. It ensures population diversity while always maintaining the best (*elite*) solutions, thereby guaranteeing good performance and avoiding premature convergence.

One of the advantages of HGS is that it is very flexible in the sense that one can apply it to every problem for which a solution can be represented as a giant tour and decoding (or splitting) the tour into a solution for that giant tour is relatively computationally efficient. Finally, note that researchers are continuously exploring improvements of HGS and its components (e.g., [67, 91]), applying the HGS framework to other routing problems (e.g., [107]) and its hybridization with other heuristic frameworks (e.g., [117]).

Iterated Local Search

The Iterated Local Search (ILS) framework [89] has been frequently applied to address routing problems. It repeatedly optimizes a solution until a local optimum is found, after which the solution is perturbed to escape from this local optimum. A nice application includes the work of [100] which is a multi-start local search where multiple neighborhoods are applied in random order. The algorithm has been enriched with a Set Partitioning phase (resulting in a matheuristic algorithm, see section "Matheuristics") and applied to a variety of routing problems by [121].

More recently, state-of-the-art results on the CVRP are obtained by [93, 96]. Máximo and Nascimento [96] propose a hybrid ILS and Path Relinking (PR) algorithm. They first propose an adaptive version of ILS (AILS) in which both the degree of perturbation and the acceptance criterion are managed by adaptive strategies. The perturbation degree is guided by the distance between local optima and reference solutions. For the adaptive acceptance criterion, the underlying rationale is the observation that promising regions of the solution space contain several good-quality solutions, calling for intensification of the search (i.e., reduce the acceptance threshold), while non-promising regions require diversification. Next, they hybridize the AILS algorithm with a PR procedure (AILS-PR). Applied to the CVRP benchmark instances of [125], the AILS-PR algorithm leads to the current state-of-the-art results. To efficiently solve very large-scale instances, [93] propose to remove the PR procedure but instead integrate its underlying idea in the AILS algorithm, leading to a so-called two-phase AILS algorithm, or AILS-II, which is competitive for small- and medium-scale instances and outperforms previous approaches on large-scale instances.

A clear advantage of ILS is its conceptual simplicity. Yet, it may require problem-tailored local search operators, making it less straightforward to develop flexible algorithms that can tackle multiple problem variants. Additionally, in order to achieve state-of-the-art performance, it seems that integration with other methodologies (e.g., set partitioning, path relinking) may be worthwhile.

Large Neighborhood Search

Large Neighborhood Search (LNS) is a metaheuristic framework which builds upon the ruin-and-recreate principle introduced by [115, 116]. The idea is to iteratively partially destroy a solution (i.e., removing some customers) and then repair the solution again (i.e., reinserting the customers in the solution). As such, a large neighborhood of the current solution is implicitly defined, making it possible to move to solutions that cannot be attained by simple local changes as in classical improvement heuristics. The successful general-purpose LNS algorithm of [101] can address a variety of VRPs and employs multiple operators to destroy and repair solutions, randomly selecting which ones to apply in each iteration. An adaptive version (ALNS) is introduced by [109] in which the selection of operators is based on their ability to improve solutions in past iterations. For more details, the reader is also referred to [102].

(A)LNS can be considered a hybrid algorithm as typically multiple destroy and repair operators are applied, and often deteriorating solutions may be accepted during the search (e.g., using a SA-like acceptance criterion). Basic removal operators include *random* (randomly selecting customers to remove), *worst* (removing customers which result in the largest objective value improvements when removed), and *related* removal (removing requests which are similar in some way, for example, with respect to spatial or temporal aspects, and hence easy to interchange in solutions). Repair operators are often based on greedy heuristic approaches, like *best*, *greedy*, or *k-regret* insertion, although exact methods could be applied as well.

Over the past two decades, (A)LNS has become one of the most commonly applied heuristic frameworks for routing problems. Although it may not (or no longer) provide the very best results on classical problems like the CVRP and VRPTW, it seems mainly popular for more complex and tightly constrained problem variants for which it may be more difficult to find powerful local search procedures, and for problems like paired pickup-and-delivery problems (e.g., the Pickup-and-Delivery Problem with Time Windows, PDPTW) for which giant tour representations (like the one used in HGS) are more difficult to handle, for example, in terms of move evaluation (see, e.g., [32, 38]). Another advantage of (A)LNS is its ease and speed of implementation, as implementing one or few operators is sufficient to obtain a working algorithm. However, achieving excellent results often requires implementing and testing multiple problem-specific removal and insertion operators (e.g., [40, 44]). Along those lines, some recent contributions have shown the value of alternating between large and small neighborhoods [44, 83].

In contrast, [32] take a different approach in their very effective LNS-based algorithm, denoted Slack Induction by String Removals (SISRs). This method only relies on a single removal and a single repair operator, *adjacent string removal*, and *greedy insertion with blinks*, respectively. The removal operator focuses on introducing both spatial and capacity slack in solutions by removing adjacent strings of customers (i.e., segments of different routes that are spatially close to each other). Repairing a solution is done through a slight variation of *greedy* insertion by randomly ignoring some insertion positions. Finally, the algorithm also contains a dedicated procedure which minimizes the number of vehicles used, and it has been shown to lead to very competitive results on the CVRP and several variants.

Unified Methods

Routing problems are ubiquitous and appear in diverse applications and contexts, each with their own specific objectives and constraints, and often part of a larger decision-making process. As such, the list of VRP variants that have been studied is endless. While early research mainly focused on a limited number of well-defined problem variants with simple objectives and few side constraints, the last decades have seen the appearance of more complex problem variants with many side constraints and more intricate objective functions (sometimes denoted *rich* VRPs or *multi-attribute* VRPs).

Even though there are some generally accepted generic metaheuristic frameworks (e.g., ILS, LNS, GA), these often require tailor-made components for searching and evaluating new solutions. As a result, in many cases, heuristic algorithms are developed for very specific problem variants, whether it being classical problems or multi-attribute ones. Although this has its merits, it often limits the generalizability of these algorithms and may hinder the uptake of new ideas.

In contrast, unified algorithms aim at addressing a variety of problems with a single algorithm implementation. Over the past decades, only limited research attention has been devoted to such unified methods. Some examples include [36, 68, 110, 121, 131]. Results indicate that having more general methods does

not necessarily come at the expense of solution quality [131]. Therefore, it seems worthwhile to further focus on such methods in the future. This may also link to the domain of hyper-heuristics in which the goal is to find automated ways of selecting or generating (meta)heuristic algorithms depending on the problem at hand (see, e.g., [30, 43] for recent overviews on this domain).

Metaheuristics: Discussion

As is clear from the previous sections, the metaheuristics field has evolved considerably over the past decades. Before the 2000s, competitive approaches for VRPs were mostly trajectory-based (e.g., [53]), relying on one of the several classical frameworks and often on simple local search procedures. Later, different new trends appeared. These include the use of multiple, more complex and larger neighborhoods and applying conceptual ideas and building blocks from multiple original frameworks, leading to hybrid algorithms. Furthermore, recent years have shown the effectiveness and efficiency of population-based algorithms based on giant tour representations, especially when being combined with local search-based intensification steps and population diversity management. At the same time, researchers are considering more and more problem extensions, inspired by real-life characteristics and constraints, leading to an ever increasing list of VRP variants being considered. Together, this has led to a huge variety of (often complex) metaheuristic algorithm configurations being applied to many different problems, making it often hard to compare contributions and generalize findings. As such, instead of developing further overly complex hybrid algorithms, a key future research opportunity may include developing more simple and more generic metaheuristic algorithms.

Matheuristics

According to the definition proposed in [25] and adopted also in [10], *matheuristics* are "heuristic algorithms made by the interoperation of heuristics/metaheuristics and mathematical programming techniques." More specifically, as done in [10], we will consider in the following only approaches embedding the solution of a mathematical programming formulation. Other approaches have been classified as matheuristics as well, like heuristics which embed an exact algorithm based on dynamic programming (see [104] and more recently [23, 48]), but they will not be the topic of this section.

Archetti and Speranza [10] classify matheuristic algorithms for routing problems in three main classes:

1. *Decomposition approaches*: As the term says, in this case the problem is decomposed into multiple subproblems and at least one of them is solved through a mathematical programming formulation.

2. *Improvement heuristics*: In this case the mathematical programming formulation is used to improve the solution found through a heuristic approach.
3. *Branch-and-price/column-generation-based approaches*: These approaches include both the well-known class of restricted master heuristics and the approaches based on heuristic column generation.

We are going to adopt the same classification in the following, as we believe it is still consistent even considering the more recent literature that was not included in the former survey. However, the goal here is to explain the general idea behind each of the matheuristic schemes mentioned above and present the most relevant applications in the routing literature, rather than presenting an exhaustive survey of contributions since the paper of [10].

Also, we will propose an analysis of the advantages and disadvantages of these schemes, discussing the motivations of why they became popular for some problem classes, when possible.

Decomposition Approaches

As their name implies, decomposition approaches are based on the idea of decomposing a problem in subproblems (typically easier to solve than the original problem). Each subproblem is solved separately, and the corresponding solutions are combined to obtain a solution to the original problem.

A first approach belonging to this class dates back to 1981 with the work by [49], in which a matheuristic is presented for the classical CVRP. Specifically, the algorithm first assigns customers to vehicles by solving to optimality an assignment problem. Then, the route of each vehicle is determined by solving a TSP over the customers assigned to the vehicle plus the depot. The assignment problem solved in the first phase uses, as objective function, an approximation of the routing cost related to the constructed assignment. The authors propose different schemes to approximate the routing cost, the first and simpler one being based on the idea of:

1. Identifying seed customers, one per vehicle
2. Assigning remaining customers to seed customers, on the basis of a given insertion cost

An illustration of the two steps of the first phase is presented in Fig. 1, taken from [49], where customers 4, 7, 10, 13, 18, 20, and 24 are seed customers (step 1) and the dashed lines represent the calculation of the insertion cost for assigning customer 23 to the cluster of seed customer 24.

In the second phase, the TSP associated with each vehicle is solved through a mathematical formulation in [49].

This scheme belongs to the class Cluster First–Route Second, already introduced earlier. Many matheuristics belonging to this class used this idea, developing different approaches for the solution of each of the two phases. Specifically, it is

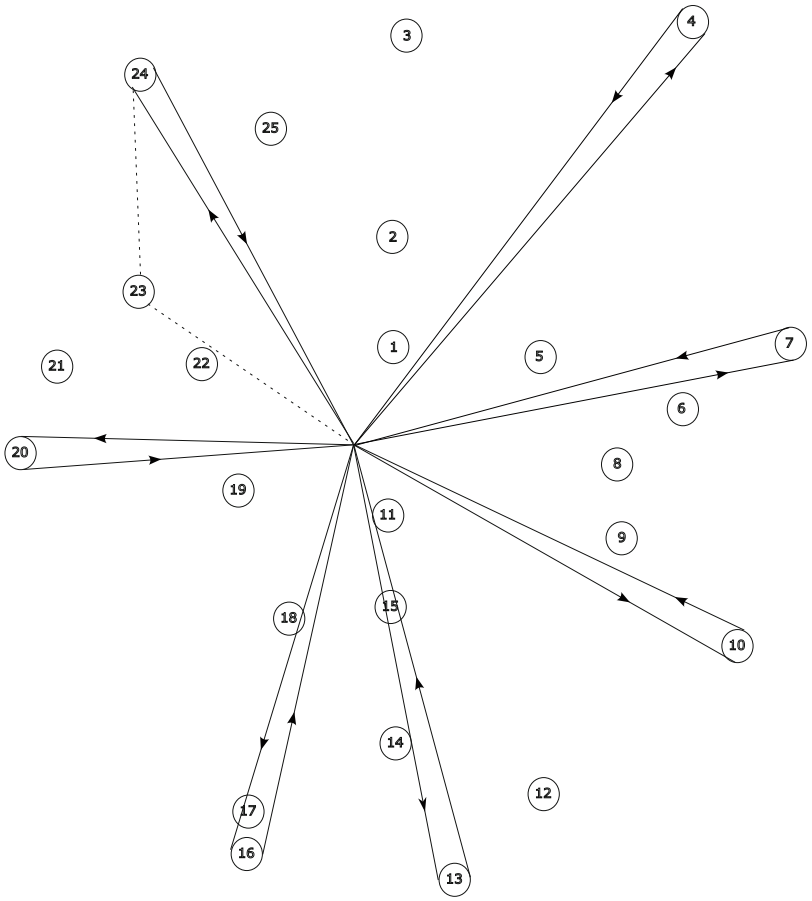

Fig. 1 Illustration of the two steps of phase 1 of Fisher-Jaikumar's algorithm

quite common to solve the second phase by using a heuristic for the TSP. For example, in [1] the authors use the Lin-Kernighan heuristic [87]. Also, as noted in [10], the scheme originally proposed in [49] has evolved in different ways, one of the most effective being the iterative use of the two steps described above. The main idea behind such an iterative approach is to modify the objective function used as an approximation of the routing cost in the first step at each successive iteration, with the aim of obtaining different (and hopefully better) solutions at each iteration. One of the first contributions proposing such a scheme is [47] where the authors solve an Inventory Routing Problem (IRP). Also, [1] proposed a similar idea for the solution of the Production Routing Problem (PRP). We now briefly describe the main idea behind the iterative approach proposed in the latter paper, as it presents a simple and easy rule for the update of the approximation cost. Specifically, the approximated routing costs are set and updated as follows:

1. In the first iteration, and differently from [49], each customer is associated with an approximated routing cost corresponding to the back-and-forth trip from the depot to the customer.
2. In the following iterations, the approximated routing cost associated with each pair customer route is calculated as the cheapest cost for inserting the customer in the route.

Thus, the idea is to keep updating the routing costs in the attempt to obtain a new (and hopefully better) solution for the PRP, once the solution is completed by determining the routes associated with the new assignment.

A second popular type of methods belonging to the class of decomposition approaches is the one known as *rolling horizon* methodologies. These methods focus on routing problems involving the time dimension, specifically, routing problems over multiple periods, and can be considered as a specific case of the general rollout policy for sequential decision-making [22]. The main idea is to decompose the problem into subproblems associated with a shorter time horizon than the original problem and to solve them sequentially. The solution of a subproblem determines the value of the corresponding set of variables which remain then fixed when solving the subsequent subproblems. This approach was first proposed in [105] for the solution of an IRP arising in maritime logistics. It is in general mostly applied to IRPs and PRPs, problems for which the time horizon spans over multiple periods. The general scheme of the rolling horizon approach is presented in Fig. 2, taken from [105]. At each iteration k, subproblems already solved determine what is referred to as *frozen periods* in the figure. The *central period* corresponds to the subproblem solved at iteration k. Subproblems corresponding to periods following the central period might be ignored or included with some relaxed constraints, as done in [105].

Finally, we mention the recent increase in contributions in which Kernel Search (KS) is applied to different variants of routing problems. KS is a matheuristic scheme, belonging to the class of decomposition approaches, consisting of the following main steps. Given a mathematical formulation of the problem to be solved:

1. Rank variables according to a given criterion.
2. Cluster the variables in bundles following the order defined in step 1.

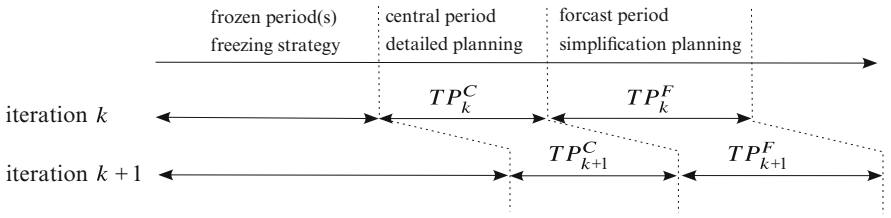

Fig. 2 Illustration of the rolling horizon approach

3. Iteratively solve subproblems corresponding to the original problem formulation restricted to the set of variables in each bundle. Bundles are considered sequentially as generated in step 2.
4. Return the best solution found in step 3.

KS is a general matheuristic scheme that has been successfully applied to many combinatorial optimization problems [23, 24, 60, 92]. However, its application to routing problems is relatively recent [8, 55, 71]. One of the reasons is related to the fact that step 1 poses specific challenges in routing problems. In fact, in most of the earlier contributions on KS applied to combinatorial optimization problems different than routing, the criterion used to sort variables in step 1 is based on the solution of the relaxation of the original problem formulation. However, in routing problems, this criterion does not work properly as:

- Compact formulations tend to provide weak bounds. Thus, the information gathered from the linear relaxation is almost useless.
- Non-compact formulations (for example, those with exponentially many subtour elimination constraints) are difficult to handle and, often, they are time-consuming so not suitable for a heuristic approach.

This drawback has been overcome in [8, 55, 71] by proposing a ranking of variables not based on solving a problem formulation but instead, for example, as in [8], on the frequency with which variables appear in good solutions found by a heuristic algorithm run a priori.

Improvement Heuristics

Improvement heuristics use a mathematical programming formulation to improve the solution found by a heuristic. As described in [10], the mathematical formulation can be used as a move operator, as an intensification operator, and, also, in a single shot or iteratively. Some interesting schemes that emerged in the literature are the following:

- *Exploiting the information gathered from the heuristic run to solve a restricted formulation*: The main idea in this case is to store information related to solutions visited by a heuristic algorithm during execution, with the assumption that these solutions are good, at least in their corresponding neighborhood. This information is then exploited by solving a restricted version of the mathematical formulation associated with the original problem, where, for example, variables associated with features of solutions that have never (or almost never) been visited by the heuristic are set to zero, as not promising. An example of this approach is provided in [9] for the solution of the Directed Profitable Rural Postman Problem (DPRPP), which is a generalization of RPP in which a profit is associated with a subset of the arcs and the objective is to find a tour that

maximizes the difference between the total collected profit and the traveling cost. The authors propose a matheuristic where first a TS is run. During execution of the TS, information about profitable arcs traversed in the visited solutions is collected. At the end of the TS run, this information is used to classify profitable arcs in *good, bad, dubious*. Finally, the DPRPP formulation is solved by imposing constraints (namely, variable fixing) that forbid to choose bad arcs, impose to choose good arcs, and leave a free decision for dubious arcs. This way the size of the solution space is reduced, and thus the formulation can be solved efficiently, hopefully providing an improving solution with respect to the one found by the TS.

- *Using a mathematical programming formulation as an operator*: There have been different applications of this kind of scheme. One that deserves to be mentioned is related to the application of such an operator to variants of routing problems which include quantity decisions, i.e., when it has to be decided what is the quantity that should be delivered to customers when visited. This situation happens, for example, in the Split Delivery Vehicle Routing Problem (SDVRP), the IRP, and the PRP. In this case, in order to decide the quantity to be delivered at each customer visit, one needs to define an operator based on continuous variables, contrary to most of the standard routing operators which are combinatorial in nature. For example, the large majority of the heuristic algorithms proposed in the literature for the solution of the IRP use a mathematical programming formulation to define delivery quantities (see [7] for an earlier example).
- *Using a mathematical programming formulation as an intensification operator*: The idea in this case is to use the mathematical programming formulation to intensify the search around an already good solution. An early example of this scheme is presented in [51] for the CVRP. The algorithm takes as input an existing solution (the best-known solution from the literature). Then, chains of customers are removed from the solution, and a Mixed Integer Linear Program (MILP) is solved to find the best reinsertion points. The procedure is iterated until improvement. Another popular scheme in this class is the one where heuristics are first run to construct multiple solutions and obtain a large number of routes (hopefully of good quality). All routes are then collected and passed to a route-based formulation which selects the best ones whose union gives a feasible solution. The scheme has been originally presented in 1976 by [50] for the solution of the CVRP and has been widely applied to different routing variants afterward. These approaches can also be classified as *column-generation-based approaches* as presented in the next section.

Branch-and-Price/Column-Generation-Based Approaches

This class of matheuristic approaches has gained popularity in the last two to three decades thanks to the success of column generation/branch-and-price exact approaches for different complex combinatorial optimization problems. For example,

branch and price is currently the leading methodology for solving different variants of routing problems to optimality. The research in the field has evolved in different directions, one of which is focused on how to exploit the potential of the column generation/branch-and-price scheme to get high-quality feasible solutions.

The approach which has by far gained the largest popularity is the so-called *restricted master heuristic*, on which we concentrate in the following. The algorithm is based on solving a master problem which typically corresponds to a set packing/set partitioning formulation. For example, the set packing formulation for the classical CVRP uses variables associated with feasible routes, i.e., routes where the vehicle capacity constraint is satisfied. As there are exponentially many feasible routes, a column generation approach is used to solve the relaxation of the master problem where variables are dynamically generated. In an exact approach, columns are generated until the relaxation of the master problem is solved to optimality. Then, the branching phases start and column generation is retrieved in every node of the branch-and-bound tree. Restricted master heuristics typically work in two ways:

1. The column generation phase is performed at the route node only. This means that once the relaxation of the original master problem is solved, all generated columns are passed to the MIP solver which solves the master problem over this restricted set of columns. This is a very popular approach, which is also often embedded in exact branch-and-price approaches with the aim of finding good primal bounds, allowing to prune nodes in the branch-and-bound tree [41, 90].
2. The column generation phase is performed heuristically, meaning that the relaxation of the master problem is not solved to optimality. This approach has the disadvantage that it does not provide a valid dual bound which can be used to measure the quality of feasible solutions. On the other side, a big advantage is that the column generation phase is much faster. Indeed, it is known [41, 90] that the most time demanding procedure in column generation/branch-and-price algorithms is the exact solution of the pricing problem.
   Concerning how to solve the pricing problem heuristically, the most common approach is to simplify the exact pricing algorithm which, in the case of routing problems, corresponds typically to a labeling algorithm solving the Elementary Shortest-Path Problem with Resource Constraints (ESPPRC). For example, one might solve the ESPPRC on a reduced graph where only a subset of arcs are considered. However, there exist also contributions in which the heuristic pricing algorithm is based on local search and/or metaheuristic algorithms (see [138] for a recent contribution).

As mentioned earlier, this class of matheuristic schemes has grown rapidly thanks to the success of branch-and-price algorithms for the solution of different classes of routing problems, even if the earliest contribution in this class is even prior to that, i.e., in 1976 by [50]. This contribution belongs also to the second class of approaches listed above.

Matheuristics: Discussion

Matheuristics have been extensively applied to different classes of routing problems [10]. Many contributions have tackled the classical CVRP. This happened for obvious reasons: The CVRP is among the most studied problems in routing, so it attracted many more contributions than other routing problems. However, the current state-of-the-art heuristic algorithms for the CVRP are based on metaheuristic schemes and local search operators, as mentioned in section "Metaheuristics." Nevertheless, there exist classes of routing problems for which the biggest effort in the development of heuristic approaches has focused on matheuristics. As an example we mention the Inventory Routing Problem (IRP). We already referred to the IRP earlier. However, we now present its definition in order to discuss why matheuristics have been so popular for its solution. The IRP is defined as follows. There is a single supplier who is responsible of defining the replenishment plan to fulfill the demand of customers over a given planning horizon. Each customer faces a demand in each period of the planning horizon. The replenishment plan has to be such that stockout never occurs at all customers nor at the supplier, and the total cost, given by the sum of routing and inventory costs, is minimized. The current state-of-the-art heuristic algorithm for the IRP is the branch-and-cut embedded matheuristic proposed in [118], which won the IRP track of the 12th DIMACS Implementation Challenge. This work presents an exhaustive review of the exact and heuristic approaches of the IRP, and what emerges is that the vast majority of the heuristics are matheuristics (11 of the 13 contributions cited in the paper). A similar situation happens for the Production Routing Problem (PRP), which is an extension of the IRP in which production decisions are included as well. So, a natural question emerges: Why have these problems been tackled mostly with matheuristics, while metaheuristics are not so popular for these classes of problems? There might be different answers to this question. However, we now discuss what is our opinion concerning the success of matheuristics for IRPs (same arguments apply for PRPs).

In the IRP, in addition to the classical combinatorial decisions related to when each customer should be visited, what are the customers visited by each vehicle, and what is the visiting sequence, there are also decisions related to the quantity that should be delivered to each customer at each visit. The latter decision has two peculiarities:

1. It is a continuous (and not combinatorial) decision.
2. Determining the best quantity to be delivered to a customer in a given visit is not straightforward as this depends on the quantity received by the customer in other visits and, also, on the quantity delivered to other customers in the same route.

Classical operators used in heuristics for routing problems have difficulties in handling the two features above: First, they deal with discrete choice sets; second, they evaluate the local change made by the move. So, in case of a continuous decision, evaluating all options is clearly not viable. Also, a local evaluation of the quantity decision does not work properly because of feature 2 mentioned above.

Instead, quantity decisions can be handled by solving a mathematical programming formulation which deals with continuous variables and includes constraints related to vehicle capacity and inventory level.

Thus, in our opinion, matheuristics have gained success for these classes of problems as they can easily handle interrelated continuous decisions, where classical local search combinatorial operators have difficulties. Also, a mathematical programming formulation might help to evaluate a move when the associated cost is not easily represented through a formula. Still, the option of tackling a problem through a matheuristic comes with a cost. Indeed, embedding the solution of a mathematical programming formulation in a heuristic scheme is time-consuming, even when the solution is fast or when it is called few times. This is why matheuristics may not be suitable for problems in which a decision has to be taken fast, like in real-time and dynamic problems.

New Research Trends

The huge efforts the community has made in past years to solve both exactly and heuristically the CVRP and most if its variants and extensions allow to safely claim that classical variants of the VRP are nowadays efficiently solvable, at least for instances with up to a few hundreds of customers. This has pushed scholars to look for other challenges and explore different research directions. In this section we discuss advances in knowledge discovery and learning approaches to tackle the CVRP and its variants (section "Knowledge Discovery and Learning") as well as the resolution of large-scale instances (section "Heuristic Methods for Large-Scale Instances").

Knowledge Discovery and Learning

In recent years, efforts have been made by the Machine Learning (ML) community to apply learning approaches to solve VRPs as well as efforts by the Operations Research community to integrate ML and Knowledge Discovery mechanisms in heuristics to solve VRPs.

The two communities share different backgrounds and practices which may lead to nonuniform performance evaluation of the proposed procedures. To fill this gap [2] have recently proposed a set of guidelines to conduct computational testing of ML approaches to vehicle routing problems.

Although a complete review of literature on the interactions between both domains is out of the scope of this chapter, we would like to point to some recent contributions that may inspire other researchers.

Knowledge Discovery

To boost the performances of heuristic algorithms, knowledge of some kind of attributes of instances and/or solutions may be collected and used. This is for

example the case in Adaptive Large Neighborhood Search (ALNS) [109] in which the success of competing subheuristics is recorded and used to determine the frequency at which they are used. Specifically for ALNS, it is worth noting that recently [124] questioned the benefits of the adaptive layer to the optimization process. In their discussion the authors conclude that the adaptive layer has most sense to be included in the algorithm if the instances tackled are heterogeneous. In this case, different destroy and repair heuristics target different categories of instances.

In recent years, it has become evident that the efficiency of a heuristic strategy is deeply affected on how well it is able to exploit the characteristics of the problem being solved. Differently said, to increase their efficiency, heuristics require some knowledge on the characteristics that distinguish a good solution from a not-so-good solution.

Whereas it is well known that good solutions share a common structure, it is not clear how to differentiate good from not-so-good solutions. Different attempts have been recently made by researchers to fill this gap, that is to investigate whether close-to-optimal solutions can be distinguished from not-so-close-to-optimal ones by looking at the structure of the solutions, disregarding their objective function values. The goal is then to guide the search based on this information, as for example by removing solution attributes that do not frequently appear in close-to-optimal solutions and replacing them with attributes that do. One successful and well-known example of this approach can be found in [122], where the authors observed that long arcs have a low chance to be part of high-quality solutions. A different approach, using similar ideas, can be found in the matheuristic approach of [9], already discussed in section "Improvement Heuristics."

Recent advancement in computation power and storage opportunities allow to examine a large amount of data, thus making data mining a viable tool. In this regard, [14] attempt to determine metrics which allow to distinguish near-optimal solutions from nonoptimal solutions. They generated 192,000 VRP solutions for which several metrics are computed. The solutions, their metrics, and a flag to characterize them as near- or nonoptimal lead to a data set that is used to train and validate a predictive model. Based on the class of the instances, a solution can be predicted to be a near- or a nonoptimal solution with an accuracy that can reach 90%. The authors show how the knowledge that is obtained can be used in a Guided Local Search algorithm to penalize edges that are likely to belong to nonoptimal solutions [13].

In the same spirit, [12] introduce pattern injection local search (PILS), an optimization strategy that uses pattern mining to discover frequent patterns in high-quality solutions. During local search, attempts of injecting such patterns in the solution are made. The authors propose a procedure to optimally reconnect the route fragments that occur during the pattern injection phase.

Machine Learning

In recent years, the Operations Research community gained interest in the exploitation of ML tools to solve combinatorial optimization problems in general [21, 70] and the VRP in particular [64, 91, 106, 135].

Routing problems have also been the subject of such studies from the ML community, and these studies can be divided in two categories: a category of works that aim at learning construction heuristics and a category that aims at learning improvement heuristics. The works of [20, 73] are of the first category. They make use of Reinforcement Learning to build heuristic solutions for different routing problems. On the improvement heuristics side, e.g., [137] propose a Deep Reinforcement Learning framework to automatically learn high-quality solution picking policies that work with pairwise operators such as 2-opt, exchange, and relocation of customers. It is worth noting that most of these works seem to focus on presenting frameworks that can automatically learn how to build or how to improve solutions without human guidance. Computational experiments are typically run on both the TSP and (variants of) the VRP. The results that are obtained are comparable to those obtained by highly optimized and specialized traditional solvers.

Learning has especially been proven to be a powerful tool to tackle dynamic and stochastic optimization problems. Recent examples from the vehicle routing literature are the works of [16], which considers the dynamic VRPTW, and [58], which considers the IRP with stochastic demands. In these contributions, the ML pipeline incorporates a combinatorial optimization layer. Roughly speaking, the ML layer incorporates uncertainty by parameterizing in an adequate way an instance of the underlying deterministic optimization problem. Such approaches may then be very useful to tackle systems that are highly dynamic or stochastic as for example the e-commerce sector, as mentioned in [16].

On the other side, it has also been shown that results obtained by introducing information that comes from sophisticated ML tools can sometimes be obtained from simpler considerations. For example, [111] integrate measures of customer relatedness in the local search and crossover procedures of HGS to prune the neighborhood exploration and to reconnect chromosomes. They show that such relatedness information is beneficial to the performance of the algorithm, regardless the source of the information (simple distance measures or heatmaps resulting from a graph neural network). However, both approaches lead to equally good solutions, i.e., simple considerations based on the distance between customers are sufficient to achieve very good results.

Heuristic Methods for Large-Scale Instances

The computational effort required to solve vehicle routing problems increases with problem size, no matter whether exact or heuristic approaches are considered. In most cases, the number of customers or nodes in a problem is used as a proxy for the problem size.

The size of the problem instances to address obviously depends on the specific problem considered and its (potential) real-life application. However, computational limitations may also force scholars to reduce instance sizes. Early research on vehicle routing problems therefore primarily focused on problems of up to at most a few hundreds of customers. For example, commonly used sets of benchmark

instances for classical problems like the CVRP and VRPTW contain instances of only up to 200 or 100 customers, respectively [33, 34, 119].

Later, at the start of the 2000s, the interest in solving larger instances grew, driven by increased computational resources and the increasing popularity of powerful metaheuristic solution frameworks compared to simple heuristic procedures. At that time, it became common to address instances of a few hundreds of customers and several new benchmark sets were proposed (e.g., CVRP instances of up to 483 and 1200 customers by [57] and [84], respectively, and VRPTW and PDPTW instances of up to 1000 customers by [52] and [85], respectively). Later, another extensive set of instances of 1000 customers for the CVRP was proposed by [125].

In recent years, there is a growing interest in even larger, the so-called very large-scale instances of tens of thousands of customers. The motivation for such large problems stems from real-life applications like waste collection, mail delivery, and urban e-commerce deliveries [11, 74].

To avoid excessive computation times for such problems, various acceleration techniques have been proposed. Generally, the difficulty lies in finding a good balance between efficiency and efficacy of local search procedures. Common techniques include filtering the neighbors considered (e.g., using granular neighborhoods [18, 122]), early pruning of certain moves (e.g., Sequential Search [69]), and using smart move evaluation procedures (e.g., Static Move Descriptors [19, 139]). In addition, there is a focus on reducing memory usage.

Another direction to tackle large-scale problems is to apply decomposition techniques [112]. Here, smaller subproblems are iteratively solved and their solutions are used to build up a global solution. Among the difficulties of such methods we can mention the design of the strategy to define the subproblems as well as to determine their dimension in order to end up with subproblems that allow to build parts of a solution while keeping the computational time reasonable.

In terms of (very) large-scale problems, we highlight a few recent contributions. [74] address problems of up to 20,000 customers. They present a Guided Variable Neighborhood Search heuristic algorithm which combines VNS with ideas from GLS. They report on several speed-up techniques and a specific data structure to reduce computation times and memory usage. Arnold et al. [11] introduce new instances of up to 30,000 customers, based on real-life parcel distribution data from Belgium and extend the algorithm in [13] to solve them. They demonstrate that in good-quality solutions nodes are nearly always connected to one of their closest neighbors. This information is used to prune the search of their local search operators, reducing computation without impacting solution quality. Additionally, to reduce memory usage, they propose to only store distance information on the shortest edges and compute distances of other edges on the fly. Accorsi and Vigo [3] propose an ILS algorithm that at each iteration maintains the optimization to the area that has been affected by the shaking step. This is accomplished through a heuristic pruning technique that uses a dedicated data structure to keep track of a limited set of vertices involved in recent solution changes. In [4], the same authors propose an extension of their algorithm which implements advanced techniques to reduce memory usage and the complexity of the neighborhood explorations. They tested the

algorithm on newly proposed instances with up to 1 million customers. Recently, as discussed in section "Iterated Local Search," [93] present a highly effective heuristic algorithm, providing state-of-the-art results on the instances of [11] with 30,000 customers.

Finally, note that tackling very large-scale instances is not a pure academic challenge but may have specific industry applications. For example, [5, 26] present a real-life, complex IRP problem with dimensions that go well beyond classical IRP benchmark instances. The problem presented in [5] considers instances with up to 324 customers, 21 planning days, and 13 drivers, while [26] tackle instances with about 600 customers, 30 commodities, 16 depots, and 21 planning days.

Instances and Libraries

In this section we give a brief overview on libraries and benchmark instances available in the literature for different classes of routing problems.

Instances

The availability of good benchmark instances plays a crucial role in research on vehicle routing heuristics as they provide a common ground for comparing different algorithms and approaches. However, it is not so obvious what determines the *goodness* of set of instances. Elements to consider are for example the level of *realism* or their representativity of real-life problems (e.g., in terms of instance size, clustering of locations, network topology, side constraints like loads, time windows, etc.), and the level of diversity.

Unfortunately, research on heuristics for classical vehicle problems has mainly been using the same sets of early artificial benchmark instances which lack realism and diversity. These include for example instances of [33, 34, 57, 84] for the CVRP, [52, 119] for the VRPTW, and [85, 108] for the PDPTW.

More recently, several researchers have proposed (ways to generate) more realistic sets of benchmark instances for these problems (see, e.g., [113, 125]). In addition, two new sets of instances based on real-life data for the CVRP were introduced in the context of the 12th DIMACS Implementation Challenge (http://dimacs.rutgers.edu/programs/challenge/vrp/), and a set of more than 9000 historical routes with diverse features was made available in the context of the 2021 Amazon Last Mile Routing Research Challenge [94]. Additionally, [4] proposed instances with up to 1 million customers. For a more detailed overview and discussion on instances for the CVRP, we refer to [125] and to the CVRPLIB repository on which instances and results are publicly available (http://vrp.galgos.inf.puc-rio.br).

For other, more specific and less commonly studied problems, researchers typically either extend instances of the classical benchmarks, or randomly generate their own instances, based on real-life data or not. For a discussion, see [61]. In recent years, there seems to be a growing request of the community to make

such problem instances publicly available for fellow researchers. Unfortunately, this process is not very streamlined. Instances are made available in different ways (e.g., personal websites, local repositories, publishers' repositories, etc.), in diverse formats, and often with limited explanation. There have been some efforts by the community to offer a more structured approach, like VRP-REP (http://www.vrp-rep.org/), an online repository to which researchers can contribute their instances and solutions using a standardized format. However, the uptake is unfortunately limited.

Publicly Available Implementations

Developing effective and efficient (heuristic) algorithms is often the primary concern of researchers when addressing vehicle routing problems. However, as the quality of heuristic algorithms is typically assessed experimentally, rather than theoretically, implementing such algorithms is another important aspect. Efficient implementations are often crucial to compete in the highly competitive research area. A discussion of best practices in this context is beyond the scope of this chapter. However, we do want to highlight a number of contributions that can be a starting point when tackling vehicle routing problems.

First, there are publicly available tools that allow to solve routing problems without any knowledge of programming or even heuristics. An example is the VRP Spreadsheet Solver developed by Güneş Erdoğan [46]. It applies the Large Neighborhood Search framework to solve many VRP variants with up to 200 customers, uses GIS to obtain real-life distances and travel times, and allows visualization of solutions. Second, in recent years, several researchers have made their code publicly available. An early example is the library coded in C/C++ presented in [59]. More recent examples include open-source implementations of state-of-the-art algorithms like the HGS algorithm of [128, 130] for the CVRP ([127], coded in C++), and for CVRP and VRPTW ([136], coded in Python), of the hybrid ILS-SP algorithm of [121] for the CVRP (https://github.com/cvneves/ILS-SP-CVRP), and of the LKH-3 algorithm of [63] (http://webhotel4.ruc.dk/~keld/research/LKH-3/) which can be applied to a large variety of problems, including the CVRP, the VRPTW, and pickup-and-delivery problems. Also, for more specific routing problems, packages/libraries are available, like `RoutingBlocks`, a Python package for developing algorithms for routing problems with intermediate stops [72].

Conclusion

In this chapter, we have provided an overview of heuristic methods for vehicle routing problems. Due to the large amount of research available on the topic, we briefly introduced the earliest and most classical heuristic algorithms for routing problems. We then concentrated on the most recent developments which have

been proposed to tackle routing problems heuristically, namely, metaheuristics, matheuristics, learning approaches, and heuristics for large-scale problems. We have provided reference contributions and discussed the key features of each class, concentrating on the most recent research trends.

Advances in both exact and heuristic methods allow to claim that classical variants of the VRP are nowadays efficiently solvable, at least for instances with up to few hundreds of customers. Challenges remain open on how to efficiently tackle the very large instances, where studies are present, but mostly limited to the CVRP.

Scholars have studied the benefits of including knowledge discovery and ML tools into the resolution of routing problems. While it is clear that including knowledge of some kind in the procedures positively impacts the quality of the outcome, further research is still needed to shed light on for which problems ML is of most interest. Indeed, studies show a positive impact of the use of ML to problems with dynamic or stochastic dimensions, while a high impact of ML to tackle normal size instances for deterministic problems has not yet been demonstrated. In the latter case, classical optimization procedures remain competitive. On the other hand, an open direction for further research is to investigate the benefits of learning to tackle large-scale instances. Works on this direction have been already conducted (see, for example, [66, 86]) but are still limited.

Finally, a discussion which is there since decades is related to the benefit of developing unified approaches which can effectively handle different problem variants. Some effort has been done, as discussed above, but still scientific contributions tend to propose approaches which are strongly tailored to the specific problem at hand. Evidence from practice instead shows the growing development of unified frameworks, proposed by consultancy companies specialized in optimization and routing. Thus, we believe some stronger effort of the research community should be made in this direction.

Abstract

Last-mile delivery with crowdshipping is a logistics solution that, besides the store's professional fleet, considers the possibility of having ordinary people with no professional relation with the store (a.k.a. occasional couriers) delivering some packages. The associated problem combines two prominent problems in the literature: routing and assignment. Packages are assigned to occasional couriers, and routes are generated for the store's professional fleet and occasional couriers. In this chapter, we describe the first mathematical model proposed to solve this problem and provide a comprehensive review of metaheuristics used in the literature to address challenges related to last-mile delivery with crowdshipping.

Keywords

Last-mile delivery · Vehicle routing problem · Crowdshipping · Occasional couriers · Metaheuristics

Introduction

E-commerce has transformed global retail, providing customers with unparalleled convenience, variety, and access to nearly every product. The technological advancements associated with changing customer preferences have established e-commerce as the main force shaping the future of retail. Customers now have the power to browse and purchase products from nearly anywhere and at any time using their electronic devices. In order to fulfill customer expectations, retailers' capacity for innovation and adaptation are key factors in their success, since they are forced to rethink their approaches and look into new solutions to remain competitive. Our work focuses on the supply chain's last-mile delivery step, which involves moving goods from distribution centers to customers' houses.

One innovative solution in last-mile delivery is based on crowdsourcing. In this concept, organizations decentralize delivery and outsource it, totally or partially, to a wide network of contributors. This allows organizations to access a wide range of skills and labor at reduced costs compared to traditional methods. Crowdsourcing has broad applications, and, when applied to last-mile delivery, it is named *crowdshipping*. In this case, the "crowd" (a.k.a. occasional couriers—OCs) are ordinary people with no professional relation with the retailers, who agree to deliver goods to the final customer for financial compensation.

Platforms such as Amazon Flex [1] and Roadie [36] are examples of crowdshipping platforms. They leverage nonprofessional couriers to carry out last-mile deliveries, allowing companies to expand their delivery capacity. Amazon Flex enables individuals to use their vehicles to deliver parcels on a flexible schedule, while Roadie connects businesses and individuals with couriers who are already en route to their delivery destinations. Both services exemplify the growth of gig economy-based logistics, which can offer cost-saving benefits for companies and flexible earning opportunities for couriers [38].

This study conducts a comprehensive analysis of academic literature concerning crowdsourcing in the last-mile delivery context. It specifically emphasizes works that incorporate metaheuristics into their proposed solutions. The remainder of this chapter introduces an optimization problem associated with last-mile delivery using crowdshipping. It provides an overview of the main scientific challenges in this area and analyzes the metaheuristics developed to address the different problem variants.

Last-Mile Delivery with Crowdshipping

In this section, we outline the problem of last-mile delivery with crowdshipping and present the mathematical model for its basic configuration. We then provide a literature overview, highlighting the key lines of research and advancements in crowdsourced last-mile delivery solutions.

The problem, first addressed in [2], and named vehicle routing problem with occasional drivers (VRPOD), can be described as follows: Given a set of online orders to be fulfilled within a specified day or time period and a workforce composed of a professional fleet (PF) and occasional couriers, we aim to find the orders assignment and delivery routes that minimize total delivery costs. The solution's total cost comprises the cost of professional fleet routes and the compensations paid to occasional couriers. We assume that each delivery route must start from a store/depot, and both professional vehicles and occasional couriers have a capacity limit restricting the number of deliveries they can handle.

Figure 1 illustrates our case. Here, the store/depot has four online orders to fulfill. Three customers are served by a professional fleet vehicle, which starts and ends its route at the store. An occasional courier handles the remaining order. This OC picks up the package at the store and incorporates the delivery into their preexisting route home, making only a slight detour to complete the task.

Mathematical Formulation

The vehicle routing problem with occasional drivers is modeled as a combination of an assignment problem (deliveries are assigned to occasional couriers) and a

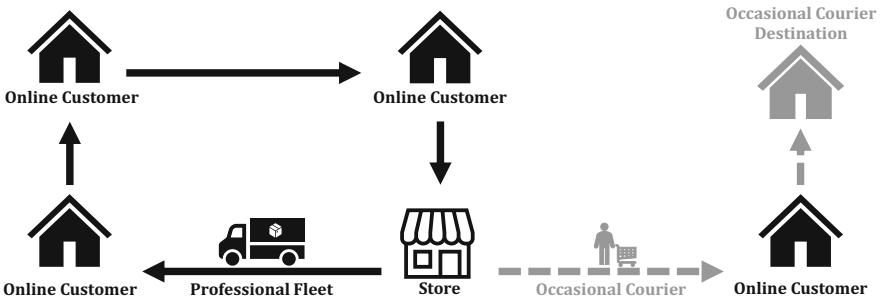

Fig. 1 Example of crowdshipping scheme

capacitated vehicle routing problem. The authors in [2] proposed a static integer programming formulation for this problem and formulated it as follows. Let $G = (N, A)$ represent a complete directed graph, where N is the set of nodes and A is the set of arcs. The node set N comprises three subsets: the store or depot (node 0), customer locations C, and destinations for occasional couriers K. For simplicity, occasional couriers are identified with their destinations. Each arc $(i, j) \in A$ has a distance d_{ij} and an associated cost c_{ij}. Each customer $i \in C$ is characterized by a demand q_i. Professional fleet vehicles have Q capacity, and an unlimited number is assumed to be available. Furthermore, customer's demand and occasional couriers' availability are known in advance.

An occasional courier $k \in K$ is willing to deliver to customer i when the extra distance incurred by the occasional courier to deliver to customer i respects a limit defined by their flexibility. Each occasional courier k can make at most one delivery and is compensated by p_{ik} when delivering to customer i. Each customer's demand must be satisfied either by the professional fleet, whose route starts and ends at the depot, or by an occasional courier, whose route starts from the depot to the customer's location and continues to the occasional courier's destination. Parameter β_{ik} indicates whether occasional courier k can serve customer i.

The following decision variables are used:

- x_{ij}, a binary variable indicating whether a regular vehicle traverses arc (i, j), or not
- y_{ij}, indicating the load a regular vehicle carries on arc (i, j)
- z_i, a binary variable indicating whether a customer is visited by a regular vehicle, or not
- w_{ik}, a binary variable indicating whether customer i is visited by occasional courier k, or not

The VRPOD can be formulated as follows:

$$\text{minimize} \quad \sum_{(i,j)\in A} c_{ij}x_{ij} + \sum_{i\in C}\sum_{k\in K} p_{ik}w_{ik}$$

$$\text{Subject to:} \quad \sum_{j|(i,j)\in A} x_{ij} = \sum_{j|(j,i)\in A} x_{ji} = z_i \qquad \forall i \in C \tag{1}$$

$$\sum_{j|(0,j)\in A} x_{0j} - \sum_{j|(j,0)\in A} x_{j0} = 0 \tag{2}$$

$$\sum_{j|(j,i)\in A} y_{ji} - \sum_{j|(i,j)\in A} y_{ij} = \begin{cases} q_i z_i & \forall i \in C \\ -\sum_{j\in C} q_j z_j & i = 0 \end{cases} \tag{3}$$

$$y_{ij} \le Q x_{ij} \qquad \forall (i, j) \in A \tag{4}$$

$$y_{i0} = 0 \qquad \forall i \in C \tag{5}$$

$$w_{ik} \leq \beta_{ik} \qquad \forall i \in C \quad \forall k \in K \tag{6}$$

$$\sum_{i \in C} w_{ik} \leq 1 \qquad \forall k \in K \tag{7}$$

$$\sum_{k \in K} w_{ik} + z_i = 1 \qquad \forall i \in C \tag{8}$$

$$x_{ij} \in \{0, 1\} \qquad \forall (i, j) \in A$$

$$y_{ij} \in [0, Q] \cap \mathbb{Z} \qquad \forall (i, j) \in A$$

$$z_i \in \{0, 1\} \qquad \forall i \in C$$

$$w_{ik} \in \{0, 1\} \qquad \forall i \in C \quad \forall k \in K.$$

The objective function aims at minimizing the total cost given by the sum of professional fleet delivery costs and the compensation given to occasional couriers. Constraints (1) and (2) ensure route flow conservation, and Constraint (3) guarantees demand satisfaction and subtours elimination. Constraint (4) guarantees that vehicle capacity is respected, and (5) ensures that they return empty to the depot. Constraint (6) ensures that a customer is only assigned to an occasional courier willing to serve that customer, and Constraint (7) guarantees that each occasional courier serves at most one customer. Constraint (8) ensures that each customer is served exactly once.

Related Problems and Variants

In last-mile delivery with crowdshipping, there are different research lines regarding the planning and operational levels involved in this delivery strategy. Extensive research followed the work of [2], with new avenues being explored. Major attention has been given to: (1) dynamic and stochastic information integration, (2) compensating strategies, and (3) usage of transshipment points.

Dynamic and Stochastic Information Integration

A main concern of this problem is guaranteeing enough delivery capacity, i.e., enough occasional couriers at the right location and time to perform the deliveries on time. The number of occasional couriers and orders to fulfill may vary in time and space and may not coincide. Moreover, companies must account for the uncertainty of occasional couriers that may not appear or decline an offered delivery, and for the uncertain demand for a specific period, since delivery requests can arrive dynamically. Different works address these challenges. Considering a setting where a delivery service platform automatically matches delivery tasks and occasional couriers, the authors in [4] propose a rolling horizon framework and design an exact solution method to solve the matching problem as new information becomes available. In [3], authors also consider a re-optimization solution, where

online orders arrive dynamically without information anticipation. They propose a solution combining insertion and re-optimization algorithms that penalize deliveries made on the same day outside specified time windows, and deliveries postponed to the next day. Insertion evaluates each delivery request individually, while re-optimization periodically passes a solution generated by insertion to a variable neighborhood search (VNS) algorithm. Computational results for different ratios between static (known in advance) and dynamic customers that arrive online during the distribution process show that dynamism highly impacts performance and that the re-optimization algorithm provides better solutions than the simple insertion rule. The authors of [8] study the impact of incorporating probabilistic information about future online orders and in-store customer arrivals. For that effect, and considering a same-day delivery setting where online orders and OCs may arrive throughout the day, they propose a sample-scenario planning solution and show that incorporating and exploiting probabilistic information about the future result in more cost-effective solutions compared to a full myopic strategy, in which only the systems' current state is considered when making decisions.

In [16], the authors integrate the OCs' willingness to accept or reject deliveries assigned to them and study the influence of their decision on the expected delivery cost. They determine the subset of customers proposed as occasional couriers by using a local search heuristic and calculating the solution's expected value, assuming that, in the second stage, a professional fleet carries out the remaining deliveries. Another two-stage stochastic model is proposed in [7]. In the first stage, partial routes are defined without knowledge of OCs that can arise later in the day. Those decisions can be revised in the second stage when OCs become available. The work is extended in [40], which presents a multistage formulation of the problem. The authors of [41] present a two-stage stochastic model that incorporates the uncertainty of the arrival of orders and the presence of customers to receive deliveries. In cases where customers are not present, the deliveries have to be returned to the depot. To solve the problem exactly, the authors propose a branch-and-price algorithm and, for larger problems, a column generation heuristic. Later, in [43], they present an extension of the model where the destinations of the online orders are not known in advance (open vehicle routing problem).

Compensation Strategies

The compensation offered to occasional couriers plays a significant role in the success of crowdsourcing solutions for last-mile delivery [2]. At the same time, companies must balance the amount offered to OCs to provide fair compensation that promotes OC participation and optimizes costs and efficiency. Some studies already focus on compensation schemes. In [42], different compensation schemes for the OCs are explored to determine the compensation that minimizes the total delivery cost. They propose a large neighborhood search (LNS) heuristic, considering the stochastic nature of occasional courier acceptance. A data-driven approach to designing a compensation scheme for crowdsourced deliveries is proposed by [5]. The authors determine an optimal compensation by modeling the OC's willingness to conduct deliveries using logistic regression based on factors

such as delivery distance and parcel weight. In contrast with previous works in which the compensation decision focuses only on the OC side, [22] also integrates the sender's willingness to pay. They advise companies by testing the model under four compensation schemes, five demand and supply scenarios, and three objectives: senders' cost minimization, platform profit maximization, and occasional couriers' compensation maximization.

Transshipment Points Integration

Intermediary facilities such as transshipment points have become increasingly popular as alternatives to traditional last-mile delivery methods. These facilities, e.g., parcel lockers, allow customers to pick up their orders conveniently. Furthermore, retailers that rely on systems that use these structures can propose to customers who pick up their orders at a locker to deliver to other customers who prefer to receive their orders at their homes. The integration of lockers from where OCs pick up parcels was proposed in [46]. The authors propose a min-cost network flow model where OCs can perform multiple deliveries and are rewarded according to the additional distance they travel. The authors in [35] consider automatic lockers for occasional couriers' drop-off, pickup, or use as intermediate transfer points where parcels can be dropped off by an OC and picked up by another, i.e., transferred from lockers. They present a stochastic dynamic algorithm for a simplified version of the problem where capacity constraints of lockers and OCs are not considered. The authors of [28] proposed a mixed-integer program and a variable neighborhood search heuristic to solve the capacitated version of the problem. In [9], the authors analyze the usage of existing urban facilities such as shops or lockers as occasional depots that are activated only when necessary. They present a mixed-integer linear programming model designed to optimize the deployment of these depots with company vehicles and two groups of OCs: classical OCs, who transport goods between the central depot and occasional depots, and neighborhood OCs, who deliver parcels from the occasional or central depot to customers. A two-echelon last-mile delivery framework incorporating parcel lockers and crowdsourcing is presented in [39]. The occasional couriers can perform deliveries by deviating slightly from their initial routes.

Metaheuristics Approaches to Related Problems

This chapter examines research that proposes and applies metaheuristics to address last-mile delivery problems with crowdshipping. While mathematical programming decomposition algorithms have advanced in solving vehicle routing problems, optimal solutions are still limited to relatively small instances. However, solutions for significantly larger instances are needed in real-world scenarios [21]. Several metaheuristics, including variable neighborhood search, genetic algorithms (GA), and tabu search (TS) (see Fig. 2), have been introduced in the literature to address large-scale instances of crowdshipping effectively. Below we review the literature on last-mile delivery with crowdshipping. Differently from previous sections, where

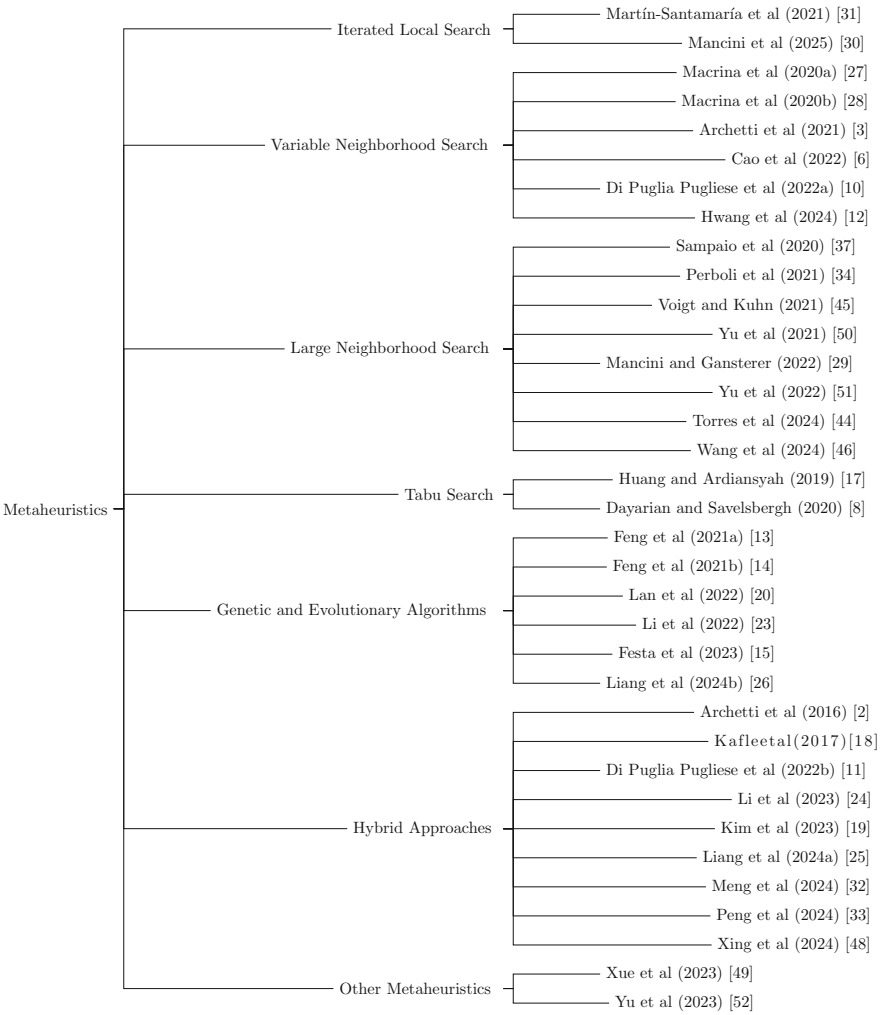

Fig. 2 Classification of metaheuristics considered for last-mile delivery with crowdshipping

contributions were aggregated by problem variant, in this section, we divide them according to the metaheuristic used to solve the problem. Table 1 provides a detailed summary of the constructive, improvement, destruction, and insertion operators employed in the reviewed studies.

Iterated Local Search

An interesting part of literature resorted to iterated local search (ILS) to solve the problem. In [31], the authors employed ILS to address the VRPOD, using greedy

randomized adaptive search procedure (GRASP) as the constructive method to generate a set of varied initial solutions. For local search, the authors employed a variety of neighborhood operators (including 2-opt, 1-move, swap-move, and in-move), while perturbation was promoted through random moves, route cost, and reassignment. Similarly, [30] applied ILS to a last-mile delivery problem, focusing on assigning bundles of customer requests to occasional couriers within an auction-based framework that considers absenteeism of OCs, which can cancel with little notice, potentially disrupting service. The authors introduced an auction-based system where couriers can bid on delivery bundles and act as reserved couriers to ensure availability (they receive a fee to ensure their presence but are not guaranteed to be assigned to a specific bundle). The problem was modeled as a two-stage stochastic recourse model, solved using a self-learning matheuristic (SLM) alongside ILS, where SLM served as the local search operator by iteratively refining first-stage decisions to minimize second-stage costs. Perturbations were introduced to diversify solutions, with computational results showing this hybrid method's superiority over deterministic approaches and VNS.

Variable Neighborhood Search

To the extent knowledge of the authors, VNS was used for last-mile delivery problem with crowdsourcing in [27]. The study addresses the vehicle routing problem with occasional drivers and time windows with multiple deliveries (VRPODTWmd), an extension of [2], which allows occasional couriers to serve multiple customers. To create the initial solution, the authors propose an insertion heuristic that prioritizes assigning customers to occasional couriers. The neighborhood search comprises operators such as 2-opt, relocation, and inter- and intra-route swaps. The shaking phase employs a semi-random operator selection strategy guided by adaptive scoring, while the variable neighborhood descent (VND) phase systematically refines the solutions. Computational experiments reveal that the proposed VNS significantly outperforms a commercial solver (CPLEX) on larger problem instances. Later, an enhanced version of this variable neighborhood search is proposed in [10] to solve the same problem variant. This approach integrates a variable neighborhood search metaheuristic with machine learning techniques, including Q-learning, to strategically explore the most promising regions of the solution space. Five variations of VNS are derived from how the learning strategies are applied in the shaking and local search phases. Computational results demonstrate that the proposed methods achieve high performance in both effectiveness and efficiency.

In [28], the authors extended the work in [2] by introducing transshipment points and time windows. They proposed a mixed-integer program and employed a variable neighborhood search to solve instances of bigger size. The proposed procedure starts by generating an initial solution using a matheuristic that initially solves an assignment model, and if the obtained solution has unserved customers, it utilizes an insertion heuristic to place them. They consider 11 local search operators based

on four local search moves (move, swap, swap intra-route, and new route). For the shaking phase, they introduce a semi-random choice based on a score for each local search move (score is incremented if there is an improvement in the solution cost; otherwise, the scores are reduced), in which they randomly select two moves among the five with the highest score. The local search phase uses a VND. The results reveal that compared to CPLEX, the proposed metaheuristic balances solution quality and computational efficiency with a reasonable optimality gap in shorter run times.

The study in [3] addresses the online vehicle routing problem with occasional drivers, a scenario in which future customer requests are unknown, and penalties are imposed for same-day deliveries outside designated time windows and for postponing deliveries to the next day. The authors present a mathematical model and design and implement a solution approach that integrates insertion and re-optimization algorithms. In this approach, a greedy insertion algorithm evaluates each delivery request independently, assigning it to the optimal position within the solution. Periodically, the re-optimization algorithm passes the insertion-generated solution to a variable neighborhood search algorithm, where routes for both PF and OCs are improved using local search procedures, including relocate and swap operations within and between routes. Computational experiments conducted for different ratios between static (pre-known) and dynamic (real-time) customer requests reveal that dynamic arrivals significantly impact performance and demonstrate that the re-optimization algorithm yields superior solutions compared to the insertion-only approach.

In [6], the authors address the green vehicle routing problem with passing-by couriers, which involves optimizing routes for both professional and occasional (passing-by) couriers to reduce costs and environmental impact while fulfilling customer delivery demands. The objective is to balance carbon emissions and operational costs and enhance driver satisfaction. To solve this problem, the authors introduce a memory-based variable neighborhood search (MVNS) metaheuristic. This approach starts by generating an initial solution for professional couriers using the put forward insertion heuristic, which computes the cost of inserting a new customer into the current route, and any remaining unrouted customers are then assigned to feasible routes of passing-by couriers using an insertion algorithm. Local search and a shaking step employ neighborhood structures with operators such as relocate, swap, 2-opt, and cross-exchange, enabling adjustments within individual routes (inner relocate and inner swap) and between routes. Throughout the search, memory-based restart mechanisms utilize historical elite solutions to guide the exploration of promising areas in the solution space. Computational results indicate that MVNS outperforms the standard VNS approach.

In [12], the authors address the supermarket chain grocery delivery crowdshipping problem by proposing a mixed-integer linear programming model and designing an adaptive variable neighborhood search (AVNS) heuristic to solve large-scale practical instances efficiently. The initial solution is constructed using a schedule concatenation method, which iteratively assigns grocery orders to couriers based on the earliest feasible delivery times, followed by a forward time slack adjustment to minimize delivery service times. The neighborhood search incorporates

intra-route operations such as 2-opt and Or-opt. The AVNS extends the traditional variable neighborhood search framework by introducing adaptive mechanisms, hybrid adaptive large neighborhood search (HALNS) elements, guided neighborhood selection, and a worse-solution acceptance strategy to handle complex constraints better and escape local optima. Computational experiments demonstrate that the AVNS achieves superior solution quality and efficiency compared to conventional methods, effectively solving instances with up to 200 orders.

Large Neighborhood Search

So far, large neighborhood search has been the most popular metaheuristic used to solve the problems associated with last-mile delivery with crowdshipping. An adaptive large neighborhood search algorithm is proposed in [37] to solve a multi-depot pickup and delivery problem with time windows and transfers, considering occasional couriers that express their availability to perform delivery tasks for a given period. A greedy insertion algorithm generates the initial solution, and the neighborhood operators focus on removing requests from the current solution (e.g., worst request removal and random request removal) and reinserting them to create a modified solution using three different insertion operators. At each iteration, one of the neighborhoods is selected, prioritizing neighborhoods that have succeeded in earlier iterations. Improved solutions are always accepted, but a diversification mechanism is incorporated, sometimes accepting worse solutions. In [34], the authors propose a large neighborhood search approach to solve the dynamic and stochastic vehicle routing problem by integrating occasional couriers within a simulation-optimization framework. The initial solution is generated using a greedy insertion heuristic, which places each request at the most cost-effective position. Different destroy operators (random, worst, related, and cluster removal) and repair operators (greedy and second cheapest) are applied to improve the solution. A case study conducted in the city of Turin (Italy) demonstrates that combining crowdsourced couriers with green carriers, such as cargo bikes, offers significant economic and environmental cost savings. However, it leads to a decrease in delivery efficiency.

An adaptive large neighborhood search algorithm with a simulated annealing (SA) acceptance criterion to diversify the search is proposed in [45]. The initial solution is obtained by randomly applying repair operators until every request is served. Five destroy operators are considered to remove requests (such as random, worst, shaw, and least efficient removal) from the current solution, and six operators are considered to build a new solution (such as random, best, and regret insertion). Compared with the exact solution methods, the proposed procedure delivers equivalent results for small instances and scales well with the problem size.

The work in [50] addresses a variant of the vehicle routing problem, specifically, the two-echelon vehicle routing problem with time windows, covering options, and occasional couriers. This problem involves two fleets, city freighters and occasional couriers, which serve customers with two delivery options: home delivery and

alternative delivery locations (covering options) for customer pickups. The objective is to minimize total costs, including routing, connection, and compensation costs for OCs. The authors propose an adaptive large neighborhood search metaheuristic to tackle this problem. The initial solution is constructed in two phases based on the cheapest insertion, first addressing second-echelon routes for city freighters and OCs and then constructing first-echelon truck routes. During ALNS iterations, destroy and repair operators are applied to iteratively modify the solution by removing and reinserting customers and reconfiguring routes. Thirteen destroy operators, targeting customer nodes or entire routes (e.g., random and worst), and seven repair operators, which reinsert customers into feasible routes while considering time windows and synchronization constraints (e.g., greedy heuristic), are employed. Additionally, the authors explore local search integration within ALNS, utilizing swap, reinsertion, and 2-opt neighborhood operators, and demonstrate that this integration leads to improved results.

The problem considered in [29] is the VRPOD and bundles of orders that optimize the assignment of customer bundles to the OCs and PF vehicles while minimizing total delivery costs. The proposed solution utilizes large neighborhood search metaheuristic, starting with an initial feasible solution obtained from a relaxed problem formulation. The LNS employs destroy operators that randomly remove customers or arcs from existing routes (e.g., random and worst removal), rebuilding it based on rules. The LNS obtained near-optimal solutions in a short computational time for the larger instances.

In [51], authors introduce a new variant of the two-echelon vehicle routing problem called the two-echelon vehicle routing problem with time windows, intermediate facilities, and occasional drivers. The problem integrates parcel lockers and crowdshipping into a two-echelon distribution network to minimize total operational costs. The authors formulate the problem as a mixed-integer linear programming model and develop a hybrid adaptive large neighborhood search algorithm to solve it. The HALNS incorporates set partitioning to collect routes generated during the destroy, repair, and VND (local search) phases. Based on extensive computational experiments, it was concluded that HALNS demonstrates strong performance. Furthermore, it was highlighted that the key components of HALNS, namely VND and the set partitioning problem, are important for ensuring its robust and reliable high-quality performance.

The study in [44] addresses optimization of route pricing to enhance the participation of occasional couriers in delivery tasks. It formulates a multi-objective problem to minimize routing costs and maximize OCs participation. The authors propose a comprehensive framework that integrates pricing, route optimization, and the uncertainty of occasional courier route acceptance, employing an adaptive large neighborhood search metaheuristic. The methodology incorporates a variety of construction algorithms and neighborhood operations, including greedy insertion, near removal, random removal, random route removal, first customer removal, and last customer removal. Additionally, the ALNS is supplied with a route assignment and pricing procedure, which determines the optimal price and acceptance probability for a subset of routes. The study also includes an econometric model to analyze the

behavior of OCs in response to route attributes. Computational experiments reveal that the proposed ALNS outperforms a column generation heuristic.

The integration of crowdshipping with high-speed railways for express delivery services is studied in [47]. A mathematical model is presented to tackle the freight allocation problem in the rail segment and the OC routing problem in the road segment. The authors employ a depth-first search-based algorithm for small-scale instances and a customized adaptive large neighborhood search algorithm for larger instances, incorporating different neighborhood operations to improve solution quality. The initial solution is generated by solving a freight allocation plan using the CPLEX solver based on the transportation plans for origin-destination pairs. At the same time, the customized ALNS algorithm employs neighborhood operators such as insertion, swap, and removal to improve the solution iteratively.

Tabu Search

Tabu search is used in [17] to study a two-echelon problem where deliveries are handled by either PF vehicles or OCs through transfer points, highlighting that not all deliveries can be outsourced due to the lack of transfer points in certain neighborhoods. The construction of initial solutions balances PF vehicles and OCs, employing a sweep algorithm combined with a nearest-neighbor heuristic for PF routes and a savings algorithm for OC routes. The improvement phase is based on tabu search, incorporating tailored intra- and inter-route neighborhood operators, such as insertion, swaps, and destroy-repair moves. Computational results indicate that the proposed solution is effective, delivering near-optimal solutions for small-scale instances and high-quality solutions for large-scale scenarios.

The authors of [8] utilize tabu search within their sample-scenario planning framework to address the dynamic and stochastic same-day delivery environment, where online orders and OCs willing to make deliveries arrive throughout the day. Their approach incorporates removal and insertion moves during TS neighborhood exploration.

Genetic and Evolutionary Algorithms

Genetic algorithm is also used to solve last-mile delivery problems with crowdshipping. The study in [14] explores the integrated production and transportation scheduling problem with crowdsourced delivery (IPTS-CD). This problem can be decomposed into two subproblems: first, solving an IPTS to obtain an integrated schedule that includes both the production schedule and truck delivery routes, and after a crowdsourced bid selection problem, in which truck delivery routes are adjusted by adding some valuable crowdsourced deliveries. The authors formulate it as a mixed-integer linear program and propose a GA to solve it. The initial population routes are obtained randomly and improved with a greedy algorithm defining the production scheduling based on when truck is dispatched. Comparative

evaluations against CPLEX demonstrated the GA's superior solution quality and computational efficiency performance. In [23], the authors propose a mathematical model and GA to solve the meal crowdsourcing delivery problem. The initial population uses an order-pair insertion method that ignores OCs locations during allocation.

The work in [26] addresses the urban parcel crowdsourced delivery problem that optimizes scheduling OCs who pass through delivery points, aiming to maximize delivery efficiency and reduce traffic and environmental costs. The authors use a genetic algorithm and an insertion heuristic, creating an initial solution by matching parcels with couriers based on proximity and capacity constraints. They apply a rolling optimization model for dynamic order insertion that reassigns new orders with minimal disruption to predefined routes based on disturbance management. Destroy and repair operators adjust parcel assignments to available couriers as routes evolve. Results show that the model increases the matching ratio between parcels and passing couriers and improves profit compared to static models.

A biased random-key genetic algorithm (BRKGA) with implicit path relinking is proposed in [15]. The authors address the variant of VRPOD with time windows. The objective is to minimize total delivery costs while satisfying time windows and capacity constraints. The BRKGA encodes solutions as random-key vectors and decodes them into the delivery router using a custom decoder. The initial population is generated randomly, and the algorithm evolves through elite preservation, mutation, and crossover operators. An implicit path-relinking mechanism (intensification strategy that exploits the neighborhood formed in the path between two feasible solutions) further refines solutions, and a restart strategy (a new seed for the random-key generator) is employed to escape local optima. The results showed that the proposed BRKGA is more effective and efficient than the VNS proposed in [27] in the instances considered.

The following studies apply evolutionary algorithms to tackle the last-mile delivery problems with crowdshipping. An evolutionary multitask optimization is employed in [13] to address the vehicle routing problem with heterogeneous capacity, time windows, and occasional drivers (VRPHTO). The authors propose an evolutionary multitasking algorithm (EMA) to solve multiple VRPHTO instances concurrently. The EMA employs a permutation-based unified representation to encode multiple VRPHTO problems within a single population. Neighbor solutions are generated via order crossover and mutation operators. Experimental results reveal that the EMA surpasses traditional single-task solvers by reducing costs and enhancing efficiency, particularly when tackling related problem instances simultaneously.

Building on evolutionary optimization techniques, [20] investigates the multi-objective two-echelon city dispatching problem with multi-sourcing and crowd-shipping. The study introduces a multi-objective mathematical model that balances company costs, customer satisfaction (measured as the deviation between actual and ideal delivery times), and crowd-shipper income satisfaction. To solve this multi-objective problem, the authors develop the multidirectional evolutionary algorithm (MDEA) that guides multiple neighborhood operators to explore the

Pareto front. The algorithm framework includes initialization, multidirectional evolution, and environment selection. In the initialization step, the population is initialized following a random strategy. The authors propose three neighborhood operators for the multidirectional evolution: basic, objective wise, and VNS. Basic neighborhood operators include commonly used operators such as relocate and 2-opt. The objective-wise operators are designed to improve each of the three objective functions considered. Finally, the environmental selection adopts a reference vector-based selection strategy to select the next generation of individuals. Results demonstrate that the MDEA outperforms several popular multi-objective approaches.

Hybrid Approaches

Hybrid approaches, combining multiple metaheuristics to leverage their complementary strengths, have also been proposed.

In the seminal work on VRPOD [2], the authors proposed a multi-start heuristic and compared it to the solutions obtained using CPLEX. Their heuristic combines variable neighborhood search, tabu search, and integer programming. The heuristic begins with five initial solutions, each differing in the method used for assigning customers to OCs. Each solution is obtained as follows: (1) all customers are served by a professional fleet (no occasional couriers are employed), (2) solve an integer program model to determine the customers served by occasional couriers seeking to serve the far-away customers first, (3) solve the same integer program model, but now maximize the demand delivered by the occasional couriers, (4) solve an integer program model that maximizes the number of used occasional couriers, followed by the minimization of the cost (hierarchically), (5) solve a relaxation of the proposed model, disregarding the integrality constraint on the variables x. Subsequently, the PF routes are constructed using a sequential greedy insertion algorithm, further refined through a 2-exchange improvement. After, a VNS-based approach is applied to each solution, with tabu search being employed in the shaking phase where all non-tabu moves, from 1-move, swap-move, in-move, and out-move, are evaluated and the best one is chosen. Tabu search is followed by a random operator (denoted as *Jump*) that randomly selects a customer and inserts it in the best route using the cheapest insertion criterion. Finally, the professional fleet routes are subject to a 2-exchange neighborhood (local search phase).

In [18], the authors consider a model where pedestrians and/or cyclists act as OCs, and a truck performs the remaining deliveries. To solve the problem, the authors decompose it into two subproblems: first, the selection of the bids submitted by OCs for undertaking a subset of jobs and, after, the routing and scheduling of trucks (modeled as a simultaneous pickup and delivery problem). The first problem is solved using a branch-and-bound algorithm, and the second is solved using simulated annealing. A tabu search iteratively solves both subproblems to improve the overall solution by exploring the selection of relay points.

A hybrid heuristic algorithm that combines genetic algorithm and tabu search is proposed in [24]. The work addresses a multistage two-echelon crowdsourcing logistics assignment model, in which parcels to be delivered in each stage are known a priori, but the information on OCs in future stages is not completely known. The authors formulated a mixed-integer linear program and proposed a genetic algorithm that integrates a tabu search to optimize the sequence of deliveries for each courier. The initial population is built using four methods: one based on pure randomization and three based on roulette wheel selection, which assign weights to couriers based on distance to subdepots, distance to destination, and length of the original route. The GA-TS algorithm outperforms CPLEX regarding computational efficiency and cost effectiveness.

The study presented in [33] addresses the outsourcing service price problem in collaborative crowdshipping, focusing on the interaction between parcel delivery service providers and on-demand mobility service providers, such as taxis and ride-hailing vehicles (acting as OCs). The problem is modeled as a bi-level optimization problem with the upper level addressing the parcel delivery service providers' objective of minimizing total costs, formulated as a multi-depot pickup and delivery problem with pricing. The lower level focuses on maximizing OCs' profit by optimizing the allocation between parcel deliveries and passenger rides, which is formulated as a crowdshipping problem with ridesharing. To solve this problem, the authors propose a customized iterative hybrid algorithm that combines two granular tabu search (GTS) algorithms within a genetic algorithm. The process begins with a randomly generated initial population of potential outsourcing service prices, represented in binary form. Afterward, the GTSs solve the lower-and upper-level problems sequentially by applying profit-oriented and cost-oriented granularity strategies. Numerical experiments are conducted on randomly generated instances and a real-life case study, demonstrating that the proposed framework effectively balances the interests of both participants.

Another work that uses genetic algorithms is [25]. The authors present a crowdsourcing framework for green urban parcel delivery, leveraging private cars (OCs) already passing delivery points. The problem focuses on optimizing urban delivery operations to minimize both environmental costs from carbon emissions and enterprise costs by utilizing existing resources and incentivizing private couriers with bonuses. A mixed-integer programming model is formulated to define the problem, and a hybrid metaheuristic algorithm, integrating a GA with ALNS, is proposed for solution optimization. The initial solution is constructed by matching parcels to OCs based on spatial and temporal constraints. Destroy operators (random and worst removal) remove parcels from delivery routes, while repair operators reassign parcels to feasible routes using greedy heuristics (minimizing distance) or random allocation, ensuring compliance with capacity and time window constraints.

Express crowdsourcing task allocation considering distribution mode under customer classification is studied in [48]. Customers can have their parcels delivered in two modes: home delivery carried by OCs and self-pickup. Customers are also

classified into three segments—efficient, potential, and marginal—based on their historical consumption pattern, analyzed using an entropy-weighted RFM (Recency, Frequency, Monetary) model so that priority is given to the high-quality customers (based on penalty cost function). To address the problem, the authors present a customer classification genetic algorithm (CCGA). The algorithm randomly generates the initial population and integrates simulated annealing to accept or reject the new individuals. Experimental results highlight the superiority of the CCGA, which combines GA and SA, over traditional GA, demonstrating its enhanced effectiveness in addressing the problem.

The work in [19] uses a hybridization of ALNS and SA to solve a two-echelon vehicle routing problem with heterogeneous OCs: the dedicated OCs, and in-store customers who deliver orders on their way home from a store (en route OCs). A mixed-integer linear programming model and an ALNS that integrates SA are proposed. The ALNS algorithm uses a greedy insertion heuristic to generate initial solutions, followed by neighborhood search heuristics such as intra-swap, inter-swap, intra-shift, inter-shift, and 2-Opt. Additionally, new local search algorithms—transfer node and candidate swap, transfer node replacement, and transfer node replacement with swap—are introduced to enhance the search space by adjusting transfer nodes for couriers and OCs. The performance of the proposed algorithm is compared with an MILP solver, GA, neighborhood search, and Monte Carlo simulation.

The work in [32] addresses the crowdsourced delivery scheduling problem in dispatch mode, combining order allocation and travel route generation. To solve this problem, the authors propose a variable neighborhood search based on the Metropolis criterion (VNSMC). This metaheuristic incorporates the concept of SA and introduces a new solution acceptance strategy based on the Metropolis criterion to enhance the exploration of the solution space. The VNSMC starts by randomly generating an initial solution and applying a shaking procedure based on order removal and reassignment. Afterward, a local search based on a combination of two local search operators (migration and exchange) is proposed. Routing decisions are carried out by a branch-and-bound method. To evaluate the performance of the proposed VNSMC, the authors also developed an SA, VNS without Metropolis criterion, and GA to solve the problem and concluded that the proposed VNSMC obtains better solutions.

Finally, in [11], the VRPODTWmd is addressed using several variants of the GRASP as the primary metaheuristic. The initial solution is constructed in a greedy randomized phase, employing two strategies: the classical restricted candidate list and a biased randomized version. Local search is performed using neighborhood operators such as 2-opt and swap. Furthermore, two hybrid approaches are proposed, integrating VNS and VND as local search strategies within GRASP. Comparative results demonstrate that the hybrid GRASP with VND and VNS achieves the best balance between computational efficiency and solution quality, outperforming the methods proposed in [2] and the VNS of [28].

Other Metaheuristics

Other metaheuristics have been proposed to address last-mile delivery with crowdsourcing problems.

In [52], the authors solve the vehicle routing problem with simultaneous pickup and delivery and occasional drivers using simulated annealing. Their approach begins with a two-phase initial solution construction: First, a relaxed mixed-integer linear programming model assigns customers to occasional couriers, and second, a nearest-neighbor insertion heuristic generates feasible routes for permanent fleet vehicles. The neighborhood search phase incorporates the operator's swap, insertion, and reverse, specifically designed to manage interactions between PF vehicles and OCs. Computational results demonstrate that the proposed SA method outperforms CPLEX in terms of solution quality and computational efficiency.

Adaptive ant colony optimization (ACO) is utilized in [49] to solve the crowdsourcing multi-depot vehicle routing problem with time windows. The problem, which only considers either traditional or crowdsourcing (separated), is divided into two stages: first, a division stage, where it employs a k-means clustering algorithm based on the elbow method to transform the multi-depot problem into several single-depot problems, and after, in the second stage, the optimization stage, where an adaptive ant colony (ADACO) algorithm is proposed to determine the distribution routes for each distribution center. The basic version of ACO is improved with state transfer and pheromone updates to avoid being enclosed in local optima. Comparative analyses show the higher capacity of ADACO to handle larger instances than a commercial solver (Gurobi).

Conclusions

This chapter presents an analytical review of the papers proposing and applying metaheuristics to solve last-mile delivery with crowdshipping problems. The integration of occasional couriers into delivery operations has introduced unique challenges, including the dynamic nature of customer requests and the need to balance cost efficiency with environmental objectives. Metaheuristic methods have proven highly effective in addressing several problem variants since they can handle large, complex search spaces and provide high-quality solutions within reasonable computational times. Methods such as genetic algorithms, tabu search, variable neighborhood search, and large neighborhood search were tailored to exploit specific problem structures, often by designing custom operators or hybrid frameworks that combine multiple metaheuristics. Furthermore, computational experiments demonstrate that metaheuristics can effectively balance trade-offs between cost, efficiency, and sustainability, making them well-suited for crowdshipping systems. As the field progresses, advancements in data-driven optimization and hybrid

computational frameworks are expected to enhance the efficiency of last-mile delivery with crowdshipping.

Abstract

Maritime container terminals are essential infrastructures in global supply chains. Their high management complexity and heterogeneous processes make them an interesting field to apply heuristics. This chapter provides a comprehensive overview of the main optimization problems found at maritime container terminals, including berth allocation, quay crane scheduling, yard planning, and

Introduction

Containerization is, without a doubt, the engine of economic globalization, which enables the move of goods worldwide within global intermodal supply chains using standardized containers. The containers are usually built of weathering steel and have locking systems and well-known international dimensions. The capacity unit of measure in transport is the 20-foot equivalent unit, which refers to a container with a length of 20 feet. Due to their physical standardized structure, containers are easily transported by different means and can be stacked on top of each other, reducing the surface dedicated to their storage.

The United Nations Conference on Trade And Development (UNCTAD) examines trends in seaborne trade and analyzes the comparative performance of different geographic regions and countries worldwide. In this regard, the Review of Maritime Transport is an annual publication edited by the UNCTAD secretariat since 1968 to present a global maritime market analysis. One of the main assertions included in the last edition of the review in 2023 [64] remarks that the merchandise trade and seaborne shipments have increased in tandem over the last years. Particularly, the world merchandise trade has grown about twice as fast as the world's gross domestic product. Simultaneously, the seaborne trade increased by green2.4% in 2023, allowing the move of about green12.4 billion tons of goods in ports worldwide. However, containerized trade is the fastest-growing market segment, giving rise to that green1.8 billion tons, which are being transported nowadays by containers worldwide.

To cope with the huge aforementioned seaborne trade, over the last decades, public institutions and freight shipping companies have funded the building of maritime container terminals in strategic regions as engines of economic development and investment elements. A maritime container terminal is an extensive infrastructure located in a seaport to join maritime and land transport means. The main transport means usually found at a maritime container terminal are vessels, trucks, inland waterway systems, and trains. The main goal of a maritime container terminal is, hence, to perform the transshipment of freights between different means of transport efficiently. With this goal in mind, a maritime container terminal is responsible for unloading and loading the incoming vessels. The freights are temporarily stored by the terminal until their final means of transport pick them up and retrieve them from the terminal.

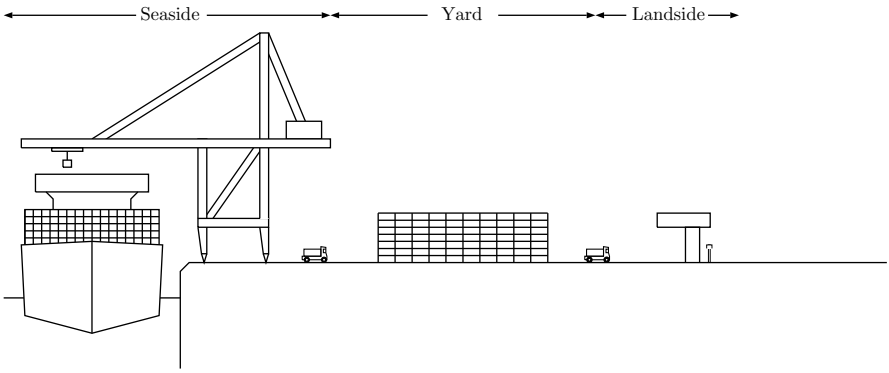

Fig. 1 Overview of a maritime container terminal

As depicted from left to right in Fig. 1, a maritime container terminal is typically split into the following main areas:

- *Seaside*. It is the part of the maritime container terminal that serves the incoming vessels. It contains the most expensive machinery found at the maritime container terminal, the quay cranes, which perform the transshipment operations of containers between the terminal and the vessels. Roughly speaking, a quay crane grabs the containers from the vessels when they are berthed through its spreader during unloading operations. Then, the containers are lifted and moved ashore. Finally, the containers are placed on trucks to be moved directly toward the yard or outside the terminal. This sequence of movements is reversed during loading operations.
- *Yard*. It is a temporal storage that usually takes up more than 50% of the terminal surface and in which those containers arrived at the terminal are stacked until their subsequent retrieval. The yard is split into several blocks, that is, sets of container bays arranged in parallel. A bay is a delimited two-dimensional stock disposed in the vertical direction, where containers can be placed one on top of another. The blocks are served by specialized machinery, such as reach stackers, rubber-tired gantry cranes, or rail-mounted gantry cranes.
- *Landside*. It is an interface to communicate the maritime container terminal with external trucks and trains. Several gates are available to supervise the movement of containers.

Some particular facilities that can be found in maritime container terminals are the container freight station, interchange area, and railhead. These are, respectively, dedicated to managing consignments, allowing road vehicles to deliver and retrieve cargoes from the terminal, and inspecting the containers arriving or leaving by train.

Nowadays, the large volume of freights and the unceasing competition among maritime container terminals give rise to increasing vessel operators' demand for reliable services. A suitable performance of a maritime container terminal is

obtained by harmonizing the technical equipment and staff. However, maritime container terminals are complex to manage due to their large number of heterogeneous processes. In this environment, heuristics stand as a promising optimization technique to be considered. The reason is that, as discussed in this chapter, most of the optimization problems addressed in a maritime container terminal belong to the $\mathcal{NP}$-hard class of problems. In this regard, even in small-size scenarios of some of these optimization problems, efficient exact approaches do not exist. Nevertheless, heuristics report high-quality solutions through affordable computational times.

In the past decade, ML approaches have gained relevant attention in addressing port optimization problems, especially those ML approaches that integrate optimization. Under this paradigm, Machine Learning techniques are used to identify data patterns, predict a variable's value, and direct the search process toward high-quality solutions. The literature reviews conducted in [29, 59] emphasize the predominant use of ML methods in predicting relevant variables in port operations. By analyzing large datasets from the maritime port sector, ML facilitates accurate estimation of variables essential for optimizing maritime container terminal management operations. Moreover, the joint use of ML with heuristics to improve port operations management has shown relevant results, e.g., [19, 20, 81].

The remainder of this chapter introduces the main optimization problems found at a maritime container terminal, how they are interconnected, and analyzes heuristics to address them. Some conclusions and further lines of study are presented at the end of the chapter.

Optimization Problems

As mentioned before, maritime container terminals are huge infrastructures aimed at managing increasing transshipment flows of containers within transport multimodal networks. Their many logistical problems and their interrelations constitute a challenge for practitioners and researchers. Henesey et al. [37] divide the problems taking place at container terminals into four large subsystems or categories, namely *ship to shore*, *transfer*, *storage*, and *delivery*. In this regard, due to the similarity of the operations between transfer and delivery, they are here considered as a single category. Moreover, in the following, some of the most highlighted problems within these categories are briefly described:

- *Ship to shore*. Movements of loaded/unloaded containers from/to the sea to the container terminal:
  - *Ship routing* (Korsvik and Fagerholt [49]). These are particular routing problems where the vessels have to be routed along a set of ports so that their cargo is picked up and delivered from/to them.
  - *Stowage planning* (Monaco et al. [61]). In these problems, the goal is to determine the positions to be occupied by each container within a container vessel along its shipping route.

  - *Berth allocation* (Bierwirth and Meisel [5]). The problems under this category seek to determine the berthing position and berthing time of those container vessels arriving at the terminal.
  - *Quay crane assignment* (Meisel and Bierwirth [60]). Once a vessel is berthed, these problems seek to determine the fixed number of quay cranes to be assigned to the vessel according to its workload.
  - *Quay crane scheduling* (Meisel and Bierwirth [4]). Given a vessel and a subset of the available quay cranes, these problems aim to determine the quay crane schedules for performing the vessel loading/unloading tasks.
- *Transfer and delivery*. Bidirectional movement of containers from the quay to the storage area, from the storage area to the hinterland, or vice versa:
  - *Vehicle dispatching* (Angeloudis et al. [1]). Internal vehicles usually move containers within transshipment flows from the quay to the yard and vice versa. In these problems, the management of those vehicles is addressed.
  - *Gate operations planning* (Chen et al. [12]). The management of vehicles with containers from the yard to the gate and vice versa is dealt by these problems.
- *Storage*. Movement and warehousing of containers until their retrieval for continuing their routes by vessels, trucks, or trains:
  - *Yard crane scheduling* (Gharehgozli et al. [33]). These problems are related to the schedule of the cranes within the yard at a container terminal in such a way that the loading, relocation, and unloading operations are performed.
  - *Container storage* (Caserta et al. [10]). These problems are aimed at determining the movements to be performed by the yard cranes to store/retrieve the containers on/from the yard.

The remainder of this chapter focuses on four particular optimization problems: berth allocation problem, quay crane scheduling problem, vehicle dispatching, and container storage.

Berth Allocation

The berth allocation problem (BAP) is an $\mathcal{NP}$-hard optimization problem that seeks to determine the berthing position and berthing time of each incoming vessel that arrives to the port within a given planning horizon. The primary constraint involved in the BAP concerns that the berthing positions of the incoming vessels cannot be overlapped in the same time step.

According to the arrival of the incoming vessels, two variants of the BAP can be identified: static BAP and dynamic BAP. Firstly, in the static BAP, all the incoming vessels are already waiting to be berthed before the planning horizon starts. Secondly, the dynamic BAP considers that the vessels arrive at the port at any moment during the planning horizon. In both cases, each vessel could have a certain time window in which the vessel must be served by the maritime container terminal.

Moreover, the berth layout of the maritime container terminal gives rise to the following variants of the BAP:

- *Continuous BAP*. In this layout, the quay is treated as a continuous length and not divided into predefined berths; thus, the vessels can berth at any position.
- *Discrete BAP*. The quay is physically divided into segments called *berths* so that each berth can serve a certain number of vessels at each time step.
- *Hybrid BAP*. This type involves discretizing the continuous quay to have intermediate options. The continuous quay is divided into a set of berths, and a vessel can occupy more than one berth at a time or share its assigned berth with other container vessels. On the other hand, other hybrid considerations might be certain parts of the quay with fixed berthing slots while others are treated as continuous.

These categories can include BAP variants that consider time-dependent quay and port access limitations (e.g., [18,52,77]), multiple quays (e.g., [30]), incorporate discontinuities within them (e.g., [58]), irregular layouts (e.g., [17]), or adjustable or mobile quays (e.g., [23]), accommodating a broader range of operational scenarios and infrastructure constraints.

According to the planning level to consider, the BAP can be classified as follows:

- *Operational*. It covers decisions ranging from one up to several days. Thus, the BAP within this level is aimed at optimizing the delays and waiting times of container vessels. This variant of BAP has received more attention than the others.
- *Tactical*. At this level, the decisions cover operations ranging from 1 week up to several months. Some of the objectives here are to optimize the transshipment flows among vessels, cycling visiting of the vessels, fulfilment of contracts among shipping companies and terminal managers, and route design.
- *Strategic*. The decisions covered at this level range from one to several years. They seek to establish specific and dedicated berths, strategic cooperation agreements between terminal and shipping companies, etc.

Over the past few years, the integration of container terminals with other types of terminals, such as bulk or RoRo (Roll-on/Roll-off), has given rise to what is known as multipurpose terminals. These terminals are capable of handling various cargo types, resulting in specific BAPs such as the Bulk Berth Allocation Problem [68] or the BAP in the context of automotive transshipment [21].

In the related literature, most works address the BAP at the operational level. To a lesser extent, some works consider the tactical level, and a few think the strategic level. Due to this, we analyze how heuristics can be used to tackle the BAP at the operational level. In this regard, one of the most used variants of BAP is the dynamic BAP (DBAP) proposed by Imai et al. [42], who address the problem over a discrete layout. Then, Cordeau et al. [16] formulate it as a multi-depot vehicle

routing problem (MD-VRP). Additionally, they also include berth and vessel time windows. The authors propose a benchmark suite based on real data from the container terminal of Gioia Tauro (Italy).

The input data for the DBAP consist of a set of n incoming vessels to serve, denoted as V, a set of m berths, denoted as B, and a planning horizon, H. Each container vessel $v \in V$ has a certain time window, $[a_v, d_v]$, which the maritime container terminal must serve, whereas its service priority is p_v. The handling time of vessel $v \in V$ in berth $b \in B$ is denoted as s_{vb}. This way, the vessel's turnaround time is the sum of its waiting and handling time to be berthed. Furthermore, each berth $b \in B$ has a known time window in which vessels can be served, $[s_b, e_b]$. This problem aims to minimize the sum of (weighted) turnaround times of the vessels.

Figure 2 shows a solution example of the DBAP. This figure shows a schedule and an assignment plan for $n = 6$ vessels in $m = 3$ berths. The rectangles represent the vessels, and service priority is provided inside each vessel. The time windows of the vessels are represented by the lines at the bottom of the figure. In this case, for example, vessel 1 arrives at time step 4, and it should be served before time step 14. Moreover, the time window of each berth is limited by the non-hatched areas. Table 1 reports the different handling times of each vessel depending on the assigned berth. For example, the handling time of vessel 1 at berth 1 would be 7, whereas its handling time would be 8 at berth 2.

As seen in the previous example, vessels 5 and 6 would have to wait for berthing in their respective assigned berths. In this regard, since their service priorities are

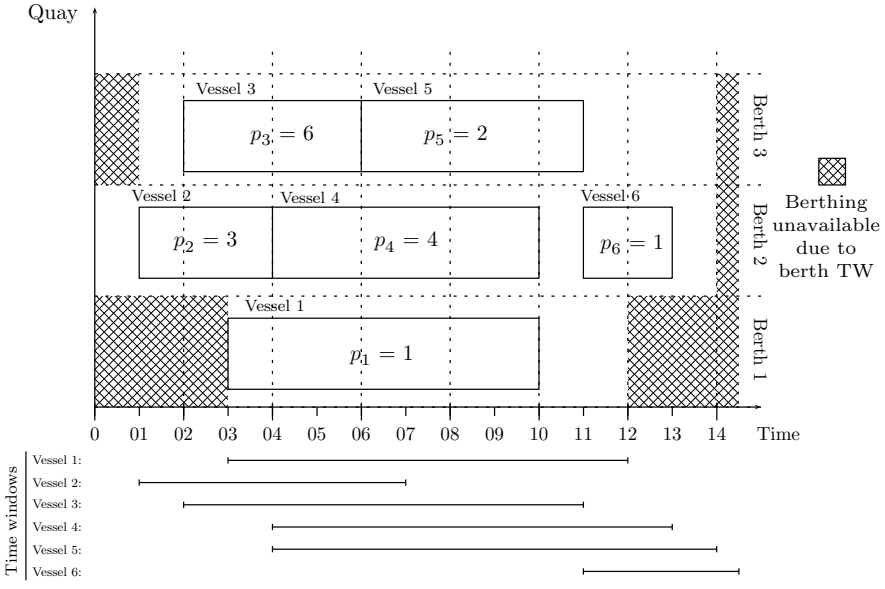

Fig. 2 Solution example of the Dynamic Berth Allocation Problem composed of 6 vessels and 3 berths

Table 1 Vessel handling times depending on the berth

Vessel	Berth 1	Berth 2	Berth 3
1	7	8	5
2	2	3	4
3	5	5	4
4	4	6	5
5	5	8	5
6	4	2	3

$p_5 = 2$ and $p_6 = 1$, their waiting times will have less impact on the objective function value than delaying other vessels, for example, vessels 3 and 4, for which their service priorities are $p_3 = 6$ and $p_4 = 4$, respectively. That is, if their berthing time is delayed, the waiting time of each vessel is multiplied by 6 and 4, respectively. In this example, the weighted turnaround time of the six vessels is calculated as follows. Starting from vessel 1 and increasing a unit until vessel 6, the objective function value is $1 \cdot 7 + 3 \cdot 3 + 6 \cdot 4 + 6 \cdot 4 + 5 \cdot 2 + 2 \cdot 1 = 76$.

At container terminals, some queue rules are used when scheduling incoming vessels to berth positions. The vessels are sorted according to a specific rule. Some examples are described in the following:

- *Random (R)*. The incoming container vessels are randomly selected to be served by the terminal.
- *First come, first served (FCFS)*. This rule is based on serving vessels according to their arrival times. That is, the earliest vessel is the first to be served.
- *Shortest processing time (SPT)*. The vessels are sorted according to their required handling times. In this case, that vessel requiring the shortest handling time berths first.
- *Earliest due date (EDD)*. It serves the vessels based on the end of their time windows. This way, that vessel whose time window ends earliest is served first.

The previous rules allow the permutation of the incoming container vessels to serve. Four heuristics can be obtained using these rules so the vessels are iteratively assigned to the best possible berth. This berth is selected by minimizing the impact on the objective function value. The names of the heuristics are derived from the names of the rules. That is, *random greedy method* (R-G, Cordeau et al. [16]), *first come, first served greedy* (FCFS-G, Cordeau et al. [16]), *shortest processing time greedy* (SPT-G), and *earliest due date greedy* (EDD-G).

Algorithm 1 presents the general framework of the heuristics proposed in the literature (FCFS-G and R-G). It should be noted that the heuristics proposed in this chapter, namely EDD-G and SPT-G, are also included within this general heuristic framework.

As indicated in Algorithm 1, the initial solution, S, is empty (line 1). Its associated objective function value, $f_{obj}(S)$, is set to 0 (line 2). Once this initialization is done, depending on the given rule, a permutation of vessels R is obtained (line 3). So, for example, in FCFS-G, the first element of the permutation, $R(1)$, is the first

Algorithm 1: General heuristic framework for the Berth Allocation Problem

5: $\quad v \leftarrow$ Select vessel $R(i)$
6: $\quad b \leftarrow$ Select berth that allows the minimum impact on $f_{obj}(S)$
7: $\quad$ Assign v to b in S
8: **end for**
9: Return S

vessel that arrives at port. With the permutation already defined, the vessels are assigned one at a time (line 5) to the best possible berth following the order given by the sorted list (lines 4–8). The best possible berth is determined according to the impact on the objective function value of the solution (line 6). Each vessel is assigned to the berth that least increases the objective function value of the solution built until the moment.

Furthermore, a tabu search (see ▸ Chap. 31, "Tabu Search") for solving this problem is proposed by Cordeau et al. [16]. Their proposed approach, $\mathtt{T^2S}$, [16] uses R-G and FCFS-G for restarting the search. In this regard, to improve the performance of their solution approach, Lalla-Ruiz et al. propose [51], on the one hand, the use of one additional neighborhood structure $\mathtt{T^2S^*}$ and, on the other hand, the use of a path-relinking procedure (see the ▸ Chap. 23, "GRASP"), $\mathtt{T^2S^*} + \mathtt{PR}$, for restating the search. In the path-reliking procedure, an elite set of solutions, ES, consisting of a subset of the local optima encountered during the process, is used to create new starting points for the tabu search. Then, a path-relinking from one solution randomly picked from ES and one generated by R-G is performed.

Algorithm 2 shows the pseudo-code of $\mathtt{T^2S^*} + \mathtt{PR}$. First of all, the elite set, ES, is initialized with the sets of local optima $\mathtt{T^2S}^*_{min}(s_{R-G})$ (line 3) and $\mathtt{T^2S}^*_{min}(s_{FCFS-G})$ (line 4). Then, a random solution, $s_{initial}$, is generated by running R-G (line 6), and a solution $s_{elite} \in ES$ is randomly selected (line 7). Once that, a path relinking connecting $s_{initial}$ with s_{elite} is performed (line 8). Finally, the midpoint solution of this path, s, is selected as the starting point to run the tabu search $\mathtt{T^2S^*}$ (line 9). The local optima reached along this search also update the elite set of solutions (line 9). These steps (lines 5–9) are repeated until a stopping condition is met.

Comparative Analysis

This subsection is devoted to comparing the heuristics to solve the DBAP. The problem instances used to evaluate the proposed heuristics represent the problems proposed by Cordeau et al. [16]. These instances were generated by considering a statistical analysis of the traffic and berth allocation data at the maritime container terminal of Gioia Tauro (Italy) [15]. Moreover, a representative set of instances from those proposed by Lalla-Ruiz et al. [51] are used. All the heuristics have

Algorithm 2: Tabu search with path relinking for the dynamic berth allocation problem

```
1: s_{R-G} = R-G()
2: s_{FCFS-G} = FCFS-G()
3: ES = T^2S^*_{min}(s_{R-G})
4: ES = ES ∪ T^2S^*_{min}(s_{FCFS-G})
5: while !stopping condition do
6:     s_{initial} = R-G()
7:     s_{elite} = Select(ES)
8:     s = PR(s_{initial}, s_{elite})
9:     ES = ES ∪ T^2S^*_{min}(s)
10: end while
```

been implemented in ANSI C and executed on a computer equipped with an Intel 3.16 GHz and 4 GB of RAM.

Table 2 illustrates the results obtained for a representative set of instances aforementioned. The first three columns correspond to the problem instance description, namely the number of vessels, n, and, number of berths, m, and the instance identifier, *Id*. In columns *R-G*, *FCFS-G*, *SPT-G*, and *EDD-G*, the objective function values provided by the different heuristics for the DBAP are reported. That is, the objective function value, $Obj.$, and the computational time measured in seconds, *t(s.)*. In the last row, the average values are provided.

Furthermore, as indicated by Lalla-Ruiz et al. [51], the GSPP model implemented in CPLEX runs out of memory for some problem instance sets where other characteristics are considered. Therefore, in Table 3, the results provided by $\mathrm{T}^2\mathrm{S}$, $\mathrm{T}^2\mathrm{S}^*$, and $\mathrm{T}^2\mathrm{S}^* + \mathrm{PR}$ are reported for a set of instances where CPLEX is not able to provide a feasible solution for any instance within it. The table is divided, in column $Instance$, containing the number of vessels, n, number of berths, m, and the instance identifier, *Id*. In columns $\mathrm{T}^2\mathrm{S}$, $\mathrm{T}^2\mathrm{S}^*$, and $\mathrm{T}^2\mathrm{S}^* + \mathrm{PR}$ the objective function value, $Obj.$, and the computational time measured in seconds, *t(s.)*, are reported. Moreover, the relative error, $Gap_1(\%)$, with respect to $\mathrm{T}^2\mathrm{S}$ is also reported. In the case of $\mathrm{T}^2\mathrm{S}^* + \mathrm{PR}$, the relative error, $Gap_2(\%)$, with respect to $\mathrm{T}^2\mathrm{S}^*$ is shown.

As seen in Table 2, the best heuristic for the DBAP, irrespective of the size of the instance, is the FCFS-G. On the other hand, R-G and SPT-G exhibit, on average, a similar performance in terms of objective function value, while the policy of serving the vessels according to the due date reports the worst values for these instances. It should be noted that the computational time required is less than 0.001 s, as expected for these heuristics. This advises their use as initialization methods. In this regard, FCFS-G and R-G are the heuristics most used in the related literature, which, in light of the results, are the best options in terms of the quality of the solutions. It is important to highlight that R-G is not a deterministic heuristic. Therefore, it provides different solutions that may be beneficial in multi-start methods.

The results shown in Table 3 indicate that among the three algorithms, the use of a restarting strategy based on path-relinking between a solution from an elite set and one generated by the R-G heuristic improves the quality of the solutions in terms

of the objective function value. In this regard, $\mathtt{T^2S^*}$, and $\mathtt{T^2S^*}$ + PR can provide a feasible solution in less than 2 s.

Recent Heuristics Developments for the DBAP

The limitations of solving the DBAP with exact algorithms have been addressed in recent years. Kramer et al. [50] proposed improved optimization models and a variable-fixing exact approach to accelerate the solving of the DBAP and enable the solving of larger DBAP scenarios. While computational times remained practical for small to medium-sized instances, solving the largest proposed scenarios, ranging from 200 to 250 vessels, to optimality within a 2-hour limit was unreachable. This finding is particularly relevant, given the need for fast approaches in port contexts

requiring frequent execution, such as re-optimization frameworks or approaches coping with dynamic events.

Regarding heuristics, despite the development of numerous metaheuristics over the past 15 years aimed at solving the DBAP, relatively few new heuristic strategies have been introduced. Wawrzyniak et al. [71] listed other possible heuristics, including FCFS, SPT, and R. The additional greedy heuristics are also based on a sorting rule and range from the Longest Processing Time (LPT) to the Greatest Importance (GI) heuristic. Moreover, combinations such as Greatest Importance-Shortest Processing time (GISPT) or vice versa (SPTGI) were considered. Lastly, Ankita and Mathirajan [2] introduced a heuristic method based on an early-to-finish strategy. This particular heuristic combines the principles of FCFS and SPT, ordering vessels by their expected completion time per each combination vessel berth and prioritizing, in case of a tie, the combination regarding the maximum difference between the two least handling times.

It is well known that the arrival times of vessels at port might differ from the scheduled ones. This fact significantly impacts and disrupts berth plans, making them less efficient and potentially unfeasible (e.g., overlap between vessel schedules). In this sense, machine learning approaches are useful for forecasting the arrival times at the port. In Lorenz et al. [48], a robust optimization procedure based on Dynamic Time Buffers that includes estimated arrival times is proposed. This combined approach significantly reduces the number of overlaps. By using ML approaches, stochastic heuristic approaches like those proposed in [20] can reinforce berth planning. The authors proposed simulation-optimization heuristic approaches to proactively and proactively-and-reactively generate robust berth plans to cope with varying arrival and handling times. Their approach also considered the incorporation of time buffers to absorb the impact of disruptions caused by changes in the vessels' arrival times.

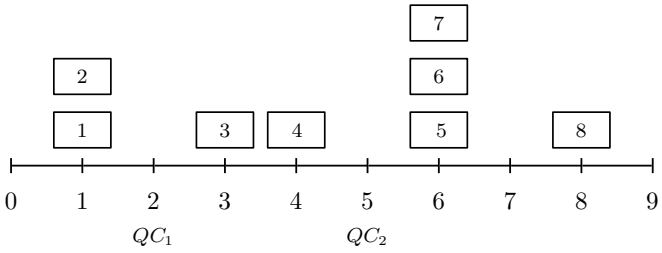
Quay Crane Scheduling Problem

The quay crane scheduling problem (QCSP) can be defined as the problem of determining the finishing times of the tasks performed by each quay crane allocated to a container vessel to minimize its turnaround time (Meisel and Bierwirth [4]). Input data for the QCSP consist of n tasks, denoted as Ω, and a set of m quay cranes, denoted as Q. Each $t \in \Omega$ comprises a set of containers with similar characteristics (e.g., weight, destination port, dimensions) placed together in the same cross section, l_t, into the container vessel. The processing time of t is the time a quay crane requires to load or unload its containers and is denoted as p_t. Furthermore, each $q \in Q$ is available after its earliest ready time, r^q; is initially located on a cross section, l_0^q; and can travel between two adjacent positions with a travel time, $\hat{t}$.

The QCSP has a set of particular constraints. In the first place, within each cross section of the container vessel, tasks are sorted according to known precedence relationships. Thus, tasks have to be performed orderly: unloading operations before

loading operations, loading operations into a hold before loading operations on the deck, and so forth. Moreover, the quay cranes are rail mounted, and then, they cannot cross each other. Additionally, they have to keep a safety distance, δ, between them in order to prevent possible collisions (Kim and Park [46]).

Figure 3 illustrates an example of the QCSP and a feasible schedule for it where quay cranes are available from the start of the service time (e.g., $r^q = 0, \forall q \in Q$), $\delta = 1$, and $\hat{t} = 1$. Within each cross section of the vessel, tasks are sorted. For instance, task 5 has to be performed before task 6 and task 6 before task 7. In this example, tasks 1, 2, 3, 5, 6, and 7 are performed by quay crane 1, and tasks 4 and 8 by quay crane 2. The turnaround time of this container vessel is 52 time units.



Task, t	1	2	3	4	5	6	7	8
Position, l_t	1	1	3	4	6	6	6	8
Processing Time, p_t	10	8	10	15	7	6	5	10

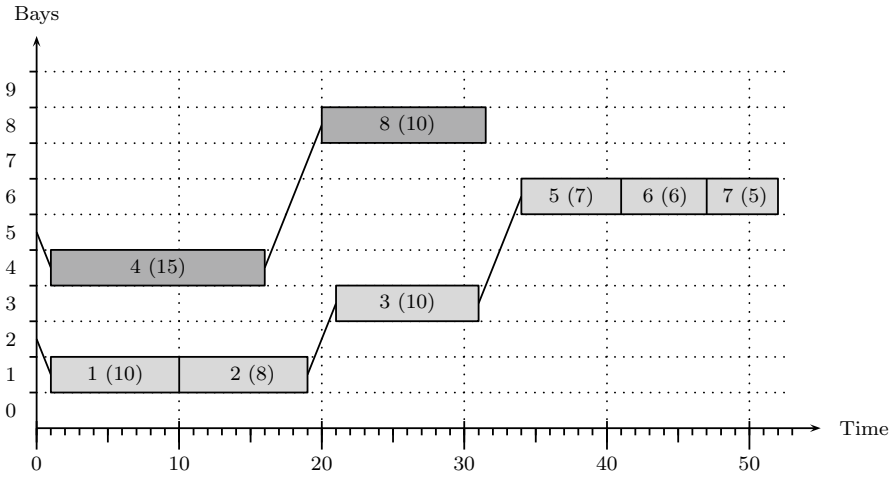


Fig. 3 Example of Quay Crane Scheduling Problem composed of $n = 8$ tasks and $m = 2$ quay cranes

Algorithm 3: Hybrid estimation of distribution algorithm with local search for the quay crane scheduling problem

1: $g = 0$
2: Initialize the probabilistic learning model, $\mathcal{P}(g)$
3: $\mathcal{S}(g) \leftarrow$ Generate the initial population from $\mathcal{P}(g)$
4: **repeat**
5: $\quad \mathcal{S}_e(g) \leftarrow$ Select the subset of elite solutions from $S(g)$
6: $\quad \mathcal{S}(g+1) \leftarrow$ Create population composed of solutions in $\mathcal{S}_e(g)$ and solutions from $\mathcal{P}(g)$
7: $\quad$ **if** λ generations without improvement **then**
8: $\quad\quad$ Apply Local Search to best solutions from $\mathcal{S}(g)$
9: $\quad$ **end if**
10: $\quad \mathcal{P}(g+1) \leftarrow$ Create next probabilistic learning model
11: $\quad g = g + 1$
12: **until** Stopping criterion is met

An interesting heuristic approach to solve the QCSP is to explore the search space of unidirectional schedules (Meisel and Bierwirth [4]). A schedule is referred to as unidirectional if all quay cranes move with a similar sense of movement along their service times. In the following, a hybrid estimation of distribution algorithm with local search (EDA/LS, Expósito-Izquierdo et al. [24]) is described to solve the QCSP from a unidirectional point of view. This approach uses prior knowledge about the problem to achieve high-quality solutions. Additionally, a novel restart strategy (see ▸ Chap. 12, "Restart Strategies") is introduced to prevent the premature convergence of the search and guide it to insufficiently explored regions. Finally, the proper finishing time of the search is determined by means of an adaptive stopping criterion.

Algorithm 3 depicts the pseudocode of the EDA/LS. The proposed scheme keeps, at each generation g, a population $\mathcal{S}(g)$ with N solutions (line 3). Additionally, a probabilistic learning model $\mathcal{P}(g)$ based on a probability matrix with m rows and n columns is considered (line 2). Each value $p_{qt}(g)$ defines the probability of assigning task $t \in \Omega$ to quay crane $q \in Q$ in the model sampling step, as follows:

$$\mathcal{P}(g) = \begin{pmatrix} p_{11}(g) & p_{12}(g) & \cdots & p_{1n}(g) \\ p_{21}(g) & p_{22}(g) & \cdots & p_{2n}(g) \\ \vdots & \vdots & \ddots & \vdots \\ p_{m1}(g) & p_{m2}(g) & \cdots & p_{mn}(g) \end{pmatrix}$$

In most EDAs, the initial population is randomly created according to the uniform distribution over all feasible solutions. The QCSP structure allows the inclusion of a priori knowledge in the scheme of EDA/LS straightforwardly. Intuitively, the probability that a quay crane performs a certain task in a promising solution is highly influenced by the distance between them. The initialization step here is based on a Gaussian function in a discrete way to compute initial assignment probabilities. Its use is based on the fact that it lets to assign a higher weight to those quay

cranes initially located close to the corresponding task, and it is decremented as the distance between them increases. At each new generation, a new population is obtained. The new population is composed of the subset of solutions with the lowest objective function value, $\mathcal{S}_e(g)$, (defined by a percentage α, whose value is set by the user) from the previous population (elitism criterion) and new unidirectional ones sampled from the probabilistic learning model (line 6). In the sampling step, the tasks are assigned to a specific quay crane considering the cross sections in which they are located (from the leftmost up to the rightmost) and following the precedence relationships. At each step, one of the available quay cranes is selected according to the roulette wheel selection based on a pseudo-random generator. The subset of elite solutions is also used to update the probabilistic learning model so that the probability of a task being assigned to a quay crane is defined by the number of times that assignment has been previously performed. This is formally expressed as follows:

$$p_{qt}(g) = \frac{c_{qt}(g)}{\sum_{k \in Q} c_{kt}(g)}, \forall q \in Q, t \in \Omega, \tag{1}$$

where $c(g)$ is a matrix composed of m rows and n columns such that $c_{qt}(g)$ is the number of times task $t \in \Omega$ has been performed by quay crane $q \in Q$ in a high-quality solution found during the search.

In order to overcome the lack of intensification of EDAs, this scheme incorporates a local search. This local search is based on a neighborhood structure composed of movements of reassignment and interchange of tasks between quay cranes. The next current schedule in the local search is selected according to the first improvement strategy. Additionally, the local search is applied to a subset of solutions with the lowest objective function value (line 8) defined by the percentage β (whose value is set by the user) after $\lambda > 0$ generations without improvement (lines 7–9). After applying the local search, a subset of problem variables, $\mathcal{V}$, is selected. $\mathcal{V}$ is defined by the set of tasks performed by different quay cranes in the improved solutions. The effectiveness of the proposed local search is used as an indicator of the search process convergence so that the algorithm execution is stopped when it is not possible to improve any solution from the selected subset of solutions from the population.

Computational Analysis

This section compares the EDA/LS described earlier and the most competitive algorithm from the related literature: unidirectional scheduling and UDS (Bierwirth and Meisel [4]). This comparison is carried out on a benchmark suite proposed by Kim and Park [46] and subsequently extended by Bierwirth and Meisel [4] (90 instances). For each instance, the EDA/LS has been executed on a computer equipped with an Intel 3.16 GHz and 4 GB of RAM, whereas the computational results presented for UDS are those reported in the corresponding original paper. Computational times for those instances that cannot be solved within the maximum computational time of 1 h by the UDS are not reported.

Table 4 Comparison between EDA/LS and UDS. Largest instances

	UDS		EDA/LS		
Instance	f_{UDS}	$t_{UDS}(m.)$	f_{EDA}	$t_{EDA}(m.)$	Gap (%)
k83	948	6,37	948	0,63	0,00
k84	897	3,29	897	0,68	0,00
k85	972	5,82	972	0,68	0,00

k89	843	10,96	843	0,66	0,00
k90	**1053**	24,95	1056	0.69	0,29
k91	**837**	10,74	840	0,70	0,36
k92	**897**	34,61	903	0,62	0,67
Avg.:	889,80	>60,00	891,30	0,69	0,17
k93	**816**	–	822	0,86	0,74
k94	**786**	–	795	0,92	1,15
k95	834	–	834	0,99	0,00
k96	819	–	**804**	0,89	−1,83
k97	720	–	**717**	**0,93**	−0,42
k98	**735**	23,97	741	0,89	0,82
k99	852	–	855	1,03	0,35
k100	900	–	**891**	**1,07**	−1,00
k101	**813**	–	816	0,87	0,37
k102	903	–	**900**	**0,86**	**−0,33**
Avg.:	817,80	>60,00	817,50	0,93	−0,04

Table 4 shows an extract of the computational results in the largest instances ($k83$–$k102$). The objective function values (f_{UDS} and f_{EDA}) and computational times ($t_{UDS}(m.)$ and $t_{EDA}(m.)$) are shown for each approach. The results demonstrate the suitability of the EDA/LS when solving the QCSP. It is effective and efficient when solving the largest problem instances since it presents short gaps, and the best solutions for four problem instances have been improved. In addition, the computational times are lesser than 1 min in all cases.

Internal Vehicle Scheduling

The internal vehicle scheduling problem (IVSP) is an $\mathcal{NP}$-hard optimization problem that consists of assigning jobs to the internal vehicles of the container terminal, in such a way that the time the incoming vessels spend at the port (i.e., their turnaround times) is minimized. In the related literature, this problem has been treated either as vehicle routing problem (VRP) or as scheduling problem (the reader is referred to ▸ Chap. 51, "Particle Swarm Optimization for the Vehicle Routing

Problem: A Survey and a Comparative Analysis" for VRP and ▸ Chap. 56, "Supply Chain Management" for further details). In the IVSP, a set of n vehicles, denoted as V, and a set of m jobs, denoted as $W = \{W_1, W_2, \ldots, W_m\}$, are known. In addition, a set of locations, denoted as L, in which the jobs can start and end is given. A job $j \in W$ corresponds to the transportation of a container from a pick-up location to a delivery location that must be performed from a certain time, t_j. There are two types of jobs:

- *Loading job*. It is the transportation of a container from the yard toward the vessel into which it is going to be loaded. Thus, the pick-up location is a stack on the yard, and the delivery location is at the corresponding quay crane.
- *Discharging job*. It is the transportation of a certain container from its source vessel toward the yard. Therefore, the pick-up location is at the corresponding quay crane, and the delivery location is a known stack on the yard.

Thereby, each job has to be assigned to one of the vehicles. This way, each vehicle can perform a sequence of jobs so that after completing a job, a vehicle can start another one. It should be noted that each job consists of (i) an empty drive of the corresponding vehicle from its last location $i \in L$ to the pick-up location, $k \in L$, whose time is t_{ik}, (ii) a hand-over time at the pick-up location, h_p, (iii) a drive to the delivery location, $l \in L$, and (iv) a hand-over time at the delivery location, h_d. Figure 4 illustrates these times involved in a job, where $departure$ corresponds to location i, $Source\ quay\ crane/stack$ corresponds to location k of the quay crane or a stack depending on the type of job, and finally, $destination\ quay\ crane/stack$ corresponds to location l of the quay crane or stack depending on the kind of job.

Once a vessel arrives at the terminal, its containers are first discharged from the vessel onto the internal vehicles by the available quay cranes. Next, the internal vehicles transport the containers to their pre-specified stacks in the yard. When a vehicle arrives at its destination, a container is unloaded from it by a yard crane. Typically, after most or all containers have been discharged from the vessel, the outgoing containers from the yard are transported to the quay by those internal vehicles and are loaded into the vessel by the quay cranes.

A fast transshipment of containers associated with the vessels is important to both the shipping companies since they can reduce their operational costs, and the

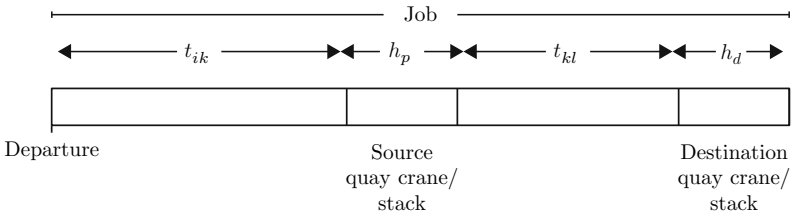

Fig. 4 Breakdown of the times involved in a job

terminal, which can serve many vessels per day. However, in order to achieve this reduction of the turnaround time, different objective functions can be defined, such as minimizing the quay crane waiting times for vehicles, minimizing the vehicles waiting times at quay cranes, minimizing the empty travel times, and minimizing of the cost associated with the jobs.

There are different dispatching approaches to establish the relationship between vehicles and quay cranes. Traditionally, in the static dispatching approach, one vehicle serves only one quay crane. When it finishes an unloading job in the corresponding block in the yard, it must travel back to the bounding quay crane for another unloading job. Empty travel always happens with this dispatching approach. Furthermore, a dynamic dispatching approach means the vehicles can serve any quay crane. When a vehicle finishes its unloading job in the blocks, it can choose either a loading job near it or an unloading job at the quayside. A dynamic dispatching model will help reduce empty travel.

Moreover, a variety of transporters are used in container terminals, such as yard trucks (YTs), multi-trailers, straddle carriers, automated guided vehicles (AGVs), and automated lift vehicles (ALVs). Their heterogeneous technical characteristics allow them to cover many practical scenarios. In this regard, selecting and dispatching technical machinery around a given maritime container terminal are a strategic decision that must be considered according to the environment's features, the cargo volume, etc.

Therefore, when addressing the IVSP, the terminal decision-maker must consider the following: firstly, how many and what type of vehicles are deployed at the terminal; secondly, what kind of relationship is established between vehicles and quay cranes; and finally, what will be the objective to achieve.

Since IVSP is an operational problem (i.e., it has to be solved daily) and is usually integrated with other closely related problems in container terminals (e.g., quay crane scheduling, container storage), it is important to solve it quickly and provide results of the highest possible quality. For this reason, heuristics are appropriate methods to tackle this problem. However, most of the heuristics proposed in the literature are based on particular formulations of the problem with different objective functions, which hinders the comparison among them (e.g. Angeloudis and Bel [1] maximize benefits; Bish et al. [6] minimize travel distances and the transportation time; Briskorn, et al. [8] minimize the weighted sum of earliness, tardiness, and empty travel time; Shang [66] minimizes a weighted sum of cost, etc.). In the following, we describe some basic heuristic strategies to solve the problem:

- *First come, first served (FCFS)*. Each idle vehicle selects the job with the earliest emergence time. In this case, the assignment concept is reversed. This is the conventional scheduling rule followed in container terminals to dispatch vehicles, and its results are taken as reference when a new method is proposed (Shang [66]):
- *First*. A due job will be assigned to the first available vehicle (Angeloudis and Bell [1]).

- *Fastest*. A due job will be assigned to the vehicle that needs less time to complete the job when it finishes its previous one.
- *Earliest*. A due job will be assigned to that vehicle, which will take less time to be available and complete the job.
- *Closest*. A newly idle vehicle will be assigned to the job with the shortest setup operation. In this case, the assignment concept is reversed (Angeloudis and Bell [1]).
- *Shortest-Empty-Travel-Time-First* ($SETTF$). This is based on the FCFS strategy. When a vehicle completes its current job, an unassigned container with the shortest empty travel time is allocated to this vehicle [70].
- *Greedy*. A vehicle will be assigned to the least costly job. The cost of performing job $j \in W$ once the job $i \in W$ has been already performed is denoted as C_{ij} and formally expressed as follows (Angeloudis and Bell [1]):

$$C_{ij} = \alpha L_{ij} + \beta T_{ij} + \gamma U_{ij} + \delta D_i \tag{2}$$

where α, β, γ, and δ are weights, L_{ij} is the distance between the location of the vehicle when finishing job i and the location of the vehicle when starting job j, T_{ij} is the travel time (expected) from the location of the vehicle when finishing of job i to the location of the vehicle when starting of job j, U_{ij} is the uncertainty index associated with transition from job i to job j, and, finally, D_i is equal to 0 if i is not a current vehicle task (assigned job, maintenance, or idle state) or equal to the expected remaining time until job completion i, otherwise.

Figure 5 illustrates an example of a solution, for instance, with four vehicles and ten jobs using $First$ heuristic. The times the jobs can be performed (i.e., t_j, where $j \in W$) are marked by a dashed line. Firstly, four jobs appear at time zero, and they are assigned to the available vehicles. Then, a new job W_5 arises at time instant 5,

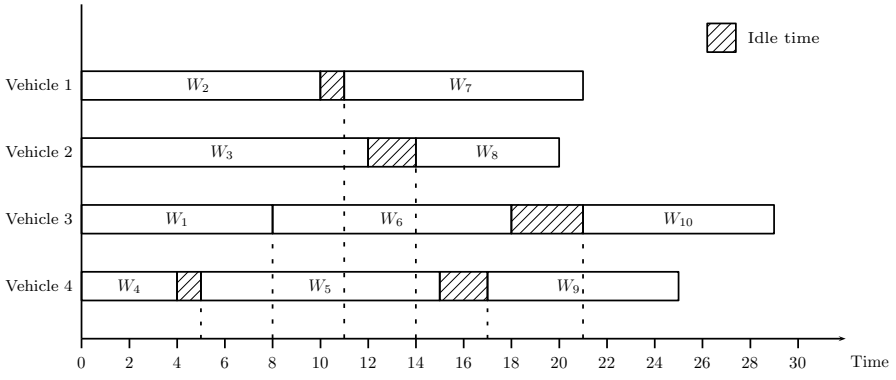

Fig. 5 Example of Vehicle Scheduling Problem using $First$ heuristic

Algorithm 4: General heuristic framework for the Vehicle Scheduling Problem

```
1: S ← ∅
2: f_obj(S) = 0
3: Ω ← List of jobs ordered by appearing time
4: V ← Set of vehicles
5: for i = 1 → m do
6:     v ← Select vehicle from V servicing Ω(i) with the minimum impact on f_obj(S)
7:     Assign v to Ω(i) in S
8:     Update the arrival and departure times of v
9: end for
10: Return S
```

and it is assigned to $Vehicle$ 4, which is the first available vehicle. Next job W_6 appears at time instant eight, and it is assigned to $Vehicle$ 3, which is available just at this time. The process continues following this strategy so that it ends at time 29. A vehicle remains idle whenever a job is not assigned to a vehicle.

Finally, Algorithm 4 shows a heuristic framework for this problem. A minimization function is supposed to be used. Firstly, an empty solution is established, and the objective function is set to zero (lines 1–2). Then, for each job that appears during the planning horizon, a vehicle $v \in V$ is chosen to make it, trying to minimize the impact on the objective function value (line 6). These partial solutions are included in the final one (line 7). Finally, when all the jobs included in Ω have been already assigned to one of the vehicles, the process finishes, and the solution is returned (line 9).

Computational Analysis

This subsection compares some heuristics for the VSP. As mentioned before, the objective function of this problem may vary from one work to another due to the different ways of reducing the turnaround. For this reason, some performance indicators have been used here to compare three of the heuristics explained earlier: $first$, $closest$, and $greedy$. In the following, several indicators are presented to evaluate the performance of the heuristics by means of simulation (Angeloudis and Bell [1]). That is:

1. Vehicle productivity (moves/h): It examines the number of container moves that can be accomplished within an hour by a single vehicle in the fleet so that, unlike the remaining indicators, the higher, the better.
2. Average job delay (s.): It measures the average period between the emergence of a new job and its execution time.
3. Fleet utilization (%): It reflects the percentage of the fleet likely to be involved in a handling operation.
4. Average distance not in-service (m./job): It measures the average traveled distance between the location of the vehicle when finishing a job and the location of the vehicle when starting another.
5. CPU time per instance (ms.): It is the CPU time for solving an instance.

Table 5 Comparison of the heuristics for the Vehicle Scheduling (Angeloudis and Bell [1]). Best heuristic values in bold

	BKS	First		Closest		Greedy	
	Value	Value	Gap(%)	Value	Gap(%)	Value	Gap(%)
1	8.87	5.43	38.78	**5.66**	36.19	5.58	37.09
2	304.00	329.00	8.22	329.00	8.22	**325.00**	6.91
3	93.00	**99.00**	6.45	**99.00**	6.45	**99.00**	6.45
4	355.92	743.11	108.79	**713.71**	100.53	744.78	109.25
5	669.00	**0.00**	−100.00	1.00	−99.85	2.00	−99.70

Table 5 summarizes the computational results for $first$, $closest$, and $greedy$ heuristics. The first column shows the number associated with each performance indicator. The second column shows the best-known solutions (BKS). The remaining columns show the results obtained by each heuristic and the gap regarding BKS values. As can be seen, the heuristic that provides the best results for more indicators is $closest$, which presents the lowest gap for indicators 1, 3, and 4, as well as a very short CPU time. This highlights that serving a job according to the closeness in terms of setup operations benefits, on the overall, the quality of the solution in the majority of the indicators.

Trends in IVSP

Research in the realm of IVSP has evolved from simple rules and heuristics to more sophisticated algorithms, particularly metaheuristics. While heuristics are computationally efficient, their inherently greedy and myopic nature often leads to suboptimal operational outcomes. Metaheuristics, on the other hand, provide superior performance by incorporating advanced search mechanisms. Unlike simpler heuristics, metaheuristics consider a broader spectrum of possibilities and interactions, allowing them to achieve optimal or near-optimal solutions. Table 6 summarizes the main features considered in the most recent IVSP studies, highlighting this shift toward more complex and effective solution strategies. Thus, the use of metaheuristics represents a paradigm shift in addressing IVSP. Among the various metaheuristics, Evolutionary Computation (EC) and, specifically, Genetic Algorithms (GA) have emerged as the forefront solutions for addressing the challenges of IVSP. These algorithms harness principles inspired by natural evolution, employing genetic operators such as crossover and mutation to refine solutions and explore the solution space more comprehensively and iteratively. The adaptability and robustness of GA and EC contribute to their effectiveness in handling the complexities inherent in the problem.

Additionally, holistic approaches to addressing the challenges within container terminals have arisen. One noteworthy trend is the integration of scheduling and routing for internal vehicles, recognizing the interdependence of these two facets in optimizing terminal operations. The joint consideration of scheduling and routing ensures a more comprehensive and synergistic approach, enabling a finer

Table 6 Features and trends in IVSP

Ref.	Problem	Vehicle	Method	Multi-objective	Objectives	Integrated (QCs and YCs)	Conflict-free path planning	Variable speed

balance between operational efficiency and resource utilization. Conflict-free path planning has also emerged as a critical aspect of IVSP, addressing the potential bottlenecks and inefficiencies arising from collisions or congested pathways. These advancements enhance operational safety, mitigate delays, and optimize overall terminal efficiency by incorporating sophisticated path-planning algorithms that ensure vehicle conflict-free trajectories.

Vehicle variable speed considerations represent yet another noteworthy trend. Recognizing that different operational scenarios may warrant varied vehicle speeds, integrating variable speed profiles into scheduling algorithms enables adaptability to dynamic terminal conditions. This flexibility enhances the responsiveness of vehicle operations. On the other hand, from an objectives perspective, another trend involves the consideration of multiple objectives in IVSP algorithms. Some recent research has recognized the multifaceted nature of terminal operations, incorporating diverse objectives such as energy efficiency and resource utilization. This multifaceted optimization contributes to a more nuanced and adaptive vehicle scheduling framework, aligning with the diverse goals of modern container terminals.

Moreover, recent research is increasingly acknowledging the interconnected nature of terminal equipment. The integration of scheduling for vehicles and other critical equipment, such as QCs and YCs, is gaining prominence. This holistic perspective recognizes that the efficiency of vehicle operations is intrinsically linked to the scheduling and coordination of various terminal resources. As such, an integrated approach ensures a synchronized and optimized workflow across different facets of terminal operations.

Container Storage

Container storage is addressed at three different levels: strategic, tactical, and operational, within maritime container terminals. At the strategic level, decisions include defining the yard layout and choosing the type of handling machinery, such as rubber-tired gantry cranes, rail-mounted gantry cranes, and overhead bridge cranes. The tactical level involves determining the storage capacity of the yard and deploying the handling machinery. Operational decisions focus on the short-term movements of containers within the yard, ranging from a few hours to several days.

Figure 6 illustrates a traditional layout of yard in a maritime container terminal in which the top and horizontal views are shown. It comprises a set of similar three-dimensional storage areas, termed yard blocks. In this case, five-yard blocks are depicted. The yard blocks can be placed in a perpendicular (as Fig. 6) or parallel direction to the quay. Each yard block is composed of a set of bays (e.g., ten bays in Fig. 6). A bay is a two-dimensional storage composed of S homogeneous stacks made up of T tiers each one (e.g., bays in Fig. 6 are composed of $S = 8$ stacks and $T = 5$ tiers). The storage capacity of a terminal is expressed in terms of the number of containers that can be stored on it and derived from the dimensions of its yard

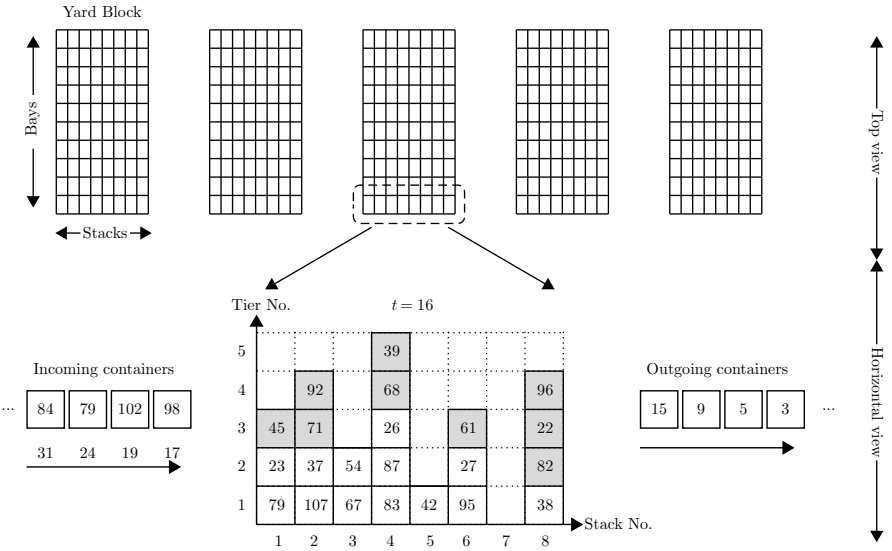

Fig. 6 Layout of a yard in a maritime container terminal

blocks. In this regard, the capacity of a given bay depends upon its stacks and tiers, whereas the capacity of a yard block is the sum of the capacities of its individual bays.

Yard Crane Scheduling Problem

Yard cranes usually manage the yard blocks in a maritime container terminal. Traditionally, one crane is deployed in each yard block. These handling machinery move along the yard blocks through a pair of rail tracks placed on both sides. To access a certain container, the crane is positioned over the bay in which the container is located. The trolley is moved toward its stack, and the spreader is lowered to achieve the container. Finally, the container is hooked up and picked up to be removed from its current location.

In container terminals, multiple challenges emerge on the yard side, necessitating strategic solutions. These include designing schedules for yard cranes and trucks, orchestrating efficient vehicle paths throughout the terminal, and making critical decisions on container storage locations and stacking methodologies within storage areas. Both incoming and outgoing containers spend some time in container terminals awaiting shipment via vessels or delivery by trucks to their final destinations. The yard cranes manage the exchange of containers within storage areas or with the yard trucks. Additionally, yard cranes carry out maintenance tasks like premarshaling and relocating containers.

The yard crane scheduling problem (YCSP) determines the order of container movements carried out by each yard crane. This plays a highlighted role in the

competitiveness of container terminals. Efficient yard crane scheduling can trim down turnaround times for external trucks, decrease energy usage, and shrink overall service duration [78]. Boysen et al. [7] introduces a framework encompassing all crane types, with terminal layout, container movement characteristics, and objectives as key components. Carlo et al. [9] provides a survey specifically focused on yard operations. These surveys encompass a range of crane numbers and configurations.

Initial research is related to non-automated Asian terminals featuring a truck lane along the block where trucks could be positioned adjacent to the bay for container storage or retrieval. Kim and Kim [45] was a pioneer study of the single-yard crane problem, focusing solely on retrieval moves to minimize total container handling time. The authors proposed an integer linear model and later explored genetic and beam search algorithms [47]. Narasimhan and Palekar [62] investigates a similar problem, suggesting exact and heuristic algorithms. Ng and Mak [63] expands the problem scope to include retrieval, storage moves, and ready times, offering first a branch and bound algorithm and later a heuristic approach to minimize job waiting times.

In recent years, attention has shifted to the challenges of automated European terminals, where containers in a yard block can only be accessed through I/O points at the seaside and landside ends of the block. Gharehgozli et al. [35] tackles retrieval moves from specified block positions and storage moves from I/O points to designated positions within the block, aiming to minimize total crane travel time. Gharehgozli et al. [36] extends this by considering open location selections for storage moves. The authors develop an exact three-phase algorithm for small instances and a heuristic for larger ones. Galle et al. [31] explores combined yard scheduling and container relocation for single crane scenarios, proposing an integer model and a local search heuristic adaptable to various yard configurations.

Another relevant aspect in yard crane scheduling problems is the objective definition. As noted in [44], yard crane operations are intertwined with seaside and landside processes, thus minimizing crane travel time may not always align with vessel and truck turnaround time minimization. Prior research predominantly focuses on minimizing total crane travel time, but some studies integrate release and due time considerations. Li et al. [53, 54] and Wu et al. [73] study non-automated terminals with multiple cranes per block, addressing crane interference and container distance requirements. Huang and Li [41] proposes a scheduling system to minimize the total weighted maximum tardiness of loading jobs. Zheng et al. [82] and Liu et al. [56] extend this with uncertain release times using stochastic programming formulations. Gao and Ge [32] jointly optimizes truck and yard crane scheduling to minimize total crane distance and truck waiting times. Chen et al. [14] tackles the problem of yard cranes and AGVs combined. Xing et al. [75] considers quay cranes, AGVs, and yard cranes together, aiming to minimize crane makespan and AGV consumption. Lastly, automated terminals with multiple cranes per block have also been studied, focusing on AGV delays and external truck waiting times [34].

Container Relocation Problems

During a certain planning horizon, H, containers arrive (incoming containers) and leave the yard (outgoing containers). The set of containers is denoted as C. In this regard, each container $c \in C$ has a known arrival time, denoted as $a(c)$, and a retrieval time, denoted as $r(c)$, where $r(c) > a(c)$. The objective of the yard cranes is to store and retrieve the containers according to their arrival and retrieval times. With this goal in mind, the feasible movements to be performed by a crane are defined on the basis of the intrinsic Last In First Out (LIFO) structure of the stacks. That is:

- *Storage movement*. The next incoming container is placed at the top of a stack with at least one empty slot.
- *Retrieval movement*. The next container to retrieve is taken out of its bay whenever it is placed at the top of a stack.
- *Relocation movement*. A container is moved from the top of a stack to the top of another one with at least one empty slot.

The incoming and outgoing containers in a bay give rise to the definition of the following closely related $\mathcal{NP}$-hard optimization problems:

- *Stacking Problem*. It aims to determine the shortest sequence of movements to be performed by the crane to store and retrieve the containers in/from the bay [25].
- *Container Relocation Problem*. It seeks to determine the shortest sequence of relocation movements to retrieve a subset of containers. It is assumed that all the containers are already stored in the bay, and no new incoming containers arrive [27].
- *Pre-Marshalling Problem*. Its objective is to find the shortest sequence of movements to arrange the containers within a given bay, such that any container is placed above another container with earlier retrieval time in the same stack. In this case, neither incoming nor outgoing containers are considered [26].

The main operational decision derived from the definitions of the previous optimization problems is how to evaluate the attractiveness of a certain stack when storing or relocating a container within the bay. Consider the example depicted in Fig. 6. The next incoming container arrives at period 17 and must be retrieved from the bay at period 98. However, its target stack must be selected adequately to minimize the number of future relocation movements. Similarly, target stacks for containers placed above the next to retrieve must be selected. For instance, see the container with retrieval time 96 placed on top of the container with retrieval time 22 in Fig. 6.

Algorithm 5 depicts a general heuristic framework to store and retrieve containers. It is composed of two main steps: retrieving and storing containers. With this goal in mind, at each time period, $t \in [1, 2, \ldots, H]$, the sets of containers to retrieve and store from/in the bay are identified. On the one hand, each container c_{out} to

Algorithm 5: General heuristic framework to store and retrieve containers

```
1: for t = 1 → H do
2:     R_C(t) ← Set of containers to retrieve at time t
3:     S_C(t) ← Set of containers to store at time t
4:     for c_out ∈ R_C(t) do
5:         O(c_out) ← Set of containers currently placed above c_out
6:         Relocate containers from O(c_out) in other stacks
7:         Retrieve c_out from the top of its stack
8:     end for
9:     for c_in ∈ S_C(t) do
10:        s ← Select target stack for c_in
11:        t ← Select target tier for c_in
12:        Relocate c_in in slot (s, t)
13:    end for
14: end for
```

retrieve at period t is checked (lines 4–8). This way, the set of containers currently placed above it, denoted as $O(c_{out})$ (line 5), must be relocated in alternative stacks due to the fact that they are avoiding the retrieval of c_{out} (line 6). How the target positions of these containers are determined constitutes the major difference among the proposals developed by different authors so far. Some examples are described in section "Container Target Positions." Lastly, c_{out} can be directly retrieved from the bay because it would be placed at the top of its stack (line 7). On the other hand, once all the containers to retrieve from the bay at time t have been already retrieved, incoming containers are stored. In this regard, a suitable target stack and tier are first determined (lines 10–11) for each container to store and then moved to them (line 12). It should be noted that in Algorithm 5, retrieval operations (lines 4–8) are performed before storage operations (lines 9–13) in the same time period; however, according to the preferences of the decision-maker, the priority of storage and retrieval operations can be easily exchanged.

Container Target Positions

The main decision to take in the previous heuristic framework is where the containers must be stored or relocated. This is the case for the incoming containers and those currently placed above the next to be retrieved from the bay. In all cases, the problem is, given a certain container, to determine its most suitable target slot (i.e., stack, and tier).

Determining the target slot of a container can be split into two parts: identifying the target stack and establishing a tier in it. Most authors have proposed attractiveness measures to select a target stack, which indicates the suitability of placing a container in a stack. This way, the attractiveness of stack s to place container c is given by a scoring function with the shape $f(c, s)$. In all cases, we define the set of feasible stacks of c, denoted as $S(c)$. It comprises those stacks in which c is not currently placed and with at least one empty slot. Thus, it is assumed that $s \in S(c)$. Some examples of scoring functions are shown in the following:

1. *Random*. The target stack is randomly selected among those feasible stacks for c. That is:

$$f(c, s) = \frac{1}{|S(c)|} \tag{3}$$

2. *Conflict Minimization* (Rei and Pedroso [65]). It seeks to place c in a stack in which it is not going to require future relocations. The set of stacks that allows this fact is denoted as $S(c)'$ and, therefore, the scoring function is defined as follows:

$$f(c, s) = \begin{cases} \frac{1}{|S(c)'|} & \text{if } S(c)' \neq \emptyset \\ \frac{1}{|S(c)|} & \text{otherwise} \end{cases} \tag{4}$$

3. *Flexibility Optimization* (Rei and Pedroso [65]). It aims to place containers with close retrieval times together, whereas in those scenarios in which future relocation movements are unavoidable, these are delayed as much as possible. This is expressed as follows:

$$f(c, s) = \begin{cases} K & \text{if } s \text{ is empty} \\ M_s & \text{if } M_s \geq r(c) \\ 2 \cdot K - M_s & \text{if } M_s < r(c) \end{cases}, \tag{5}$$

   where K is a constant representing a value larger than the latest retrieval time of a container in the bay, and M_s represents the earliest retrieval time of a container in the stack s. These are formally defined as follows: $K = 1 + \max\{r(c')|c' \in C\}$ and $M_s = \min\{r(c')|c' \in C \wedge c' \text{ in } s\}$.
4. *Parameterized Flexibility Optimization* (Rei and Pedroso [65]). It is an extension of the FO in which the best stack is selected with probability $1 - \rho$ (where ρ is a parameter whose value is set by the user), whereas one of the remaining stacks is selected with probability ρ.

In the previous functions, the best stack is selected as the target of c. Moreover, other authors have proposed explicit expressions to select the target stack of container c, denoted as s^*. This is the case, for instance, of Caserta et al. [11], who propose to select the target stack as follows:

$$s^* = \begin{cases} \arg\min_{s \in S(c)}\{\min(s) | \min(s) > r(c)\} & \text{if } \exists s : \min(s) > r(c) \\ \arg\max_{s \in S(c)}\{\min(s)\} & \text{otherwise} \end{cases}, \tag{6}$$

where

$$\min(s) = \begin{cases} 1 + \max\{r(c')|c' \in C\} & \text{if } s \text{ is empty} \\ \min\{r(c')|c' \in C \wedge c' \text{ in } s\} & \text{otherwise} \end{cases}.$$

In this case, Eq. (6) seeks first to place container c in one of the stacks in which it is not going to require additional relocations. Particularly, that stack storing a container with the earliest retrieval time is chosen. However, when this is not possible, c is placed in that stack in which the next retrieval movement must be performed as later as possible.

Computational Analysis

The previous heuristics' performances are assessed in the following. With this goal in mind, a benchmark suite has been considered. It is composed of a wide range of problem instances with a number of containers ranging from 50 to 300. In each case, the containers must be stored in and retrieved from a bay composed of $S = 10$ stacks and without a maximum stacking limit.

Table 7 reports the computational results obtained by the heuristics under analysis over the problem instances from the aforementioned benchmark suite. In this regard, all the heuristics have been implemented in Java and executed on a computer equipped with an Intel 3.16 GHz and 4 GB of RAM. Ten problem instances with a certain number of containers have been used in each case. The column *Containers* shows the number of containers. Furthermore, columns *Random*, *CM*, *FO*, *PFO* ($\rho = 0.001$), and *CSV* present the average number of relocation movements of the solutions reported by the heuristics. The computational times required by the heuristics are not included in the comparison due to the fact that all of them are, even in large-scale scenarios, too negligible to draw any relevant conclusions.

As can be checked in the computational results, FO reports solutions with the lowest number of relocation movements of those heuristics in the comparison. The reason is that this heuristic allows the minimization of the differences in retrieval times of consecutive containers in the same stack of the bay. It should be noted that placing a container at the top of a stack by minimizing the differences in retrieval times reduces the probability of requiring additional relocation movements in the future. Analogously, CSV exploits this idea, and consequently, it also reports high-quality solutions.

Trends in Container Relocation Problems

In recent times, incorporating predefined knowledge has led to the development of heuristic methods designed to enhance computational speed, as exemplified

Table 7 Performance of the heuristics on a wide range of practical-size scenarios

Instance	Random	CM	FO	PFO ($\rho = 0.1$)	CSV
50	73.6	32.9	3.3	5.3	3.5
100	308.4	263.3	29.4	40.5	31.1
150	714.3	680.9	114.0	134.6	114.2
200	1270.2	1329.3	246.3	289.9	247.0
250	1949.4	2222.3	438.6	496.3	443.5
300	2879.4	3501.8	624.1	720.3	635.1

[3]. Despite these advancements, both exact and heuristic algorithms continue to require considerable time to solve numerous variants of container relocation problems. Machine learning algorithms are increasingly being utilized to address container relocation problems. However, research on applying this approach to problems regarding the placement of containers is notably sparse in scientific literature. A novel Deep Learning Heuristic Tree Search (DLTS) approach is proposed to tackle the container pre-marshaling problem in [38]. This study utilizes deep neural networks to extract strategies from existing near-optimal solutions to relocation scenarios. Other work in the same direction is [81]. Furthermore, as suggested in [28], reinforcement learning offers viable alternatives for addressing container relocation challenges. Wei et al. [72] and Jiang et al. [43] are illustrative examples.

Conclusion

Maritime container terminals are large infrastructures in which heterogeneous logistic processes are combined. This fact and the increasing volume of containers moved worldwide make their management extremely complex.

Up to now, exact approaches have not been demonstrated to be efficient due to the $\mathcal{NP}$-hard nature of most of the optimization problems found at maritime container terminals. In this regard, heuristics have stood as the most competitive alternatives because they report (near) optimal solutions within short computational times. This chapter presents and discusses several heuristics to solve several relevant optimization problems. The analysis of the performance of the heuristics indicates that some of them are appropriate when addressing realistic-size scenarios.

The synergies between machine learning and metaheuristics constitute a promising future research line. Machine learning techniques are useful for estimating the value of the variables used to model the problems of a maritime container terminal. Furthermore, they can be used and integrated as a component of metaheuristic frameworks to solve port logistics problems efficiently.

Other progress in heuristics also deserves attention. Namely, hybrid heuristics, which combine different heuristics approaches, have shown the potential to improve solution quality within reasonable computational times. Also, investigation and application of adaptive heuristics that adjust their search strategy based on the search's history or the dynamism present in the maritime terminal environment arise as a relevant future direction.

problems, including remote sensing, medical imaging, artificial vision, and computer-aided design. In particular, medical IR is a mature research field with theoretical support and two decades of practical experience. Formulated as either a continuous or combinatorial optimization problem, medical IR has been traditionally tackled by iterative numerical optimization methods, which are likely to get stuck in local optima and deliver suboptimal solutions. Recently, a large number of medical IR methods based on different metaheuristics, mostly belonging to evolutionary computation, have been proposed. In this chapter, we review the most recognized of these algorithms and develop an experimental comparison over real-world IR scenarios.

Keywords

Medical imaging · Image registration · Image segmentation

Introduction

In its most general formulation, image registration [60] is the task of aligning two or more images in order to establish a spatial correspondence of their common content. These images usually have the same or a similar subject but have been acquired under different conditions, such as time and viewpoint, or by multiple sensors. In medical image analysis, IR is a key technology that allows to "fuse" visual information from different sources [56]. Applications include combining images of the same subject from different modalities, detecting changes before/after treatment, aligning temporal sequences of images to compensate for motion between scans, image guidance during interventions, and aligning images from multiple subjects in cohort studies. The remarkable developments in medical imaging technology over the last few decades determine a constant demand for better image processing and analysis techniques. Dealing with novel, more diverse, and increasingly accurate sources of imaging data is the main challenge in IR, and it explains why it is still a very active research field.

The alignment between two images is specified as a spatial transformation, mapping the content of one image to the corresponding area of the other through a composition of translation, rotation, shear, and other kind of operations. A popular strategy among IR methods is to perform the alignment based on only salient and distinctive parts of the image, such as lines, corners, and contours, called *features*, ignoring the rest of the image content. This approach, called *feature based* [56], has the advantage of greatly reducing the complexity of the problem but relies on the ability to precisely detect the features, either manually or automatically. Any error during the feature extraction stage will propagate into the registration and can hardly be recovered at a later stage. Moreover, this approach is limited to the cases in which features provide enough information to characterize the image content. To avoid these drawbacks, it is possible to use the image intensities directly without any feature extraction, an approach called *intensity based* (or voxel-based)

[60]. Though more expensive in computational terms, intensity-based methods can achieve a superior level of accuracy and robustness.

Regardless of the division, the core of every IR technique is an *optimization process* that explores the space of geometrical transformations. Two strategies are available. In *parameters*-based approaches, the search is directly performed in the space of the registration transformation parameters, turning the registration into a continuous optimization problem. In *matching*-based approaches, instead, features or regions of the image are matched through a search in the space of possible correspondences. In this case, IR is formulated as a combinatorial optimization problem. Once a suitable matching has been found, the transformation parameters are derived accordingly through numerical methods. In both cases the search is guided by a *similarity metric*, a function that measures the degree of resemblance between the input images after the alignment. This can be done either by comparing the whole images or just their corresponding features. Traditional parameters-based methods use classic numerical optimization algorithms [32], while matching-based methods use matching algorithms like iterative closest point (ICP) [5].

Many characteristics of the IR problem, such as noise, discretization, and large differences in the order of magnitude of the transformation parameters, still pose a challenge to traditional optimization methods. A number of alternative approaches based on *metaheuristics* (MHs) [19] are often used to deal with complex real-world problems in computer vision and image processing. In the literature, despite their common structure, feature- and intensity-based methods are usually regarded as different categories of algorithms, therefore most publications deal with either one group or the other. Besides, feature-based approaches based on MHs are much more common than intensity-based ones, as the larger computational cost makes them less suitable for MHs. Nevertheless, both groups have been recently reviewed [13, 52], although separately.

This chapter is structured as follows. Section "Image Registration" provides a general introduction to medical IR and the traditional optimization algorithms used to solve it. Section "Metaheuristics-Based Image Registration" deals with the application of MHs to IR, while section "Outstanding IR Methods Based on MHs" reviews the most important medical IR methods of this kind. Section "Experimental Study" develops two experimental studies, comparing traditional and MH-based methods of the two different families, feature- and intensity-based, over real-world medical applications. Finally, conclusions are provided in section "Conclusion".

Image Registration

Problem Statement

A typical IR problem involves two images, conventionally called *model* (I_M) and *scene* (I_S), with different roles in the registration process. The model is the reference (or target) image, while the scene is the image that is transformed to reach the geometry of the other. Figure 1 illustrates such a process. The registration aims to

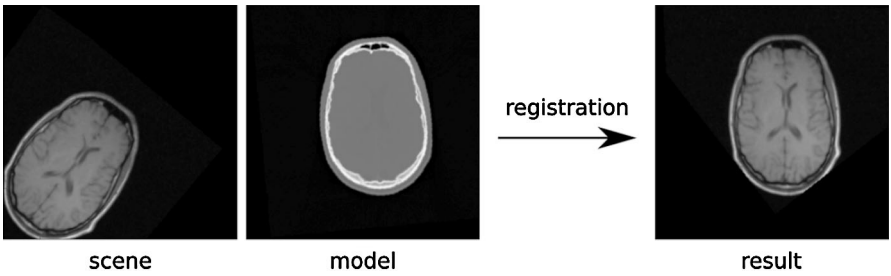

Fig. 1 An example of image registration. A MRI brain scan (*left image*) is aligned to the pose of the CT scan (*middle image*), resulting in the right image

find a geometric transformation T that aligns the scene to the model. In other words, T is the transformation that makes the model I_M and the transformed scene $T(I_S)$ as similar as possible according to the similarity metric of choice. In other terms, IR is a maximization problem over transformations, formally stated as

$$\underset{T \in \text{Transformations}}{arg\ \max} \quad \text{Similarity}\,(I_M, T\,(I_S))$$

A number of components characterize an IR method, but the main ones are just three: the kind of transformation used to relate the images, the similarity metric that measures the quality of the alignment, and the optimization procedure that performs the search for a suitable transformation. The optimization is usually an iterative process. The optimizer computes a candidate transformation, which is then applied to the scene image. Next, the similarity metric compares the model with the transformed scene image and returns a quality value that is sent back to the optimizer. Figure 2 shows a flow chart of the process. The loop ends when a suitable transformation has been found or the algorithm has performed a certain number of iterations.

Transformation Model

The transformation model determines which kind of geometrical transformation can be applied to the scene image to reach the model. This also controls which geometrical properties (e.g., size, shape, position, orientation, etc.) are preserved through the process. Figure 3 shows the effect of three common transformation models.

A rigid transformation involves arbitrary translation and rotation operations, thus it has six degrees of freedom for 3D images. A similarity transform also admits a scaling operation, specified by a seventh parameter. In more complex scenarios, it may also be necessary to correct for shears, for example, those caused by the gantry tilt of CT scanners, or for scaling on a per axis basis. Thus, an affine transformation (nine parameters) is required.

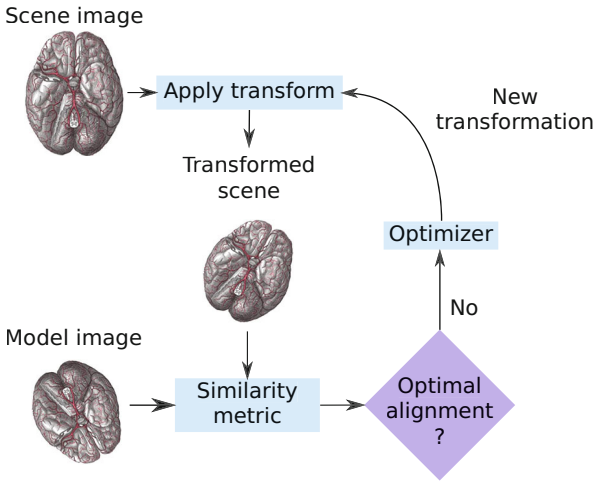

Fig. 2 The interactions among the components of a registration technique

Rigid, similarity, and affine transformations are frequently used for the registration of anatomical structures like the brain or bones; they are not applicable in the case where a significant local deformation is expected, e.g., in soft tissues like the breast. In these cases, deformable or non rigid transforms are required. In a typical approach, an object is deformed by manipulating an underlying mesh of control points. The resulting deformation controls the shape of the 3D object and produces a smooth and continuous transformation between control points.

The choice of the transformation model depends entirely on the needs of the application at hand. A too flexible transformation model is not just more complex and computationally expensive to apply but can also lead to results that are undesired or implausible with respect to the phenomenon under study. Bones being bent and tissues growing at an unrealistic rate are examples of such unacceptable outcomes in the medical context.

Similarity Metric

The performance of any IR method depends on an accurate estimation of the degree of alignment between the images, therefore the similarity metric is considered a crucial component [48]. Technically, a similarity metric is a real-valued function $F(I_A, I_B)$ that measures the resemblance of two images I_A, I_b. The quality of a transformation T is assessed by computing the similarity metric over the model I_M and the transformed scene $T(I_S)$, i.e. $F(I_M, T(I_S))$. The actual evaluation mechanism depends on the nature of the registration approach. In feature-based methods, the similarity metric usually measures the distance between corresponding features [1]. For instance, if the features are points, the alignment can be evaluated using the mean square error (MSE) between the position of a point in the model and that of the corresponding (or closest) point in the transformed scene, i.e.,

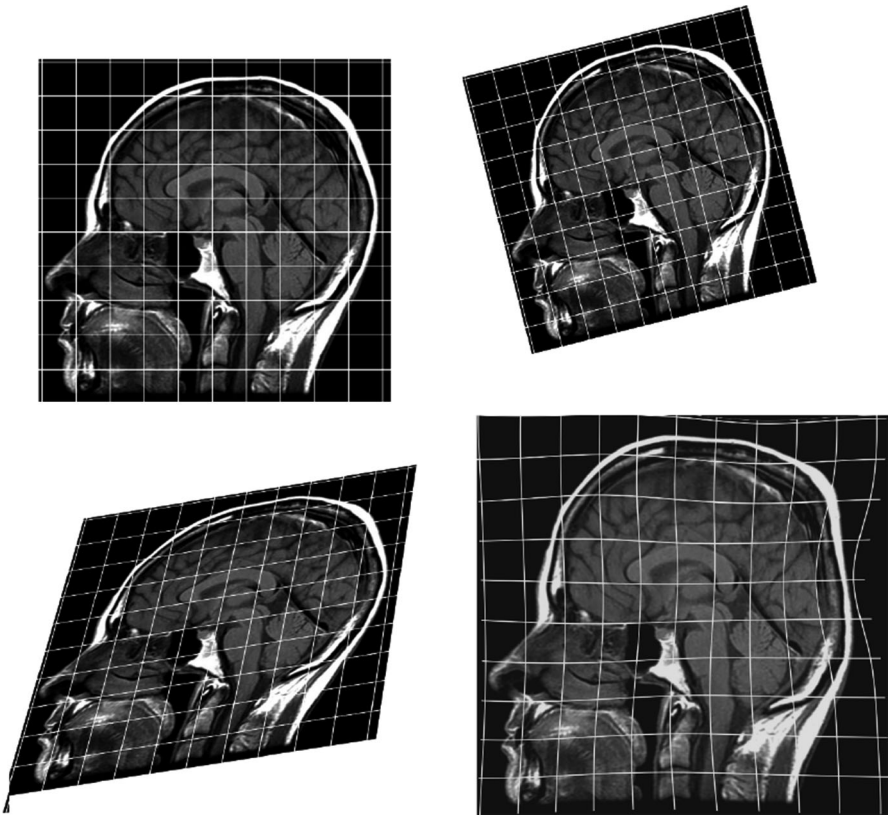

Fig. 3 Images obtained from the same scene (*top left*) by applying different transformations: similarity (*top right*), affine (*bottom left*) and B-spline (*bottom right*)

$$\text{MSE} \;=\; \frac{1}{r}\sum_{i=1}^{r} \|x_i - c\,(T\,(x_i))\|^2$$

where r is the number of points and c is the correspondence criterion.

In intensity-based approaches, similarity metrics are usually based on the resemblance of the intensity values in the two images. The subject of the images along with their modality determine what kind of relationship is established between their intensity distributions. For instance, if one assumes this relationship to be linear, the similarity between the images can be assessed by computing the linear correlation coefficient. When two images have been acquired using different sensors, a scenario called *multi modal* registration, the relationship between their intensity values can be strongly nonlinear. Metrics based on information theory, such as mutual information (MI) [39], are better suited for this scenario. MI is defined as

$$\mathrm{MI}\left(I_A, I_B\right) = \sum_{a \in I_A} \sum_{b \in I_B} p_{AB}\left(a, b\right) \log \frac{p_{AB}\left(a, b\right)}{p_A(a)\ \ p_B(b)}$$

where p_{AB} and p_A, p_B are, respectively, the joint and marginal probability distributions of the intensity values of the images.

Optimization Procedure

The third main component of an IR method is the *optimizer*. It is responsible for finding the best transformation, in terms of similarity metric, among the candidate transformations in the transformation model. Each optimizer has a different search strategy, which also depends on the nature of the algorithm. One approach is to perform the search directly in the space of the transformation parameters. This turns the registration into a continuous optimization problem; therefore classic numerical optimization algorithms can be used. Gradient descent, conjugated gradient descent, Newton's and quasi-Newton methods, Powell's method, and discrete optimization [25, 32] are among the most common choices along with approaches based on evolutionary computation and other metaheuristics [8, 43, 57]. IR algorithms that follow this approach are called *parameters based*. An alternative approach consists in searching for a matching between features, in feature-based methods, and areas of the image, in intensity-based ones. From the match, one can derive the parameters of the corresponding transformation using least-squares estimation or other more robust model fitting techniques [58]. This class of algorithms is called *matching based*. The ICP algorithm is the most representative example of this second approach [29, 44, 59].

Classic IR Algorithms

Iterative Closest Point

ICP [5] is a well-known feature-based algorithm in computer-aided design, originally proposed to recover the 3D transformation of pairs of range images. We are given a point set P of N_p points $\mathbf{p_i}$ from the data shape (the scene) and the model image X of N_x. In the original contribution, the approach dealt with 3D rigid transformations stored in a solution vector $\mathbf{q} = [q_1, q_2, q_3, q_4, t_1, t_2, t_3]$. The first four parameters correspond to a quaternion, determining the 3D rotation component, while the remaining three parameters store the translation vector. The procedure is initialized by setting $P_0 = P$, the initial registration transformation to $\mathbf{q_0} = [1, 0, 0, 0, 0, 0, 0]$ and the iteration counter k to zero. The next four steps are applied until reaching convergence within a tolerance threshold $\tau > 0$:

1. Compute the matching between the scene and the model points using the closest assignment rule. $Y_k = C(P_k, X)$.
2. Estimate the registration by least squares. $f_k = \rho(P_o, Y_k)$.
3. Apply the registration transformation to the scene image: $P_{k+1} = f_k(P_0)$.

4. Terminate the procedure if the change in MSE falls below τ. Otherwise increase k and go to step 1.

Note that ICP is not directly guided by a similarity metric but rather by the computed matching, as other matching-based IR methods. In this strategy, the function MSE only plays the role of the stopping criterion. Moreover, the transformation estimator is a numerical method that depends on the good outcomes of the matching step. Thus, the better the choice of the correspondences that is performed, the more precise the estimation of the transformation f. Consequently, the value of the similarity metric will be more accurate, leading to a proper convergence.

Gradient Descent

In intensity-based IR, gradient-based continuous optimization algorithms are the reference methods [25]. These algorithms consist of an iterative optimization process $\mu_{k+1} = \mu_k + a_k d_k$ where d_k is the search direction at iteration k, and a_k is a gain factor that controls the step size along the search direction. The search directions and the gain factors are chosen such that the sequence μ_k converges to a local minimum of the similarity metric.

The difference between gradient-based optimizers lies in the way the search direction and the gain factor are computed. The gradient descent method (GD) takes steps in the direction of the negative gradient of the cost function, i.e., $\mu_{k+1} = \mu_k - a_k g(\mu_k)$ where g is the derivative of the cost function, and the gain factor is the decaying function $a_k = a/(k + A)^\alpha$ with $a > 0$, $A \geq 1$ and $0 \leq \alpha \leq 1$. The quasi-Newton method (QN) also moves along the negative gradient direction. The gain factor is an approximation of the inverse Hessian matrix $[H(\mu_k)]^{-1}$, computed using the Broyden–Fletcher–Goldfarb–Shanno method. The adaptive stochastic gradient descent (ASGD) [26] is based on the Robbinsâ "Monro stochastic optimization procedure," which is designed to deal with noisy observation of the objective function. ASGD considers the solutions $\mu_{k+1} = \mu_k - \gamma_k(t_k) g_k$ where $t_{k+1} = \max(0, t_k + \text{sigm}(-g_k \cdot g_{k-1}))$ and $\gamma_k = \frac{a}{t_k + A}$. The "time" t_k is adapted depending on the inner product between the current and the previous gradients. If the gradients have the same direction, the time is reduced, leading to a larger step size.

Metaheuristics-Based Image Registration

Suitability of MHs in Image Registration

There are different strengths and limitations that have been stated either to justify or to avoid the use of these methods when tackling IR. Some of the advantages are:

- MHs do not depend on the starting solution, thus being more robust approaches, and provide specific strategies to escape from local optima.

- MHs have been used in a wide variety of optimization tasks within IR including numerical optimization and combinatorial optimization problems, i.e., facing both the transformation parameters and the matching-based IR approaches.
- MHs can easily handle arbitrary kinds of constraints and objective functions.
- MHs offer a framework in which including prior knowledge about the problem is easy. Thus, the search process is more appropriate, yielding a more efficient exploration of the search space. For instance, some feature-based IR approaches [7, 9, 12] improved the design of the objective function to exploit information related to the geometry of the images.
- MHs can also be easily combined with more traditional optimization techniques such as gradient-based methods [23, 45]. An outstanding approach to exploit the benefits of both strategies is their hybridization in the memetic computation paradigm [36, 37].

The most important shortcomings related to the use of MHs are:

- They require a tuning of the control parameters, which is often a manual, error-prone, expert-based procedure. This issue has been addressed using approaches based on automatic parameter tuning [51] or MHs with an adaptive behavior [36].
- Most MHs are time consuming; therefore they are usually avoided in real-time applications. Parallel and GPU implementations are increasingly more common [18, 42].
- Some MHs lack a formal proof of convergence to the global optimum, and there is hardly any theoretical result on the performance of MH. However, there is a very large amount of empirical results to support their effectiveness.

Early Evolutionary Image Registration Methods

The application of MHs to medical IR enjoyed a growing interest in the scientific community over the last 15 years, as shown in Fig. 4. The first attempts at IR can be found in the early eighties. The size of data as well as the number of parameters that are looked for prevent from an exhaustive search of the solutions. An approach based on a genetic algorithm (GA) [21] was proposed in 1984 for the 2D case and applied to angiographic images [17]. Later, in 1989, Mandava et al. [33] used a 64-bit structure to represent a possible solution when trying to find the eight parameters of a bilinear transformation through a binary GA. Brunnström and Stoddart [7] proposed a new method based on the manual prealignment of range images followed by an automatic IR process using a novel GA that searches for solutions following the matching-based approach. Tsang [49] used 48-bit chromosomes to encode three test points as a base for the estimation of the 2D affine registration function by means of a binary-coded GA. In the case of Yamany et al. [57] and Chalermwat et al. [8] proposals, the same binary coding is found when dealing with 3D and 2D rigid transformations, respectively. Yamany et al. enforced a range of $\pm 31°$

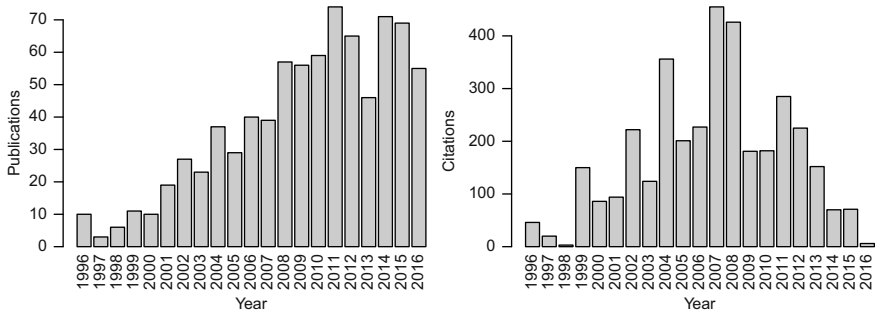

Fig. 4 The number of publications (*left*) and the number of citations (*right*) of literature contributions proposing MHs to solve medical image registration (The data shown in the graph was obtained from Thomson Reuter's Web of Science on November 29, 2016, using the query (Title OR Abstract OR Keywords) = ("image registration" OR "image alignment" OR "image matching") AND ("evolutionary algorithm" OR "evolutionary computation" OR "genetic programming" OR "genetic algorithm" OR "evolutionary programming" OR "evolution strategy" OR "differential evolution" OR "swarm intelligence" OR "bacterial foraging"))

over the angles of rotation and ± 127 units in displacement by defining a 42-bit chromosome with eight bits for each translation parameter and six bits for each rotation angle. Meanwhile, Chalermwat et al. used 12 bits for the coding of the 2D rotation parameter to get a search scope of $\pm 20.48°$, therefore allowing the use of a precision factor for the discretization of the continuous rotation angle interval. Other ten bits stored each of the two translation parameters (± 512 pixels).

All the latter approaches showed several pitfalls from an evolutionary computation perspective. On the one hand, they make use of the basic binary coding to solve inherently real-coded problems, when it is well known that binary coding suffers from discretization flaws (as problem solutions of search space never visited) and requires transformations to real values for each solution evaluation. Moreover, the kind of GA considered is usually based on the old-fashioned original proposal by Holland [22]. In this way, a selection strategy based on fitness-proportionate selection probability assignment and the stochastic sampling with replacement, as well as the classical one-point crossover and simple bit flipping mutation, are used. On the one hand, it is well known that such selection strategy causes a strong selective pressure, thus having a high risk of premature convergence of the algorithm. On the other hand, it has also been demonstrated that it is difficult for the single-point crossover to create useful descendants as it is excessively disruptive with respect to the building blocks.

Outstanding IR Methods Based on MHs

This section reviews the state of the art in MH-based proposals for medical IR, grouping the algorithms according to their nature.

Feature-Based Techniques

De Falco et al.'s Differential Evolution

In [14], the authors proposed an IR method based on the differential evolution (DE) [47]. DE is a parallel direct search method that has proved to be a promising candidate to solve real-valued optimization problems. DE combines simple arithmetic operators with the classical crossover, mutation, and selection genetic operators within an easy to implement scheme. It shows the advantage of considering few control parameters, namely, mutation factor and recombination rate. The fundamental idea of DE is a new scheme for generating trial solutions by adding the weighted differenced vector between two population members to a third one. The proposed method is applied to two 2D IR problems: mosaicking and changes in time of satellite images. Registration is carried out from the transformation parameters-based approach searching for the most suitable affine transformation (given by 11 real-coded parameters) in terms of maximization of the MI similarity metric.

Lomonosov et al.'s Genetic Algorithm

In [30], the authors tackle pairwise IR of range images, facing three real-world noisy measured datasets provided by their REPLICA laser range scanner and other two from the SAMPL database. They considered the transformation parameters-based approach using rigid transformations. The main novelties of this contribution are the inclusion of a degree of overlapping parameter in the solution vector and the utilization of the trimmed squares metric as objective function to be minimized. They constitute a different schematic approach for the IR problem that offers correct coarse IR results at overlaps under 50%. A random sampling procedure is performed in order to speed up the performance of the method. According to the evolutionary design of their method, a generational GA performing search in the seven-dimensional space formed by three translation parameters, three rotation parameters, and the newly added degree of overlapping parameter is considered. They used an integer coding representation of solutions which should be properly normalized onto the corresponding real-value range. Simple one-point crossover was employed, and two mutation operators were introduced. Shift mutation alters one parameter randomly by a value not exceeding 10% of the parameter range. Meanwhile, replacement mutation substitutes a parameter with a random value. Tournament and elitism were also employed.

Wachowiak et al.'s Particle Swarm Optimization

The authors contributed with a broad study of the performance of particle swarm optimization (PSO) algorithms [24] for solving the IR problem in biomedical applications [55]. In particular, they consider registering single slices (2D images) of 3D volumes to whole 3D volumes of medical images. In contrast to usual EAs which exploit the competitive characteristics of biological evolution (e.g., survival of the fittest), PSO exploits cooperative and social aspects, such as fish schooling, birds flocking, and insects swarming. However, both EAs and PSO approaches are considered population-based schemes. In particular, PSO algorithms start with a

random population (swarm) of individuals (particles) which iteratively change their search space location by performing movements based on a velocity vector. The authors addressed the IR problem from the transformation parameters-based approach, considering a rigid transformation and the MI similarity metric as the objective function to be maximized. The variant called *PSO7* is the one achieving the best performance. It refers to a basic PSO with the following formulation for the velocity vector update $v_i(t) = \chi[v_i(t-1) + \varphi_1\mu_1(p_i - x_i(t-1)) + \varphi_2\mu_2(g - x_i(t-1))]$ with $\varphi_1 = 2.1$, $\varphi_2 = 1.3$, and the constriction coefficient $\chi = 0.7298$. However, the performance of the method is dependent on the initial orientation of the images to be registered that should be provided by the user.

Cordón et al.'s Scatter Search

The main idea behind scatter search (SS) [28] is a systematic combination between solutions (as opposed to a randomized one, usually employed in GAs) taken from a considerably reduced pool of solutions, named reference set. The fact that the mechanisms within SS are not restricted to a single uniform design allowed the authors to explore and design different strategies that demonstrated to be effective tackling point matching IR problems [12]. Furthermore, new designs for three of the five SS components—the generator of diverse solutions, the improvement, and the combination methods—were proposed to develop a method outperforming the state-of-the-art point matching approaches. In particular, the authors adopted the same feature-based approach and the same representation of solutions based on permutations previously proposed in [9]. Similarity transformations present in 3D MRIs of human brains and 3D CTs of human wrists were also considered in this work. In particular, they succeeded at dealing with significant transformations between the two registered images, one of the ICP's pitfalls.

Santamaría et al.'s Scatter Search

In [45], the authors specifically performed a broad study about the performance capabilities of different memetic IR algorithms. The authors combined three existing MH-based methods [10, 11, 14] with several local search algorithms: XLS [6], Solis and Wets [46], and Powell [41]. Two different criteria (deterministic and probabilistic) were taken for the application of the local search, and different search intensity levels were tested. Thus, 57 different memetic IR methods were designed overall. The obtained experimental results in the 3D reconstruction of different human skull models, supported by a complementary nonparametric statistical test, revealed that the SS variant that made use of the deterministic local search application criterion and the XLS local search algorithm offered the best performance among all the developed memetic-based IR methods.

Intensity-Based Techniques

Valsecchi et al.'s Genetic Algorithm

r-GA$^+$ is an evolutionary IR method for medical imaging [50]. The optimization component of r-GA$^+$ is based on a GA with a real-coded design. A solution is

encoded as a real vector, storing the transformation parameters, and the variation operators are common choices for real-coded genetic algorithms: blend crossover (BLX-α) [16] and random mutation [2]. The fitness value of a solution t is simply the similarity metric between the two images when aligned according to t. No changes are required to handle different transformation models or similarity metrics. A distinctive feature of r-GA$^+$ is the use of multiple resolutions combined with a *restart* and a search space adaptation mechanism. The key idea is that if a low-quality solution is carried over to the second resolution, the process is unlikely to recover and produce a good final solution. Therefore, restart is used at the end of the first resolution until a suitable solution if found. This process is computationally cheap, because in the first resolution the algorithm is using a small version of the imaging data, and most of the total effort is spent on the further resolutions. In addition, as the second resolution is meant to be a refinement phase, the search is focused around the best solution by restricting the range of the transformation parameters.

Valsecchi et al.'s Scatter Search

The SS$^+$ algorithm [53] is based on a two-tier SS design, meaning there are two reference sets containing, respectively, the most high-quality and diverse solutions. The methods of the SS template have been specifically chosen for IR. The diversification generation method is based on frequency memory [20] to ensure the search space is explored in a uniform manner. The solution combination method is the BLX-α crossover, while the improvement method is a local search based on a the "parent-centric" version of BLX-α called PMX-α [31]. Last, the reference set update method maintain the highest-quality solutions in the quality reference set and the most diverse solutions in the diversity one, where the diversity value of a solution x measures the distance between the solution and the quality reference set S. SS$^+$ also includes a duplication control method, in order to prevent the reference set to contain only almost identical copies of the same solution. Moreover, SS$^+$ implements the same multi-resolution strategy as r-GA$^+$, including the restart and the dynamic boundary mechanism.

Bermejo et al.'s Bacterial Foraging Optimization Algorithm

r-BFOA is an evolutionary IR method for complex 3D scenarios [3]. The global optimization process of the original BFOA proposal [38] has been adapted to the IR problem, using a hybrid approach. Likewise r-GA$^+$, a solution is encoded as a real vector, which allows the use of a recombination mechanism between two solutions by means of the crossover operator BLX-α after each chemotactic step. In addition, after each reproduction step, XLS is applied to the best bacterium in the population. A comparative study of some design variants modifying the original BFOA scheme when applied to the IR problem is presented in [4]. Even though the BFOA algorithm provides an elimination-dispersal step which reintroduces random bacteria in the population, a restart mechanism has been applied to prevent the stagnation of the bacteria. This mechanism simulates the death of all the population, reintroducing new bacteria with the aim of providing a good solution to the second resolution.

Experimental Study

The aim of the experimentation is to carry out an objective, quantitative comparison of the methods described in section "Outstanding IR Methods Based on MHs". Two separated experiments have been developed considering, respectively, feature- and intensity-based methods. We also included the traditional optimization algorithms presented in section "Metaheuristics-Based Image Registration" as baseline. See [13, 53] for a more detailed description of these comparisons.

Each experiment uses a different dataset, from which we have created a number of registration scenarios. As most of the algorithms involved are of non-deterministic nature, we carried out a number of independent runs on each scenario. The analysis measures the performance of the algorithms on each scenario by computing their mean and standard deviation values and ranking the algorithms accordingly.

Feature-Based Comparison: Registration of Brain Magnetic Resonance Images

We use a dataset from the BrainWeb public repository of the McConnell Brain Imaging Centre [27]. The BrainWeb repository is a Simulated Brain Database (SBD) providing synthetic MRI data computationally generated. Full 3D data volumes have been simulated for both models using three sequences (T1-, T2-, or proton density- (PD) weighted) and a variety of slice thickness, noise levels, and levels of intensity nonuniformity (RF). Table 1 describes the particular settings considered to generate every BrainWeb image of our study (named BW1, BW2, and BW3).

To obtain a suitable set of features, we extracted the isosurface and selected the crest-line points with relevant curvature information from the original images, using a 3D crest-line edge detector [35] (Fig. 5). The resulting datasets have between 300 and 600 points per image (see Table 1).

We considered the parameter values originally proposed by the authors in every contribution. Nevertheless, we have adapted the majority of the methods by using the same objective function in order to carry out a fair comparison. We designed several IR problem instances, taking into account similarity transformations (rotation, translation, and uniform scaling) for medical applications, thus coping with the specific characteristics of this application domain. For each problem instance

Table 1 Detailed description of the BrainWeb image dataset generated by the on-line SBD system

Image	Model	Modality	Noise	Protocol	RF (%)	Crest-line points
BW1	Normal	T1	0	ICBM	20	583
BW2	Mild MS	T1	1	AI	20	348
BW3	Mild MS	T1	5	AI	20	284

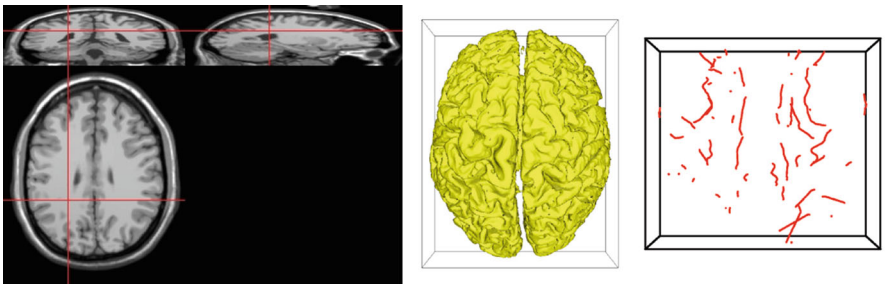

Fig. 5 From *left* to *right*: the original medical image, the corresponding extracted isosurface, and the crest line extracted from the isosurface

tackled by the IR methods, 30 different runs are performed. Each run considers a different similarity transformation. In order to perform a fair comparison among the methods included in this study, we considered CPU time as the stop criterion. After a preliminary study, we found that 20s was a suitable stop criterion to allow all the algorithms to converge properly.

The way a particular run is performed is as follows: a random (similarity) transformation is applied to the ground-truth image and then the IR method estimates the unknown inverse transformation. In particular, similarity transformations are randomly generated following a uniform probability distribution as follows: each of the three rotation axis parameters will be in the range $[-1, 1]$; the rotation angle will range in $[0°, 360°]$; the three translation parameters in $[-40$ mm, 40 mm$]$; the uniform scaling ranges in $[0.5, 2.0]$.

Results

The results of the first experiment are reported in Table 2. We computed the mean and standard deviation of the MSE and ranked the algorithm accordingly for each scenario. Table 3 shows the average rankings.

The average MSE values are considerably different in one algorithm to another even when the same scenario is considered. This, together with the generally high standard deviation values, points to the fact that the algorithms can occasionally perform poorly. Nevertheless, considering the results of Liu-ICP [29] as a baseline, all algorithms performed better than the baseline on average. Indeed, Liu-ICP delivered a consistent but poor performance, ranking last on all scenarios, with MSE values just below 3000. Cordón-SS, Lomonosov-GA, and Wachowiak-PSO have slightly similar results, with MSE values in mostly the range 500–1000 and similar rankings (3.67, 4 and 4.33, respectively). Santamaría-SS and DeFalco-DE delivered much better results compared to the rest of the algorithms. Impressively, Santamaría-SS always returned MSE values below 0.01. The same applies to DeFalco-DE in BW1-3 and BW2-3, but the algorithm scored 132 on BW1-2, a much higher value but still enough to rank second on that scenario. Therefore, while the two algorithms have quite similar rankings (1.33 and 1.67), in addition to ranking

Table 2 Detailed results of the first experiment. For each scenario, the table reports the average MSE, standard deviation and ranking of the algorithms in the comparison

		MSE

Cordón-SS	3.67
Lomonosov-GA	4
Wachowiak-PSO	4.33
Liu-ICP	6

first overall, there is a clear advantage for Santamaría-SS in terms of consistency of its performance.

Second Experiment: Atlas-Based Segmentation of Brain Deep Nuclei

In the second experiment, we compare intensity-based algorithms over the registration of real brain MRI images without applying any transformation. The registration is used to perform atlas-based segmentation of deep brain structures [54]. The quality of the segmentation obtained in this phase is used to assess the effectiveness of the registration methods.

Atlas-based segmentation is a procedure that aims to automatically delineate a region of an image using an atlas (or an "average" image) of a similar subject in which the desired region has been already segmented. The first step is to register

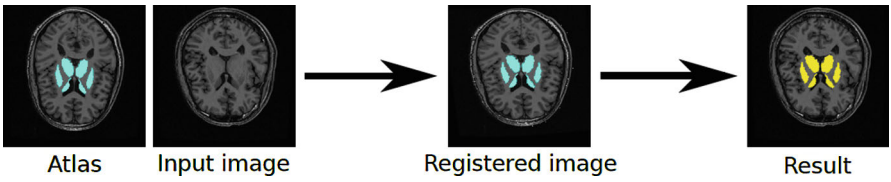

Fig. 6 The atlas-based segmentation of deep brain structures in brain MRI. First, the atlas is registered to the input image and the resulting transformation is applied to the labeled region of the atlas (*in blue*). The resulting region is overlapped on the input image (*in yellow*) to determine the output of the process

the atlas (the scene) to the input image (the model). The transformation resulting from this phase is then used to overlap the segmented region of the atlas to the scene. The region of the scene that overlaps the segmented region of the atlas is the result of the segmentation process. Figure 6 illustrates the process. Often, atlas-based segmentation is used as preliminary step in a more complex segmentation approach [34].

Thirteen T_1-weighted brain MRI were retrieved from the NMR database [40]. The deep nuclei structures in each image have been manually delineated by an expert in order to create the ground-truth data used to evaluate the registration. Figure 6 shows one of the images along with the corresponding deep nuclei. Eighteen registration scenarios were created by selecting pairs of different images at random.

The algorithms under comparison are SS^+, r-GA^+, r-BFOA, QN, and ASGD. The transformation model is affine transform, which involves rotation, translation, scaling, and shearing, and it can be represented using 12 real parameters. The stopping criterion is a time limit of 10 min. Note that no synthetic transformation is applied on the images; the registration aims to compensate for the variability in the pose of the patient during the acquisition of the images.

Results

The quality of atlas-based segmentation depends closely on the accuracy of the registration step, although the anatomical variability of the target region can limit its effectiveness. For each scenario we performed 32 independent runs of each algorithm. The segmented region obtained from the registration V_R is then compared with the ground-truth V_{GT}. The overlapping of the two regions is commonly measured using the Dice's coefficient [15], given by $\text{Dice}\ (V_R, V_{GT}) = \frac{2|V_R \cap V_{GT}|}{|V_R|+|V_{GT}|}$ where $|\cdot|$ is the number of voxels. A value of 1 means perfect overlapping, while 0 means the two regions do not overlap at all.

The results of the second experiment are reported in Table 4. We computed the mean and standard deviation of the overlap and ranked the algorithm accordingly for each scenario. Table 5 show the mean rankings for the algorithms in the comparison.

Table 5 Second experiment: the average rankings of the algorithms

Algorithm	Mean rank
SS^+	1.61
r-GA^+	2.22
ASGD	2.94
QN	3.72
r-BFOA	4.50

The overlap values can differ considerably across the scenarios, reflecting the fact that the effectiveness of this kind of segmentation can vary depending on the concrete anatomy of the patients. On average, r-BFOA scored the worst results in the comparison, ranking last in 10 out of 18 scenarios, with a mean rank of 4.5. High standard deviation values point to a quite uneven performance across different runs. QN ranked fourth on average, but overall the results are very inconsistent, with QN scoring in the top three in 7 out of 18 scenarios, but delivered much worse results in the remaining ones.

In general, r-GA^+ and ASGD have similar results, whereas SS^+ ranked constantly better than the others. ASGD delivered an acceptable performance, due to the low "magnitude" of the transformations involved, which is quite suitable for a local search method. However, note that the low variability of its overlap values means almost all solutions have a lower quality than the average solution found by the other two algorithms. r-GA^+ had a similar performance, while that of SS^+ is the best one of the comparison, with a mean rank of 1.61 against 2.22 and 2.94.

Conclusion

The adoption of MHs in order to solve optimization problems in the area of computer vision is steadily increasing. Medical IR is an excellent example of this trend, with feature-based being the most prevaling and mature approach. This chapter introduced the IR problem in depth and reviewed the design of some outstanding methods in the field, showing how IR have been successfully tackled using a wide spectrum of MH techniques. Despite the large interest in the community toward improving the traditional, well-known optimization methods for IR such as ICP, the experimentation in this chapter shows how algorithms based on MHs can provide superior results in terms of accuracy and robustness on challenging, real-world medical IR scenarios.

Abstract

In this chapter, an overview on metaheuristic algorithms that have been very successful on tackling a particular class of natural gas pipeline network optimization problems is presented. In particular, the problem of minimizing fuel consumption incurred by the compressor stations driving natural gas in pipeline networks is addressed. This problem has been studied from different angles over the past few years by virtue of its tremendous economical impact. First, a general mathematical framework for this class of problems is presented. Then, the most relevant model properties and fundamental network topologies are thoroughly discussed. It is established how these different network topologies play a very important role on choosing an appropriate solution technique. This is followed by a presentation of current state-of-the-art metaheuristics for handling different versions of this problem. A discussion on metaheuristics developed to address related problems is included. Finally, some of the most relevant and important challenges of this very exciting area of research in natural gas transportation networks is highlighted.

Natural gas transmission systems · Pipeline optimization · Nonlinear programming · Mixed-integer nonlinear programming · Tabu search · Ant colony optimization

Introduction

There are many interesting decision-making problems in the natural gas industry that have been studied over the years. These include fields such as pipeline design, gas storage, gathering, transportation, and marketing, to name a few. An important class of these problems, referred to as the minimum fuel consumption problem (MFCP), deals with how to operate a natural gas transportation network for delivering the gas from storage facilities to local distribution companies so as to minimize the fuel consumption employed by the compressor stations moving the gas along the network. Efficient design and operation of these complex networks can substantially reduce airborne emissions, increase safety, and decrease the very high daily operating costs due to the large amounts of fuel per day needed to operate the compressor stations driving the gas.

This type of networks is very complex and highly nonlinear, since the relationship between the flow variables in every arc and the pressure values at the interconnection points is represented by nonlinear equations, and, in some cases, by partial differential equations. Thus, in general, the class of MFCPs is very challenging due to the presence of nonlinearities and nonconvexities in the models representing such problems. These problems have been studied since the late 1960s

from many different angles, most of them based on classical hierarchical control and mathematical programming approaches.

It was until very recently that metaheuristics techniques were introduced for addressing some of these problems. One of the great advantages of metaheuristic algorithms over existing approaches is that the former does not depend on gradient-based information, so they can handle the nonlinear and nonconvex nature of the problems with relative ease. Furthermore, they can be combined with existing mathematical programming approaches in intelligent ways to derive hybrid metaheuristic methods.

The purpose of this chapter is to introduce the reader with an important class of challenging optimization problems in natural gas transportation networks and to give a detailed discussion on how metaheuristics have been successfully applied on addressing these problems. There are of course other important decision-making problems in the natural gas industry for which optimization techniques have made important contributions. A survey by Zheng et al [65] surveys optimization models in the natural gas industry, focusing on natural gas production, transportation, and marketing. Ríos-Mercado and Borraz-Sánchez [50] present an extensive review on classical techniques for fuel consumption minimization on transmission systems, including gathering, transmission, and local distribution. Schmidt et al. [53] present stationary nonlinear programming models of gas networks that are primarily designed to include detailed nonlinear physics in the final optimization steps for midterm planning problems. Farrokhifar et al. [19] present a comprehensive survey of literature in the contexts of coordinated planning of both natural gas and electricity systems.

It is important to note that we are focusing in the decision-making process of operating a pipeline network assuming the network is already designed. The problem consisting of how to design such network, known as a pipeline network design problem, is also an optimization problem where the decision variables are the diameter choices of the pipes, the flows, the potentials, and the states of various network components [25, 31]. This design problem is usually cast as a nonconvex mixed-integer nonlinear programming problem, and it is out of scope of the present work. The distribution problem [63] which consists of delivering the gas from the demand stations to the end customers is not considered either.

The chapter is organized as follows. The basic mathematical framework for the steady-state case, including important model properties, is presented in the first section. Then, in the following section, the existing classical approaches for handling different versions of this problem including steady-state and transient models are briefly highlighted. This is followed by two sections where both a Tabu Search algorithm for handling a nonlinear programming model and an Ant Colony Optimization algorithm for handling a mixed-integer nonlinear programming model are described. Other metaheuristic approaches for related problems in the natural gas industry are reviewed next. Final remarks and discussion on future research trends about metaheuristic techniques in natural gas optimization problems are given in the last section.

Problem Description and Modeling Framework

Background

Basically, the main purpose of a natural gas transmission network is to transport gas from storage facilities to local distribution companies. The gas is moved by pressure, and pressure is lost due to the friction of the gas flow with the inner wall of the pipelines. Thus, to keep the gas moving, compressor stations, whose primary role is to increase gas pressure, are needed. In turn, every compressor station is composed of several compressor units. These units may be identical or nonidentical and hooked up in different ways. The most typical configuration, which is assumed throughout this chapter, is that of identical compressor units hooked-up in parallel. It is well known that most of the operating costs in a pipeline network are due the amount of fuel consumed at the compressor stations.

When operating a natural gas transmission system aiming at minimizing fuel consumption, there are two main groups of decision variables that must be taken: (i) the mass flow rate through every pipe and compressor stations, and (ii) gas pressure values in each interconnection point. Additionally, decisions such has how many individual compressor units to operate within stations may be taken. Hence, the objective for a transmission network is to minimize the total fuel consumption of the compressor stations while satisfying specified delivery flow rates and minimum pressure requirements at the delivery terminals. The MFCP is typically modeled as a nonlinear or mixed-integer nonlinear network optimization problem. It is of course assumed that the network is given; that is, this is not a design problem.

Depending on how the gas flow changes with respect to time, we distinguish between systems in steady state and transient state. A system is said to be in steady state when the values characterizing the flow of gas in the system are independent of time. In this case, the system constraints, particularly the ones describing the gas flow through the pipes, can be described using algebraic nonlinear equations. In contrast, transient analysis requires the use of partial differential equations (PDEs) to describe such relationships. This makes the problem considerably harder to solve from the optimization perspective. In fact, optimization of transient models is one of the most challenging ongoing research areas. In the case of transient optimization, variables of the system, such as pressures and flows, are functions of time.

Gas transmission network problems differ from traditional network flow problems in some fundamental aspects. First, in addition to the flow variables for each arc, which in this case represent mass flow rates, a pressure variable is defined at every node. Second, besides the mass balance constraints, there exist two other types of constraints: (i) a nonlinear equality constraint on each pipe, which represents the relationship between the pressure drop and the flow; and (ii) a nonlinear nonconvex set which represents the feasible operating limits for pressure and flow within each compressor station. The objective function is given by a nonlinear function of flow rates and pressures. The problem is very difficult due to the presence of a nonconvex objective function and a nonconvex feasible region.

Description of Basic Model

Let $G = (V, A)$ be a directed graph representing a natural gas transmission network, where V is the set of nodes representing interconnection points, and A is the set of arcs representing either pipelines or compressor stations. Let V_s and V_d be the set of supply and demand nodes, respectively. Let $A = A_p \cup A_c$ be partitioned into a set of pipeline arcs A_p and a set of compressor station arcs A_c. That is, $(u, v) \in A_c$ if and only if u and v are the input and output nodes of compressor station (u, v), respectively.

Two types of decision variables are defined: Let x_{uv} denote the mass flow rate at arc $(u, v) \in A$, and let p_u denote the gas pressure at node $u \in V$. The following parameters are assumed known: B_u is the net mass flow rate in node u, and P_u^L and P_u^U are the pressure limits (lower and upper) at node u. By convention, $B_u > 0$ ($B_u < 0$) if $u \in V_s$ ($u \in V_d$) and $B_u = 0$ otherwise.

The basic mathematical model of the minimum fuel cost problem (MFCP) is given by:

$$\text{Minimize} \quad g(x, p) = \sum_{(u,v)\in A_c} g_{uv}(x_{uv}, p_u, p_v) \tag{1}$$

$$\text{subject to} \quad \sum_{v:(u,v)\in A} x_{uv} - \sum_{v:(v,u)\in A} x_{vu} = B_u \qquad u \in V \tag{2}$$

$$(x_{uv}, p_u, p_v) \in D_{uv} \qquad (u, v) \in A_c \tag{3}$$

$$x_{uv}^2 = R_{uv}(p_u^2 - p_v^2) \qquad (u, v) \in A_p \tag{4}$$

$$p_u \in [P_u^L, P_u^U] \qquad u \in V \tag{5}$$

$$x_{uv} \geq 0 \qquad (u, v) \in A \tag{6}$$

The objective function (1) measures the total amount of fuel consumed in the system, where $g_{uv}(x_{uv}, p_u, p_v)$ denotes the fuel consumption cost at compressor station $(u, v) \in A_c$. For a single compressor unit, the following function is typically used:

$$g^{(1)}(x_{uv}, p_u, p_v) = \frac{\alpha x_{uv}}{\eta} \left\{ \left(\frac{p_v}{p_u} \right)^m - 1 \right\},$$

where α and m are assumed constant and known parameters that depend on the gas physical properties, and η is the adiabatic efficiency coefficient. This adiabatic

coefficient is a function of (x_{uv}, p_u, p_v), that is, in general, a complex expression, implicitly defined. A function evaluation of η requires solving a linear system of algebraic equations. In practice, though, polynomial approximation functions that fit the function relatively well and are simpler to evaluate are employed. In other cases, when the fluctuations of η are small enough, η can be assumed to be a constant.

For a compressor station (u, v) with n_{uv} identical compressor units hooked-up in parallel which is very commonly found in industry, the fuel consumption is given by:

$$g_{uv}(x_{uv}, p_u, p_v) = n_{uv} g^{(1)}(x_{uv}/n_{uv}, p_u, p_v). \tag{7}$$

When all n_{uv} units are fixed and operating, we have a nonlinear programming (NLP) model. Treating n_{uv} as decision variables leads to mixed-integer nonlinear programming (MINLP) models.

Constraints (2) establish the mass balance at each node. Constraints (3) denote the compressor operating limits, where D_{uv} denote the feasible operating domain for compressor $(u, v) \in A_c$. Equations (4) express the relationship between the mass flow rate through a pipe and its pressure values at the end points under isothermal and steady-state assumptions, where R_{uv} (also known as the pipeline resistance parameter) is a parameter that depends on both the physical characteristics of the pipeline and gas physical properties. When the steady-state assumption does not hold, this relationship is a time-dependent partial differential equation which leads to transient models. Constraints (5) set the lower and upper limits of the pressure value at every node, and (6) set the nonnegativity condition of the mass flow rate variables. Further details of this model can be found in Wu et al. [61] and Ríos-Mercado [49].

Network Topology

There are three different kinds of network topologies: (a) linear or gun-barrel, (b) tree or branched, and (c) cyclic. Technically, the procedure for making this classification is as follows. In a given network, the compressor arcs are temporarily removed. Then each of the remaining connected components is merged into a big super-node. Finally, the compressor arcs are put back into their place. This new network is called the *associated reduced network*. Figure 1 illustrates the associated reduced network for a 12-node, 11-arc example. As can be seen, the reduced network has four supernodes (labeled S1, S2, S3, S4) and three arcs (the compressor station arcs from the original network).
Types of network topologies:

Linear topology: Reduced network is a single path.
Tree topology: Reduced network is a tree.
Cyclic topology: Reduced network has cycles (either directed or undirected).

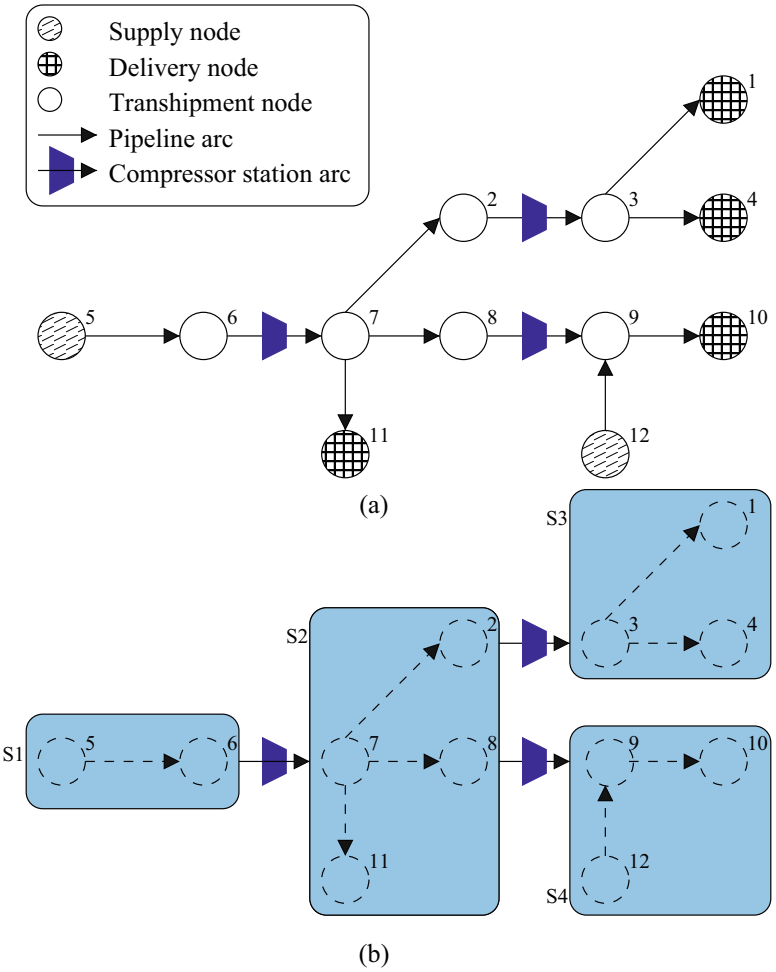

Fig. 1 Illustration of a reduced network. (**a**) Original network. (**b**) Associated reduced network

These different types of network topologies are shown in Fig. 2, were the original network is represented by solid line nodes and arcs, and the reduced network by dotted super nodes. Note that even though networks in Fig. 2a and b are not acyclic from a strict network definition, they are considered as noncyclic pipeline network structures.

Importance of Network Topology on Solution Algorithms

Let us consider the MFCP model given by (1)–(6), that is, the number of compressor units operating in each compressor station is known and fixed in advance. This is a

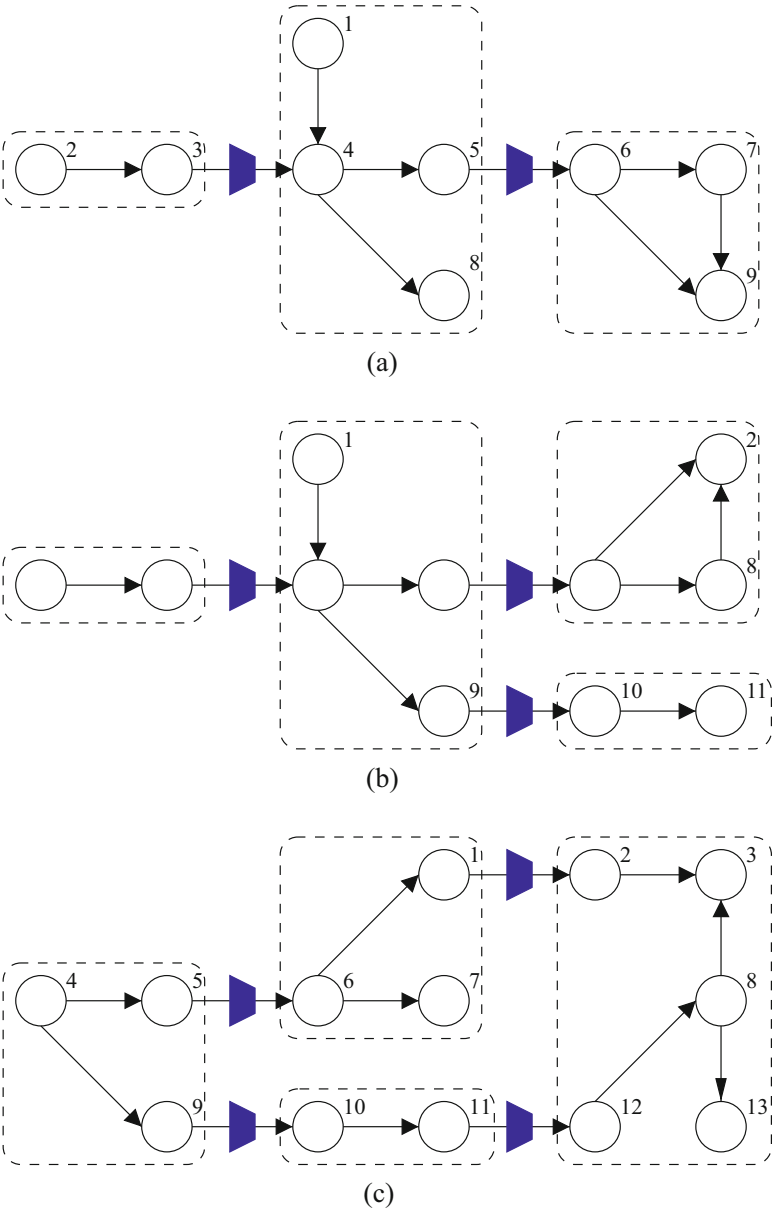

Fig. 2 Different kinds of pipeline network topologies. (**a**) Linear topology. (**b**) Tree topology. (**c**) Cyclic topology

nonconvex NLP. The network topology plays an important role, particular in steady-state topologies, when deriving algorithms for finding the optimal set of variables. Current state of the art on solution techniques for this steady-state MFCP reveals these important facts:

- There are theoretical results indicating that in noncyclic systems, the values of the flow variables can be uniquely determined and fixed beforehand [51]. Therefore, the problem reduces to finding out the optimal set of pressure variables at each node in the network. Of course, the problem is still hard to solve, but it reduces its dimension in terms of the decision variables.
- As a direct consequence of this, there exists successful implementations mostly based on dynamic programming (DP) that efficiently solve the problem in noncyclic instances by appropriately discretizing the pressure variables.
- When in a cyclic system, we impose the limitation of fixing the flow variables in each arc, a nonsequential dynamic programming (NDP), developed by Carter [8], can been successfully applied for finding the optimal set of pressure variables. Although this algorithm has the limitation of narrowing the set of solutions to those subject to a fixed set of flows, it can be used within other flow-modification-based approaches.

Solution Techniques: Classical Approaches

There is certainly a number of different optimization techniques that have been tried in the past to address problems in fuel cost minimization of natural gas transportation networks.

Steady-State NLP models: Most of the work for nonconvex NLP models has been based on steady-state models. One can find work on dynamic programming based techniques [5, 8, 15, 26, 29, 34, 52, 59, 60], including attempts to handle nonidentical compressor units [15], methods based on gradient search [20, 23, 45, 47], global optimization methods [24, 26], linearization techniques [12, 22], interior-point methods [21], exploiting model properties and lower bounding schemes [7, 51, 61], multi-objective optimization models [14], and multi-criteria approaches [40].

Steady-State MINLP models: There has also been studies on developing optimization methods for addressing MINLP models. In most of these models, integer variables for deciding which individual compressor units must be operating within a compressor station are introduced. Solution methodologies include mainly successive branch and bound [48, 56], outer approximation with augmented penalty [11, 66], sequential linear programming [23], and linearization techniques [38].

Transient models: Transient models are more challenging as the governing PDEs associated with the dynamics of the gas system must be taken into consideration. Efforts on addressing this class of very difficult problems include hierarchical control techniques [3, 30, 41–43, 46] in the early years, and, more recently, mathematical programming approaches [1, 16, 17, 28, 32, 36, 37, 44, 57, 64], Multi-objective optimization methods [10], and deep learning methods [2].

For a complete literature review and detailed discussion of some of these techniques, the reader is referred to the surveys of Zheng et al [65], Ríos-Mercado and Borraz-Sánchez [50], and Arya et al. [4]. In the following sections, we review

the most successful metaheuristic techniques applied to variations of the MFCP. Bear in mind that we are not including in the review below some papers on metaheuristics for natural gas pipeline optimization when the authors do not provide a full description of the algorithm (e.g., [58]).

Tabu Search: An Approach for NLP Models

For the past few years, Tabu Search (see ▸ Chap. 31, "Tabu Search") has established its position as an effective metaheuristic guiding the design and implementation of algorithms for the solution of hard combinatorial optimization problems in a number of different areas. A key reason for this success is the fact that the algorithm is sufficiently flexible to allow designers to exploit prior domain knowledge in the selection of parameters and subalgorithms. Another important feature is the integration of memory-based components.

When addressing the MFCP, even though we are dealing with a continuous optimization problem, Tabu Search (TS), with an appropriate discrete solution space, is a very attractive choice due to the the non-convexity of the objective function and the versatility of TS to overcome local optimality.

We now describe the TS-based approach of Borraz-Sánchez and Ríos-Mercado [6, 7], which is regarded as the most successful implementation of a metaheuristic for the MFCP. This TS takes advantage of the particular problem structure and properties and in fact can be regarded as a hybrid metaheuristic or matheuristic (see ▸ Chap. 8, "Matheuristics by Examples")

Let us consider the MFCP model given by (1)–(6), that is, the number of compressor units operating in each compressor station is known and fixed in advance. As established earlier, this is a nonconvex NLP.

Recall, from last section, that, in a cyclic system, if we fix the flow variables in each arc, NDP [8] can been successfully applied for finding the optimal set of pressure variables. Although this algorithm has the limitation of narrowing the set of solutions to those subject to a fixed set of flows, it can be used within flow-modification-based approaches such as the TS presented here.

It is clear that the TS approach is aiming at finding high-quality solutions for cyclic systems. It exploits the fact that for a given set of flows, an optimal set of pressure values can be efficiently found by NDP.

Nonsequential Dynamic Programming

We include in this section a brief description of the essence of the NDP algorithm. Further details can be found in [6]. Starting with a feasible set of flow variables, the NDP algorithm searches for the optimal set of node pressure values associated with that prespecified flow. Rather than attempting to formulate DP as a recursive algorithm, at a given iteration, the NDP procedure grabs two connected compressors and replace them by a "virtual" composite element that represents the optimal

operation of both compressors. These two elements can be chosen from anywhere in the system, so the idea of "sequential recursion" in classical DP does not quite apply here. After performing this step at a stage t, the system with t compressor stations has been replaced by an equivalent system with $t - 1$ stations. The procedure continues until only one virtual element, which fully characterizes the optimal behavior of the entire pipeline system, is left. Afterward, the optimal set of pressure variables can be obtained by a straightforward backtracking process. The computational complexity of this NDP technique is $O(|A_c|N_p^2)$, where N_p is the maximum number of elements in a pressure range discretization.

The Tabu Search Approach

The main steps of the algorithm are shown in Fig. 3. Here, a solution $Y = (X, P)$ is partitioned into its set of flow variables X and set of pressure variables P. First note that the search space employed by TS is defined by the flow variables X only because once the flow rates are fixed, the corresponding pressure variables are optimally found by NDP. Furthermore, we do not need to handle the entire set of flow variables, but only one per cycle. This is so because once you fix a flow rate in a cycle, the rest of the flows can be uniquely determined. Thus, a given state is represented by a vector $\hat{X} = (X_{\alpha_1}, \ldots, X_{\alpha_m})$, where α_w is an arc that belongs to a selected cycle w. Note that this set of arcs is arbitrarily chosen and that converting a flow from X to and from $\hat{X}$ is straightforward, so in the description, X and $\hat{X}$ are used interchangeably. This situation is illustrated in Fig. 4. The network represents the associated reduced network. It is clear that given a specified amount of net flow entering at node 1, only one arc in each cycle is needed to uniquely determine the flows in each arc of the network. In this case, the bold arcs (5,6) and (10,11), one per cycle, suffice.

We now describe each component.

- *Initial set of flows*: First, in Step 3, an initial set of feasible flows is found. Here, different methods such as classical assignment techniques can be applied in a straightforward manner.
- *Neighborhood definition*: In Step 5, a neighborhood $V(\bar{X})$ of a given solution $\bar{X} = \{\bar{x}_1, \bar{x}_2, \ldots, \bar{x}_m\}$ is defined as the set of solutions reachable from $\bar{X}$ via a modification of the current flow in each arc by Δ_x units in each of its components. This is given by

$$V(\bar{x}) = \{X' \in R^m \mid x'_w = \bar{x}_w \pm k\Delta_x, k = 1, 2, \ldots, N/2,\ w = 1, \ldots, m\}$$

where N is the predefined neighborhood size, Δ_x accounts for the mesh size, and the index w refers to the w-th cyclic component. Note that, for a given solution, the entire solution does not need to be stored but only the flow in the selected arc component to be modified. Note also that once this value is set, the rest of the

```
begin TS()
Input: An instance of the MFCP.
Output: A feasible solution (X, P).
1   (X, P)^best ← ∅;
2   TabuList ← ∅;
3   X̄ ← FIND_INITIAL_FLOW( );
4   while ( stopping criteria not met ) do
5       for ( X ∈ V(X̄) such that X ∉ TabuList ) do
6           P ← NDP( X );
7       end-for
8       Choose best (non-tabu) solution (X, P);
9       if (|TabuList| == TabuTenure) then
10          Remove oldest element from TabuList;
11      end-if
12      TabuList ← TabuList ∪ X;
13      (X, P)^best ← Best( (X, P), (X, P)^best );
14  end-while
15  return (X, P)^best;
end TS
```

Fig. 3 Pseudocode of Procedure TS

flow variables in the cycle are easily determined, so in this sense, it is precisely this mass flow rate which becomes the attribute of the solution.

- *Optimal pressure values*: In Steps 6–8, the corresponding set of pressure values for the given flow is found by invoking the NDP algorithm only for those flow values that are non-tabu.
- *Tabu list*: Then in Step 9, the best $X' \in V(\bar{X})$ which is non-tabu is chosen, and the corresponding subsets are updated accordingly. A tabu list (TabuList) stores recently used attributes, in our case, values of the X variables. The size of the

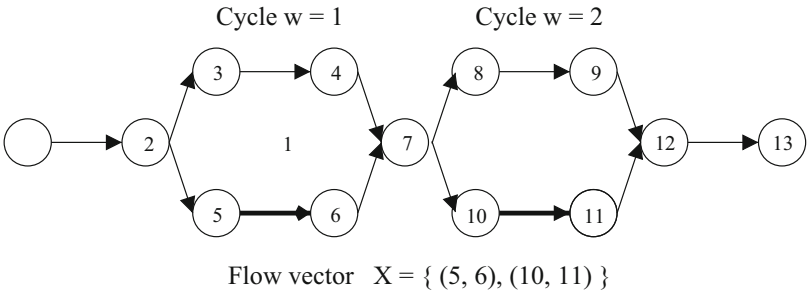

Fig. 4 Flow components of a feasible solution on a cyclic topology

TabuList (*TabuTenure*) controls the number of iterations a particular attribute is kept in the list.

- *Stopping criterion*: The search usually terminates after a given number of iterations, or when no significant change has been found in certain number of iterations.

As we know from theoretical properties of pipeline networks [51], the flow modification step is unnecessary for noncyclic topologies, because there exists a unique set of optimal flow values which can be determined in advance at preprocessing.

Empirical Performance

To illustrate the effectiveness of the TS, Table 1 shows the performance of the TS approach when it is compared with NDP. The table indicates the objective function value obtained by both methods and the relative improvement (RI) of the TS over the NDP solution when applied to 11 cyclic real-world size instances of up to 19 super-nodes and 7 compressor stations. As we can see, the TS method significantly outperformed NDP in terms of solution quality. The running times of the TS were about 220 and 400 CPU seconds. The running times of NDP were less than 20 CPU seconds. Although the NDP runs faster, the TS obtains solutions in less than 7/8 minutes, which is still very reasonable. Thus, it clearly pays off to spend additional computational effort, because the improvement in solution quality leads to substantial economical savings in real-world instances.

Ant Colony Optimization: An Approach for MINLP Models

Let us consider now the problem where, in addition to the flow variables in each arc and the pressure variables in each node, the decision process involves determining the number of operating units in each compressor as well. This leads to a MINLP

Table 1 Comparison between NDP and TS

model. In this section, the ant colony optimization (ACO) algorithm by Chebouba et al. [9] for this version of the MFCP is described.

Ant colony optimization (see ▸ Chap. 19, "Ant Colony Optimization: A Component-Wise Overview") is a relatively new evolutionary optimization method that has been successfully applied to a number of combinatorial optimization problems. ACO is based on the communication of a colony of simple agents (called ants), mediated by (artificial) pheromone trails. The main source of ACO is a pheromone trail laying and following behavior of real ants which use pheromones a communication medium. The pheromone trails in ACO serve as distributed, numerical information which the ants use to probabilistically construct solutions to the problem being solved and which the ants adapt during the algorithm's execution to reflect its search experience.

Regarding natural gas pipeline network optimization, Chebouba et al. [9] present an ACO metaheuristic for the MFCP with a variable number of compressor units within a compressor station. They focus on the linear topology case. As it was mentioned earlier, solving the MFCP on linear topologies has been successfully addressed by dynamic programming approaches when the number of compressor units is fixed and known, however, when the number of individual compressor units is variable and part of the decision process leads to a MINLP that has a higher degree of difficulty.

Consider the MINLP given by objective function (7) subject to constraints (2)–(6). When the number of individual compressor units within a compressor station are identical and hooked up in parallel, the linear system, as depicted in Fig. 2a, can be represented by a multigraph with the compressor stations aligned sequentially where the i-th compressor station (compressor arc $(i, i+1)$ in the figure) is modeled by a set of n_i arcs between suction node i and discharge pressure $i+1$ (see Fig. 5). Here, n_i is the number of individual compressor units, and each of the multi-arcs $(i, i+1)$ represents a decision on how many units are used in that particular station. Each multi-arc in the i-th station is denoted by $(i, i+1, r)$ (or simply (i, r)), where r identifies the number of individual compressor stations to be used in a particular solution. Let L be the set of edges in this multigraph given by

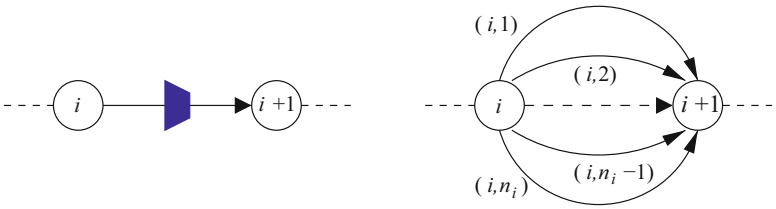

Fig. 5 Modeling compressor unit choices as a multigraph

$L = \{(i, r) : i \in \{1, \ldots, n\}, r \in \{1, \ldots, n_i\}\}$. In this case, the cost of arc (i, r) given by c_{ir} depends on the values of the pressure variables p_i and p_{i+1}. This will be determined during the construction of the solution. Following Eq. (7), the cost is then given by

$$c_{ir} = rg^{(1)}(x_{i,i+1}/r, p_i, p_{i+1}).$$

where it can be seen in a straightforward manner that, in the case of linear systems with known supply/demand values, the flow variables $x_{i,i+1}$ through the entire network can be determined and fixed beforehand. Furthermore, this cost is heuristically estimated once at the start of the procedure.

At the start of the algorithm, m ants are placed at the starting node. Ants build a solution while moving from node to an adjacent node by choosing one of the multi-arcs and by randomly generating values of the pressure variables for correct computation of the arc cost. During iteration t, each ant k carries out a partial path $T^k(t)$, and in this step, the choice of arc (i, r) depends on both the cost c_{ir} and the concentration of pheromone $\tau_{ir}(t)$ on arc (i, r) at iteration t. The pheromone trail takes into account the ant's current history performance. This pheromone amount is intended to represent the learned desirability of choosing the r-th edge at node i. The pheromone trail information is changed during problem solution to reflect the experience acquired by ants during problem-solving.

First, the algorithm introduces a transition rule depending on parameter $q_0 \in [0, 1]$, which determines the relative importance of intensification/diversification trade-off, every time an ant at node i chooses arc (i, r) according to the following transition rule:

$$r = \begin{cases} \arg\max_u (\tau_{iu}(t))^\alpha / (c_{iu})^\beta & \text{if } q \leq q_0, \\ s & \text{otherwise.} \end{cases}$$

where q is random variable uniformly distributed in [0, 1] and s is a random variable chosen according to the following probability function:

$$p_{is}^k(t) = \frac{(\tau_{is}(t))^\alpha / (c_{is})^\beta}{\sum_u (\tau_{iu}(t))^\alpha / (c_{iu})^\beta}$$

```
begin ACO()
Input: An instance of the MFCP.
Output: A feasible solution X.
1   t ← 0;
2   while ( stopping criteria not met ) do
3       t ← t + 1;
4       X^best ← ∅;
5       for (k = 1,....,m) do
6           Build solution X;
7           Apply local updating rule along path of X;
8           X^best ← Best(X, X^best);
9       end-for
10      Apply global updating rule along path of X^best;
11  end-while
12  return X^best;
end ACO
```

Fig. 6 Pseudocode of procedure ACO

As can be seen, low values of q_0 lead to diversification, and high values of q_0 stimulate intensification. Parameters α and β control the relative importance of the pheromone trail and greedy construction value. The main steps of the algorithm are shown in Fig. 6.

The pheromone trail is changed both locally (Step 7) and globally (Step 10) as follows:

- *Local updating*: Every time arc (i, r) is chosen by an ant, the amount of pheromone changes by applying this local trail update:

$$\tau_{ir}(t) \leftarrow (1 - \rho)\tau_{ir}(t) + \rho\tau_0$$

  where τ_0 is the initial pheromone value and ρ the evaporation rate.

Table 2 Comparison between DP and ACO

	DP		ACO		
Instance	OFV	Time	OFV	Time	RD (%)
Cs11–Nb6	49,114	10,332	49,217	721	0.21
Cs17–Nb9	81,050	28,262	81,052	1251	0.13
Cs23–Nb12	112,985	55,168	113,390	1869	0.36

- *Global updating*: Upon completion of a solution by every ant in the colony, the global trail updating is done as follows. The best ant (solution) from this finished iteration is chosen according to the best objective function value g^*. Then, in each arc $(i, i+1, r)$ used by this best ant, the trail is updated as:

$$\tau_{ir}(t+1) \leftarrow (1-\rho)\tau_{ir}(t) + \frac{\rho}{g^*}$$

Empirical Performance

To illustrate the usefulness of the ACO, the algorithm was tested on the Hassi R'mell-Arzew real-world pipeline network in Argelia consisting of five pipes, six nodes, five compressor stations, and three units in each compressor. The authors also built three additional cases with up to 23 compressor stations and 12 compressor units in each compressor. We must point out that these are noncyclic instances. The empirical evaluation includes a comparison with DP. Although these are noncyclic systems, the number of individual compressor units within each compressor station is considered a decision variable as well; thus, the DP may not guarantee an exact solution.

Table 2 displays the results in terms of objective function value (OFV) and running time when both DP and ACO are applied to three instances. The last column (RD) indicates the relative difference between the DP solution and the ACO solution. As we can see, the DP gives a slightly better solution, but it takes considerable more running time than the ACO. In the other hand, the difference in solution quality is very slim (less than 0.36%).

We conclude that ACO method performs reasonably well on these type of noncyclic networks. A great advantage is its relatively ease of implementation. The issue on how this algorithm can be modified so as to handle noncyclic systems remains an interesting topic for further investigation along this area.

Metaheuristic Approaches to Related Problems

In this section, we review some other related optimization problems in natural gas pipeline networks that have been addressed by metaheuristic methods.

Particle Swarm Optimization for Non-isothermal Systems

Wu et al [62] address a variation of the problem where, rather than minimizing fuel consumption, the focus is on maximizing a weighted combination of the maximum operation benefit and the maximum transmission amount. The operation benefit is defined as the sales income minus the costs. These costs include gas purchasing cost, pipeline's operation cost, management cost, and compressors running cost. The transmission amount is defined as the total gas volume that flows into the pipeline. In addition, a non-isothermal model is considered; that is, the authors consider the dynamics of the pipes being a function of temperature. Most of the literature focus on the isothermal case. They develop a particle swarm optimization (PSO) metaheuristic enhanced by an adaptive inertia weight strategy to adjust the weight value dynamically. In a PSO implementation (see ▶ Chap. 28, "Particle Swarm Optimization"), the inertia weight parameter is used to balance the global and local search ability. If the weight has a large value, the particle will search in a broader solution space. If the weight has a small value, the evolution process will focus on the space near to the local best particle. Thus, the global and local optimization performances of the algorithm can be controlled by dynamically adjusting the inertia weight value. This method adjusts the inertia weight adaptively based on the distance from the particles to the global best particle [55].

They tested their metaheuristic (named IAPSO) in the Sebeie-Ningxiae-Lanzhou gas transmission pipeline in China. Nine stations along the pipeline distribute gases to 16 consumers. There are four compressor stations with eight compressors to boost the gas pressure. The results show that IAPSO has fast convergence, obtaining reasonably good balances between the gas pipeline's operations benefit and its transportation amount.

Simulated Annealing for Time-Dependent Systems

As mentioned earlier, the previous two chapters addressed steady-state systems. However, when the steady-state assumption does not hold, the constraints that describe the physical behavior through a pipeline cannot be represented in the simplifying form as in (4). On the contrary, this behavior is governed by partial differential equations with respect to both flow and time. Therefore, to handle this situation, a discretization over the time variable must be done resulting in a highly complex optimization problem.

The resulting model is a mixed-integer nonlinear problem where now both flow variables and pressure variables are also a function of time; that is, we now have x_{ij}^t and p_i^t variables for every arc $(i, j) \in A$ and time step $t \in T$, where T is the set of time steps.

Although some efforts have been made to address transient systems, one of the most successful techniques for handling this problem is the simulated annealing (SA) algorithm of Mahlke et al. [35]. In that work, the authors use the following main ideas. First, they relax the equations describing the gas dynamic in pipes

by adding these constraints combined with appropriate penalty factors to the objective function. The penalty factor is dynamically updated resembling a strategic oscillation strategy. This gives the search plenty of flexibility. Then, they develop a suitable neighborhood structure for the relaxed problem where time steps as well as pressure and flow of the gas are decoupled. Their key idea of the neighborhood generation is a small perturbation of flow and pressure variables in the segments and nodes, respectively. An appropriate cooling schedule, an important feature of each SA implementation, is developed. They tested their metaheuristic on data instances provided by the German gas company E.ON Ruhrgas AG. The proposed SA algorithm yields feasible solutions in very fast running times.

Simulated Annealing for Integrated Preventive Maintenance in Natural Gas Transmission Networks

An interesting work proposing a framework for optimizing a natural gas pipeline including preventive maintenance scheduling operations is due to [39]. In his dissertation, the author proposes a simulated annealing metaheuristic to minimize compressor fuel cost in a natural gas transmission network through the integration of an annual maintenance plan for compressors in the network. The underlying multi-period mathematical model is an extension of the typical single-period MFCP models. Its solution is an operational/maintenance plan based on the best set of values uncovered for the operational and maintenance decision variables which results in the approximate overall minimization of the fuel consumed by the compressors in the network.

The proposed solution approach is applied to three different case studies from the literature which were developed for the evaluation of single-period MFCP models. The first case study involves a linear transmission network, the second a tree transmission network, and the third a cyclic transmission network. The time horizon of each case study is 52 weeks. Before execution of the SA algorithm, a set of experiments were carried out in order to determine appropriate combinations of model parameter values for each of the three case studies. The numerical results indicate that the algorithm is capable of finding high-quality solutions to all three instances.

NSGA-II for Multi-objective Optimization

The non-dominated sorting genetic algorithm II (NSGA-II) [13] is a multi-objective evolutionary heuristic that is used to tackle optimization problems with multiple objectives. This algorithm has been successfully applied to a variety of real-world multi-objective optimization problems, in particular with nonlinear objective functions. See ▸ Chap. 10, “Multiobjective Optimization.”)

The solution delivered by the NSGA-II is a set of non-dominated solutions which are a trade-off between the two objectives. Generally, every non-dominated solution is an acceptable solution. However, a decision-maker has to choose a single solution

from the optimal set by incorporating practical information and experience which significantly improves the operation of the system.

Kashani and Molaei [27] present a study that aims to find optimum values of three conflicting objective functions, namely, maximum gas delivery flow, maximum line pack, and minimum operating cost (sum of fuel consumption and carbon dioxide emission costs), simultaneously, for a natural gas pipeline network. They apply NSGA-II tom solve a small-scale case study with 5 compressor stations, 8 pipelines, and 14 nodes.

Demissie et al. [14] present a nonlinear multi-objective optimization model for optimizing the operation of natural gas pipeline networks in steady state. They consider linear, tree, and cyclic topologies. Their bi-objective optimization model aims at both minimizing fuel consumption and maximizing gas delivery flow rate. To address the problem, they apply a NSGA-II heuristic. They tested their algorithm in the data set instances by Wu et al. [61].

In a related work, Su et al [54] use NSGA-II to solve a bi-objective optimization problem that assesses the trade-off between reliability and power demand in natural gas pipeline networks under steady state. The model considers the uncertainties of the supply conditions and customer consumptions The effectiveness of the algorithm is tested on two typical pipeline networks, a tree-topology network and a loop-topology network. The results show that the developed optimization model is able to find solutions which effectively compromise the need of minimizing gas supply shortage risk and minimizing energy cost.

Conclusion

In this chapter, we have presented a description of successful metaheuristic implementations for handling very difficult optimization problems in fuel cost minimization of natural gas transportation networks. Compared to existing approaches, metaheuristics have the great advantage of not depending on gradient-based information such that they can handle nonlinearities and nonconvexities with relatively ease.

Nonetheless, metaheuristics have been widely applied mostly to discrete linear optimization problems and not to fully extent to handle the nasty problems within the natural gas industry. Therefore, there is a tremendous area of opportunity from the metaheuristic perspective in this very important field. One must have in mind that these are real-world problems where even a marginal improvement in the objective function value represent a significant amount of money to be saved given the total flow operation of these networks throughout the year. Therefore, further research in this area is justified and needed from the practical and scientific perspective.

Important research issues such as how to derive new metaheuristics or how the developed metaheuristics can be applied, extended, modified, so as to handle MFCPs under different assumptions (e.g., non-isothermal models, nonidentical compressor units, non-transient models, uncertainty) remain to be investigated. In

these lines, we have seen some preliminary efforts citing, for instance, the work of Mahlke et al. [35] who present a simulated annealing algorithm for addressing a MFCP under transient conditions. However, further work is needed. We know that advanced concepts in metaheuristic optimization research such as reactivity, adaptive memory, intensification/diversification strategies, or strategic oscillation are worthwhile investigating. Furthermore, as we have seen in this chapter, these models have a rich mathematical structure that allow for hybridization where part of the problem can be solved with mathematical programing techniques while being guided within a metaheuristic framework.

Over the past few years, we have also seen an increased interest in using machine learning techniques for handling certain variations of natural gas pipeline networks. One interesting feature of machine learning techniques such as deep reinforcement learning (DRL) is that they employ a model-free mechanism to optimize the system. For instance, Fan et al. [18] propose a method based on Bayesian networks and DRL to optimize the reliability of gas supply in natural gas pipeline networks. More recently, Liu et al. [33] propose an optimization framework for natural gas transportation pipeline networks based on DRL. The mathematical simulation model is derived from mass balance, hydrodynamics principles of gas flow, and compressor characteristics. The optimization control problem in steady state is formulated into a one-step Markov decision process and solved by DRL. The decision variables are selected as the discharge ratio of each compressor. This technique was empirically tested on very small scale noncyclic systems (gun-barrel and tree topologies). Although the technique was compared with DP and a GA, a step forward on this direction would be to investigate its applicability on the more challenging cyclic systems on larger real-world instances.

We hope we can stimulate the interest of the scientific community, particularly from the metaheuristic optimization field, to contribute to advance the state of the art in this very challenging research area.
